## PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

	PAGE
I.—The Estimation of Methyl Alcohol in presence of Ethyl Alcohol. By THOMAS EDWARD THORPE, C.B., F.R.S., and JOHN HOLMES . . . . .	1
II.—Halogen Derivatives of Diphenyl and Dihydroxydiphenyl. By JOHN CANNELL CAIN . . . . .	7
III.—Separation and Estimation of Silver Cyanide and Silver Chloride. By ROBERT HENRY ADERS PLIMMER, D.Sc. (Grocers' Company's Research Student) . . . . .	12
IV.—Action of Malt Diastase on Potato Starch Paste. By BERNARD F. DAVIS, B.Sc., and ARTHUR R. LING . . . . .	16
V.—The Action of Halogens on Compounds containing the Carbonyl Group. By ARTHUR LAPWORTH . . . . .	30
VI.—Derivatives of Menthyl Cyanoacetate. By DOUGLAS ANDERSON BOWACK and ARTHUR LAPWORTH . . . . .	42
VII.—Optically Active Esters of $\beta$ -Ketonic and $\beta$ -Aldehydic Acids. Part IV. Condensation of Aldehydes with Menthyl Acetoacetate. By ARCHIE CECIL OSBORN HANN and ARTHUR LAPWORTH . . . . .	46
VIII.—Notes on some Natural Colouring Matters. By ARTHUR GEORGE PERKIN, F.R.S., and SAMUEL PHIPPS . . . . .	56
IX.—The Four Optically Isomeric <i>l</i> -Menthylamines and their Salts. By FRANK TUTIN and FREDERIC STANLEY KIPPING . . . . .	65
X.—Peroxyaminesulphonates and Hydroxylaminetrisulphonates (Sulphazilates and Metasulphazilates). By TAMEMASA HAGA, D.Sc. . . . .	78
XI.—Peroxyaminesulphonic Acid. By EDWARD DIVERS . . . . .	108
XII.—Constitution of Nitric Peroxide. By EDWARD DIVERS . . . . .	110
XIII.—The Solubility Curves of the Hydrates of Nickel Sulphate. By BERTRAM DILLON STEELE, D.Sc., and F. M. G. JOHNSON . . . . .	113
XIV.—The Relative Strengths of the Alkaline Hydroxides and of Ammonia as Measured by their Action on Cotarnine. By JAMES JOHNSTON DOBBIE, M.A., D.Sc., ALEXANDER LAUDER, B.Sc., and CHARLES KENNETH TINKLER, Research Student of the University of Edinburgh . . . . .	121

	PAGE
XLV.—Freezing Point Curves of Dynamic Isomerides: Ammonium Thiocyanate and Thiocarbamide. By ALEXANDER FINDLAY . . . . .	403
XLVI.—A Note on Phenyl dimethylallylammonium Compounds. By ALFRED WILLIAM HARVEY . . . . .	412
XLVII.—A Note on the Composition of Distilled Oil of Limes and a New Sesquiterpene. By HERBERT EDWARD BURGESS and THEODORE HENRY PAGE . . . . .	414
XLVIII.— $\delta$ -Keto hexahydrobenzoic Acid. By WILLIAM HENRY PERKIN, jun. . . . .	416
XLIX.—The Arrangement in Space of the Groups Combined with the Tervalent Nitrogen Atom. By FREDERIC STANLEY KIPPING and ARTHUR HENRY SALWAY . . . . .	438
L.—Contributions to the Knowledge of the $\beta$ -Diketones. By SIEGFRIED RUHEMANN and EDWIN ROY WATSON . . . . .	456
LI.—The Formation of Periodides in Organic Solvents. By HARRY MEDFORTH DAWSON . . . . .	467
Annual General Meeting . . . . .	477
Presidential Address to the Chemical Society . . . . .	493
THE FARADAY LECTURE. Elements and Compounds. By WILHELM OSTWALD . . . . .	506
LII.—Mercuric Nitrate and its Decomposition by Heat. By PRAFULLA CHANDRA RAY, D.Sc. (Edin.) . . . . .	523
LIII.—The Reduction of 2:6-Dinitrotoluene with Hydrogen Sulphide. By JULIUS BEREND COHEN and JOSEPH MARSHALL . . . . .	527
LIV.—Studies in the Acridine Series. Part I. By JOHN JACOB FOX and JOHN THEODORE HEWITT . . . . .	529
LV.—The Acid Esters of Methyl Substituted Succinic Acids. By WILLIAM ARTHUR BONE, JOHN JOSEPH SUDBOROUGH, and CHARLES HENRY GRAHAM SPRANKLING . . . . .	534
LVI.—Chemical Dynamics of the Alkyl Iodides. By KATHARINE ALICE BURKE and FREDERICK GEORGE DONNAN . . . . .	555
LVII.—Isomeric Change of Diacylanilides into Acylamino-ketones. Transformation of the Dibenzoyltoluidines into the Isomeric Benzoylaminomethylbenzophenones. By FREDERICK DANIEL CHATTAWAY and WILLIAM HENRY LEWIS . . . . .	589
LVIII.—Estimation of Hydrogen Peroxide in the presence of Potassium Persulphate by means of Potassium Permanganate. By JOHN ALBERT NEWTON FRIEND, M.Sc. . . . .	597
LIX.—The Heat of Formation of Glucinum Chloride. By JAMES HOLMS POLLOK, B.Sc. . . . .	603
LX.—The Action of Ethyl $\beta$ -Iodopropionate on Ethyl Disodio-ethanetetracarboxylate. By OSWALD SILBERRAD, Ph.D. . . . .	611

LXI.—A Comparison of the Products of the Hydrolysis of Potato Starch with those obtained from Cereal Starches. By JAMES O'SULLIVAN . . . . .	616
LXII.—A Lævorotatory Modification of Quercitol. By FREDERICK BELDING POWER and FRANK TUTIN . . . . .	624
LXIII.—The Constituents of the Essential Oil of Californian Laurel. By FREDERICK BELDING POWER and FREDERIC HERBERT LEES . . . . .	629
LXIV.—Some Derivatives of Umbellulone. By FREDERIC HERBERT LEES . . . . .	639
LXV.—Picryl Derivatives of Urethanes and Thiourethanes. By JAMES CODRINGTON CROCKER, B.A., and FRANK HAROLD LOWE, B.Sc. . . . .	646
LXVI.—Experiments on the Synthesis of the Terpenes. Part I. Synthesis of Terpin, Inactive Terpeneol, and Dipentene. By WILLIAM HENRY PERKIN, jun. . . . .	654
LXVII.—Ammoniacal Double Chromates and Molybdates. By SAMUEL HENRY CLIFFORD BRIGGS . . . . .	672
LXVIII.—The Hexahydrated Double Chromates. Magnesium and Nickel Compounds. By SAMUEL HENRY CLIFFORD BRIGGS . . . . .	677
LXIX.—Reduced Silicates. By CHARLES SIMMONDS, B.Sc. . . . .	681
LXX.—Studies on Optically Active Carbinimides. Part I. By ALLEN NEVILLE, B.Sc. (Lond.), and ROBERT HOWSON PICKARD . . . . .	685
LXXI.—Hydrocellulose. By CHARLES FREDERICK CROSS and EDWARD JOHN BEVAN . . . . .	691
LXXII.—The Slow Combustion of Ethane. By WILLIAM ARTHUR BONE and WILLIAM ERNEST STOCKINGS . . . . .	693
LXXIII.—Studies in the Tetrahydronaphthalene Series. Part II. Halogen Derivatives of <i>ar</i> -Tetrahydro- $\beta$ -naphthylamine. By CLARENCE SMITH, D.Sc. . . . .	728
LXXIV.—Studies in the Tetrahydronaphthalene Series. Part III. Reaction between <i>ar</i> -Tetrahydro- $\beta$ -naphthylamine and Formaldehyde. By CLARENCE SMITH, D.Sc. . . . .	732
LXXV.—A Study of the Substitution Products of <i>ar</i> -Tetrahydro- $\alpha$ -naphthylamine. 4-Bromo- <i>ar</i> -tetrahydro- $\alpha$ -naphthylamine and <i>ar</i> -Tetrahydro- $\alpha$ -naphthylamine-4-sulphonic Acid. By GILBERT THOMAS MORGAN, FRANCES MARY GORE MICKLETHWAIT, and HERBERT BEN WINFIELD . . . . .	736
LXXVI.—The Action of Nitrosyl Chloride on Pinene. By WILLIAM AUGUSTUS TILDEN . . . . .	759

	PAGE
LXXVII.—The Comparison of the Rotation-values of Methyl, Ethyl, and <i>n</i> -Propyl Tartrates at Different Temperatures. By THOMAS STEWART PATTERSON . . . . .	765
LXXVIII.—A Revision of the Atomic Weight of Rubidium. By EBENEZER HENRY ARCHIBALD . . . . .	776
LXXIX.—The Action of Sodium Methoxide and its Homologues on Benzophenone Chloride and Benzylidene Chloride. Part II. By JOHN EDWIN MACKENZIE and ALFRED FRANCIS JOSEPH . . . . .	790
LXXX.—The Formation of Periodides in Nitrobenzene Solution. Part II. Periodides of the Alkali and Alkaline Earth Metals. By HARRY MEDFORTH DAWSON and ETHEL ELIZABETH GOODSON, B.Sc. . . . .	796
LXXXI.—Caproylthiocarbimide. By AUGUSTUS E. DIXON, M.D. . . . .	807
LXXXII.—The Action of Radium Rays on the Halides of the Alkali Metals and Analogous Heat Effects. By WILLIAM ACKROYD . . . . .	812
LXXXIII.—The Viscosity of Liquid Mixtures. Part I. By ALBERT ERNEST DUNSTAN, B.Sc. . . . .	817
LXXXIV.—The Action of Heat on $\alpha$ -Hydroxycarboxylic Acids. Part I. $\alpha$ -Hydroxystearic Acid. By HENRY RONDEL LE SUEUR . . . . .	827
LXXXV.—The Constituents of Chaulmoogra Seeds. By FREDERICK BELDING POWER and FRANK HOWORTH GORNALL . . . . .	838
LXXXVI.—The Constitution of Chaulmoogric Acid. Part I. By FREDERICK BELDING POWER and FRANK HOWORTH GORNALL . . . . .	851
LXXXVII.—Studies on Ethyl Carboxyglutarate. By OSWALD SILBERRAD, Ph.D., and THOMAS HILL EASTERFIELD, M.A., Ph.D. . . . .	862
LXXXVIII.—The Nitration Products of the Isomeric Dichlorobenzenes. By PERCIVAL HARTLEY and JULIUS BEREND COHEN . . . . .	865
LXXXIX.—The Fermentation of the Indigo-plant. By CYRIL BERGTHEIL . . . . .	870
XC.—Studies in the Camphane Series. Part XIV. isoNitroso-camphor. By MARTIN ONSLOW FORSTER . . . . .	892
XCI.—The Vapour Density of Hydrazine Hydrate. By ALEXANDER SCOTT . . . . .	913
XCII.—The Basic Properties of Oxygen. Additive Compounds of the Halogen Acids and Organic Substances and the Higher Valencies of Oxygen. Asymmetric Oxygen. By EBENEZER HENRY ARCHIBALD and DOUGLAS MCINTOSH . . . . .	919
XCIII.—Limonene Nitroso-cyanides. By WILLIAM AUGUSTUS TILDEN and FREDERICK PEACOCK LEACH . . . . .	931

XCIV.—Estimation of Hydroxyl Groups in Carbon Compounds. By HAROLD HIBBERT and JOHN JOSEPH SUDBOROUGH . . .	933
XCV.—Influence of Moist Alcohol and Ethyl Chloride on the Boiling Point of Chloroform. By JOHN WADE, D.Sc., and HORACE FINNEMORE, A.I.C. . . . .	938
XCVI.—The Mechanical Analysis of Soils and the Composition of the Fractions Resulting Therefrom. By ALFRED DANIEL HALL, M.A. . . . .	950
XCVII.—The Effect of the Long-continued Use of Sodium Nitrate on the Constitution of the Soil. By ALFRED DANIEL HALL, M.A. . . . .	964
XCVIII.—The Action of Acetyl Chloride on the Sodium Salt of Diacetylacetone, and the Constitution of Pyrone Com- pounds. By JOHN NORMAN COLLIE, F.R.S. . . . .	971
XCIX.—Note on the Hydrolysis of Starch by Diastase. By JOHN SIMPSON FORD . . . . .	980
C.—Imino-ethers and Allied Compounds Corresponding with the Substituted Oxamic Esters. By GEORGE DRUCE LANDER . . . . .	984
CI.—The Additive Products of Benzylideneaniline with Ethyl Acetoacetate and Ethyl Methylacetoacetate. By FRANCIS ERNEST FRANCIS and MILLICENT TAYLOR . . . . .	998
CII.—Notes on Analytical Chemistry. By GILBERT THOMAS MORGAN . . . . .	1001
CIIL.—The Constitution of Hydrastinine. By JAMES JOHN- STON DOBBIE, D.Sc., F.R.S., and CHARLES KENNETH TINKLER, Research Student of the University of Edinburgh. . . . .	1005
CIV.—The Absorption Spectrum of <i>p</i> -Nitrosodimethylaniline. By WALTER NOEL HARTLEY, D.Sc., F.R.S. . . . .	1010
CV.—The Electrolytic Estimation of Minute Quantities of Arsenic. By HENRY JULIUS SALOMON SAND, Ph.D., M.Sc., and JOHN EDWARD HACKFORD . . . . .	1018
CVI.—The Ultra-violet Absorption Spectra of Certain Enol-keto- tautomerides. Part I. Acetylacetone and Ethyl Aceto- acetate. By EDWARD CHARLES CYRIL BALY and CECIL HENRY DESCH, D.Sc. . . . .	1029
CVII.—The Action of Chromyl Chloride on Stilbene, Styrene, and Phenanthrene. By GEORGE GERALD HENDERSON and THOMAS GRAY . . . . .	1041
CVIII.—Stereoisomeric Glucoses and the Hydrolysis of Gluco- sidic Acetates. By EDWARD FRANKLAND ARMSTRONG (Salters' Company's Research Fellow) and PAUL SEIDELIN ARUP . . . . .	1043
CIX.—The Stereoisomeric Tetramethyl Methylglucosides and Tetramethyl Glucose. By THOMAS PURDIE, F.R.S., and JAMES COLQUHOUN IRVINE, Ph.D., D.Sc., Carnegie Fellow . . . . .	1049

	PAGE
CX.—The Alkylation of Galactose. By JAMES COLQUHOUN IRVINE, Ph.D., D.Sc., Carnegie Fellow, and ADAM CAMERON, M.A., B.Sc. . . . .	1071
CXI.—Ionisation and Chemical Combination. By JAMES WALLACE WALKER . . . . .	1082
CXII.—Ionisation and Chemical Combination in the Liquefied Halogen Hydrides and Hydrogen Sulphide. By JAMES WALLACE WALKER, DOUGLAS MCINTOSH, and EBENEZER ARCHIBALD . . . . .	1098

I.—*The Estimation of Methyl Alcohol in presence of Ethyl Alcohol.*

By THOMAS EDWARD THORPE, C.B., F.R.S., and JOHN HOLMES.

It is well known that when methyl and ethyl alcohols are treated with a mixture of potassium dichromate and sulphuric acid, the nature of the reaction and the character and relative quantity of the products vary with the conditions under which the process is conducted. Under one special set of conditions, ethyl alcohol furnishes a mixture of aldehyde, acetic acid, and acetal, whereas methyl alcohol under similar circumstances gives rise to formic acid and methylal (Trillat, *Compt. rend.*, 1898, 127, 232—234).

If, however, ethyl alcohol in aqueous solution is digested for a sufficient length of time with a mixture of potassium dichromate and sulphuric acid in a closed vessel at 100°, it furnishes very nearly its theoretical equivalent of acetic acid. Frankland and Frew (*Trans.*, 1891, 59, 93), found that 1 part by weight of ethyl alcohol furnished 1.281 parts of acetic acid, the theoretical amount being 1.305.

The same result follows if the dilute ethyl alcohol is treated in the cold with the oxidising mixture in quantity sufficient to oxidise it to acetic acid, and is then subsequently boiled with an additional amount of the same mixture.

Direct experiments have shown that the process of oxidation of the ethyl alcohol under these circumstances is always accompanied by the

liberation of a small quantity of carbon dioxide in amount equivalent to 0·5 per cent. of alcohol.

It is possible that the slight difference between the observed and calculated amounts of acetic acid observed by Frankland and Frew may be due to this cause.

It will be noticed that the amount of carbon dioxide formed is relatively very small—so small indeed that we were inclined at first to attribute it to some constant impurity in the alcohol rather than to a normal change under the influence of the oxidising mixture. We find, however, that it is invariably formed, no matter what may have been the origin of the alcohol employed. It is yielded by carefully dehydrated alcohol, however frequently it may have been redistilled, or apparently however much it may have been fractionated. We have experimented with a number of samples of the rectified spirits of commerce obtained on the large scale from a great variety of materials, for example, malt, maize, molasses, rye, &c., and such alcohol, after rectification, invariably gives practically the same relative amount of carbon dioxide, that is an amount directly proportionate to the quantity of alcohol which is being oxidised. Alcohol recovered from medicinal tinctures, or from cognac, rum, gin, sherry, or beer, after rectification, behaves in exactly the same way. No variation in the relative amount was noticed when the proportions of alcohol, potassium dichromate and sulphuric acid were considerably altered. The acetic acid formed by the oxidation, and recovered by distillation, when again treated with the same quantities of oxidising materials, gave no further evolution of carbon dioxide.

The amount of carbon dioxide formed is not affected by a preliminary boiling with caustic potash, or by distilling the alcohol from an acid solution, or by treating it with sulphurous or nitrous acid or bromine, or by the action of iodine in presence of an alkali.

It is unnecessary to set out here the details of these experiments, some 40 in number. The inference we draw from them is that the formation of the carbon dioxide is a constant and necessary product of the chemical change, and that under the conditions of oxidation employed by us the quantity formed is directly proportionate to the amount of ethyl alcohol present.

The main result as regards ethyl alcohol may be stated thus:—that under the conditions of oxidation employed, a minute quantity, not exceeding 0·5 per cent., of the alcohol undergoing oxidation is transformed into carbon dioxide, the remainder being converted into acetic acid.

In the case of methyl alcohol, the results are altogether dissimilar. No formic acid is produced—at least as an ultimate product—but the methyl alcohol is wholly decomposed into carbon dioxide and water.

The following experiments may be cited in proof of this: a sample of methyl alcohol, boiling between  $64.9^{\circ}$  and  $65.2^{\circ}$  and having a sp. gr. 0.7992 at  $15.5^{\circ}/15.5^{\circ}$ , was mixed with water in such proportion that 50 c.c. of the mixture contained 1.0118 grams of methyl alcohol. Fifty c.c. of the mixture were placed in a 300 c.c. flask, which could be closed with a ground-in stopper, and which was fitted with a funnel and side-tube; 10 grams of potassium dichromate and 25 c.c. of dilute sulphuric acid (1:4) were added, and the mixture allowed to remain for 18 hours. A further quantity of 10 grams of potassium dichromate and 50 c.c. of sulphuric acid mixed with an equal volume of water was added, and the contents of the flask heated to the boiling point for about 10 minutes, the evolved carbon dioxide being swept out of the apparatus by a current of air and collected in weighed soda-lime tubes. Two experiments gave 1.3810 and 1.3854 grams of carbon dioxide, equivalent to 99.4 and 99.7 per cent. of methyl alcohol respectively.

This difference in the behaviour of the two alcohols has already been made the basis of a method of examining whisky and other spirits for methylated spirit. Dupré (*Analyst*, 1876, 1, 4. Compare also Thudichum and Dupré, *Origin, Nature, and Use of Wine*, p. 205) has made use of the fact that ethyl alcohol may be converted into acetic acid by means of a mixture of potassium dichromate and sulphuric acid as a means of determining the actual amount of ethyl alcohol in a mixture of ethyl and methyl alcohols, and of thereby inferring the amount of admixed methyl alcohol. Dupré's method was examined by Hehner (*Analyst*, 1887, 12, 25), who preferred to measure the quantity of dichromate reduced instead of the acetic acid formed.

In the present communication, we describe a method of estimating methyl alcohol in presence of ethyl alcohol based on the determination of the amount of carbon dioxide evolved in the process of oxidation.

The process is as follows: the sample is mixed with water in such proportion that 50 c.c. of the mixture shall contain not more than 1 gram of methyl alcohol, and in the presence of ethyl alcohol not more than 4 grams of the mixed alcohols. Fifty c.c. of this mixture are then introduced into the oxidation flask, 20 grams of potassium dichromate and 80 c.c. of dilute sulphuric acid (1:4) added, and the mixture allowed to remain for 18 hours. A further quantity of 10 grams of potassium dichromate and 50 c.c. of sulphuric acid mixed with an equal volume of water are now added, and the operation conducted as already described.

When ethyl alcohol is present, a subtractive correction must be applied to the weight of carbon dioxide thus obtained, in the proportion of 0.01 gram of carbon dioxide for each gram of ethyl alcohol present.

The relative densities of the two alcohols being almost identical, the same table of densities can be used, with a sufficient approximation to accuracy, for the determination of the aggregate quantity of the two alcohols present.

As evidence of the trustworthiness of the method, the following results of a series of determinations on mixtures of methyl and ethyl alcohols in known proportions may be given.

*Percentage of Methyl Alcohol.*

Present...	9.0	9.0	8.0	6.9	5.6	4.8	2.5	1.0
Found ...	8.8	9.0	7.9	6.8	5.5	4.6	2.5	1.0

Ordinary methylated spirits must, according to law, consist of a mixture of plain or unsweetened spirits with one-ninth of their volume of wood naphtha.

It is required that the wood naphtha used for denaturing spirits shall contain at least 72 per cent. of methyl alcohol; that it shall not contain more than a certain proportion of aldehyde, acetone, and higher ketones, estimated as acetone by Messinger's method, nor more than a certain proportion of esters estimated as methyl acetate by hydrolysis; that it shall behave in a certain manner with an aqueous solution of bromine, and that it shall have a certain alkalinity.

The wood naphtha which is now used by methylators is fairly uniform in character as regards its content of methyl alcohol; thus, of 936 samples of wood naphtha which passed through the Government Laboratory during the year ending March 31st, 1903, 47 per cent. was found to contain between 72 and 75 per cent. of methyl alcohol, and 52 per cent. to contain between 75 and 80 per cent. of this alcohol by volume. The quantity of acetone and the higher ketones varied from 3.5 to 14 per cent., and the esters, mainly methyl acetate, ranged from 0.2 to 4 per cent. In addition, there were small quantities of unsaturated alcohols, amines, and other nitrogenous basic substances.

As regards the behaviour towards the oxidising solution of the substances other than methyl alcohol which may be present in wood naphtha, it is found that, on heating, ordinary acetone is almost wholly converted into acetic acid and carbon dioxide. In the cold, as with ethyl ether, no action occurs even after a long interval. Methyl acetate, in like manner, yields its theoretical equivalent of carbon dioxide and acetic acid. Allyl alcohol is wholly broken down, yielding carbon dioxide. Pyridine is not changed.

By experiments made with synthetically prepared mixtures, that is,

mixtures containing known amounts of ethyl and methyl alcohols mixed with known quantities of acetone, methyl acetate, allyl alcohol, and pyridine, it was found that the amount of carbon dioxide evolved corresponded closely with that theoretically producible. Thus, rectified spirits, to which was added one-ninth of its volume of a mixture consisting of :—

Methyl alcohol	80.6 per cent.	Allyl alcohol	0.2 per cent.
Acetone .....	14.0 „	Pyridine ...	0.2 „
Methyl acetate	5.0 „		

gave on oxidation 10.51 grams of carbon dioxide, as against a theoretical yield of 10.61 grams of carbon dioxide per 100 c.c. of the mixture.

From the circumstance that the wood naphtha now employed for methylation is of much more uniform quality than that formerly used, it is possible to ascertain, with a considerable approximation to accuracy, whether a sample of methylated spirits does actually contain its statutory quantity of wood naphtha, and also what is the amount of methylated spirits which may be present in a mixture of methylated spirits and ordinary spirits of wine.

It is obvious that the results, and therefore the inference to be drawn from them, may be affected to a slight extent by the circumstance that the substances commonly associated with the methyl alcohol in wood naphtha may be present in variable amounts. The difficulty due to this circumstance may, however, be largely removed by first treating the methylated spirits with light petroleum in the manner described in our recent communication (*Trans.*, 1903, **83**, 314), and then estimating the amount of carbon dioxide afforded by oxidising the distilled spirit.

Estimations made in this manner on synthetically prepared mixtures containing these substances in quantities varying from the highest to the lowest percentages commonly found in wood naphtha afforded the following results :

*Percentage of Methyl Alcohol.*

Present .....	8.0	8.0	7.5
Found .....	8.3	8.3	7.8

The slight increase in the amount found as compared with that known to be present is due to the circumstance that small quantities of acetone equal to 0.5 per cent. of this ketone are not extracted by the light petroleum ; this residue furnishes carbon dioxide equivalent to 0.3 per cent. of methyl alcohol by volume.

A similar result was obtained on submitting a mixture of the two alcohols with acetone to the above treatment.

Estimations were then made on methylated spirits prepared with samples of commercial wood naphtha, in which the ketones, esters, and other substances had been determined by the methods already referred to, and the following results were obtained :

*Percentage of Methyl Alcohol.*

(1) Found .....	8.3	8.1	7.9
(2) Calculated .....	8.3	8.3	7.8

Series (1) gives the corrected results obtained after treatment by the petroleum method, whilst series (2) gives the calculated results obtained by deducting in each case the amount of carbon dioxide theoretically producible from the quantities of ethyl alcohol, acetone, methyl acetate, &c., present, as determined by experiment, from the total amount of carbon dioxide yielded by the direct oxidation of the sample.

A general method for ascertaining whether tinctures or other medicinal preparations contain methylated spirits, and to what extent, is as follows : the spirit from 25 c.c. of the sample, or from 50 c.c. if it contains less than 50 per cent. of alcohol, is treated with light petroleum to remove essential oils, &c., in the manner described in our recent communication (*loc. cit.*), and then distilled and diluted with water to a volume of 250 c.c. ; 50 c.c. of this mixture are then oxidised with 20 grams of potassium dichromate and 80 c.c. of dilute sulphuric acid (1 : 4), and further treated as already described in this communication.

If the weight of carbon dioxide thus obtained does not exceed 0.01 gram for each gram of alcohol present, this amount being equivalent to 0.7 vol. of methyl alcohol in 100 vols. of the alcohol, then it may be concluded that the sample contains only spirits of wine.

Should the weight of carbon dioxide exceed this amount, its equivalent in methyl alcohol by volume must be subjected to a subtractive correction of from 0.7 to 1 per cent. (depending on the amount of methylated spirits present), the percentage of methylated spirits being calculated on the assumption that the quantity of methyl alcohol occurring in dehydrated methylated spirit does not exceed 8.8 per cent.

## II.—*Halogen Derivatives of Diphenyl and Dihydroxydiphenyl.*

By JOHN CANNELL CAIN.

In an investigation on the action of water on the diazonium salt prepared from 3:3'-dichlorobenzidine (Trans., 1903, 83, 688), only a very small quantity of 3:3'-dichloro-4:4'-dihydroxydiphenyl was obtained, the chief product being of a quinonoid nature. It appeared, therefore, of interest to study the behaviour of this diazonium salt when subjected to the processes employed in replacing the diazo-groups by hydrogen, chlorine, bromine, iodine, cyanogen, and carboxyl radicles.

A very convenient method of preparing 3:3'-dichloro-4:4'-dihydroxydiphenyl has been devised, which consists in chlorinating 4:4'-dihydroxydiphenyl in glacial acetic acid solution with the calculated quantity of chlorine. In connection with this part of the work, both the monochloro- and the trichloro- derivatives were prepared, the limit of the chlorination being the tetrachloro-compound, which has already been described by Magatti (*Bér.*, 1880, 13, 224).

### EXPERIMENTAL.

#### 3:3'-Dichlorodiphenyl.

3:3'-Dichlorobenzidine (25 grams) was dissolved in ethyl alcohol, a mixture of strong sulphuric acid and alcohol added, and then, after cooling, a slight excess of dry sodium nitrite. The alcoholic solution of the diazonium sulphate thus obtained was boiled for half an hour, the alcohol evaporated off, and the residue distilled in a current of steam. The easily fusible yellowish-white solid collecting in the distillate was recrystallised from dilute alcohol. The 3:3'-dichlorodiphenyl thus obtained crystallises from dilute alcohol in white needles and is easily soluble in ether, alcohol, and benzene; it melts at 29° and boils at 298°.

0.1789 gave 0.2308 AgCl. Cl = 31.9.

$C_{12}H_8Cl_2$  requires Cl = 31.8 per cent.

#### 3:4:3':4'-Tetrachlorodiphenyl.

3:3'-Dichlorobenzidine (12.7 grams) was dissolved in 90 c.c. of hydrochloric acid of sp. gr. 1.16, diluted with 45 c.c. of water, the solution being cooled and diazotised with 6.9 grams of sodium nitrite dissolved

in a very small quantity of water. The resulting brownish-yellow solution was filtered and added to copper powder (the "copper bronze" of commerce) which had been moistened with hydrochloric acid. Nitrogen was immediately evolved, and on the following day the mixture was filtered and extracted with ether. After evaporating off the solvent from the extract, the dry residue was distilled under diminished pressure, and by this means the tetrachlorodiphenyl was freed from a red by-product. The solid distillate was crystallised twice from glacial acetic acid, from which it separates in fine white needles, melting at  $172^{\circ}$  and boiling at  $230^{\circ}$  under 50 mm. pressure. The tetrachlorodiphenyl thus obtained dissolves easily in ether, alcohol, or benzene.

0.1392 gave 0.2741 AgCl. Cl = 48.70.

$C_{12}H_6Cl_4$  requires Cl = 48.58 per cent.

*3 : 3'-Dichloro-4 : 4'-dibromodiphenyl.*

3 : 3'-Dichlorobenzidine (12.7 grams) was diazotised as in the preceding case, except that sulphuric acid was used instead of the hydrochloric acid; the filtered solution was poured into a solution of 20 grams of potassium bromide, to which copper powder had been added. The mixture was left for a time, then filtered, and extracted with ether. The red residue obtained after removing the solvent was distilled under diminished pressure. The dichlorodibromodiphenyl, which is soluble in the ordinary organic solvents, on crystallisation from glacial acetic acid separated in white needles melting at  $176-177^{\circ}$ .

0.1784 gave 0.2969 AgCl + AgBr. Halogen = 60.89

$C_{12}H_6Cl_2Br_2$  requires Cl + Br = 60.60 per cent.

*3 : 3'-Dichloro-4 : 4'-di-iododiphenyl.*

A solution of the diazonium sulphate was added to 20 grams of potassium iodide dissolved in water. Nitrogen was at once evolved, and after about 12 hours the mass was filtered, boiled with water to expel traces of free iodine, dried, and distilled under diminished pressure. The product was recrystallised from glacial acetic acid and obtained in pale yellow, fern-like aggregates of needles, melting at  $162^{\circ}$  and boiling at  $275^{\circ}$  under 10 mm. pressure; it is easily soluble in the ordinary organic solvents.

0.1552 gave 0.2448 AgCl + AgI. Halogen = 67.69.

$C_{12}H_6Cl_2I_2$  requires Cl + I = 68.39 per cent.

The effect of metallic sodium on the two foregoing substances was studied in the hope of obtaining a new condensation product, for

although Fittig has shown (*Annalen*, 1864, 132, 205) that this metal has no action on 4:4'-dibromodiphenyl, yet a 4:4'-dibromo- or 4:4'-di-iodo-diphenyl which contained a chlorine atom immediately adjacent to each atom of bromine or iodine might conceivably be more easily decomposed. Experiments were made in both ethereal and benzene solutions, but no action could be detected either with the dichlorodibromodiphenyl or the di-iodo-compound. These substances can even be heated with copper powder considerably above their melting points without any condensation taking place.

*The Nitrile of 3:3'-Dichlorodiphenyl-4:4'-dicarboxylic Acid*  
(3:3'-Dichloro-4:4'-dicyanodiphenyl).

A solution of the diazonium salt was added to a boiling solution of cuprous cyanide. After some time, the nitrile was collected, a small portion extracted with ether, the ethereal solution evaporated, and the red residue distilled. The red by-product was not volatile, and the nitrile was thus obtained as a white substance which crystallised from alcohol in white, flocculent needles melting at 152—153°.

*3:3'-Dichlorodiphenyl-4:4'-dicarboxylic Acid.*

The bulk of the crude nitrile was saponified by boiling with dilute caustic soda for a few hours. On filtering and acidifying, the acid separated out and was filtered, dried, and crystallised, first from glacial acetic acid and then from alcohol. From the latter solvent, it separates in small needles melting at 287—288°.

The substance thus obtained is very sparingly soluble in water, but dissolves more easily in alcohol or ether.

0.1280 gave 0.11753 AgCl.  $\text{Cl} = 22.71$ .

$\text{C}_{14}\text{H}_8\text{O}_4\text{Cl}_2$  requires  $\text{Cl} = 22.80$  per cent.

*Chlorination of 4:4'-Dihydroxydiphenyl.*

As already indicated, Magatti (*loc. cit.*) obtained a tetrachlorodiphenol by the complete chlorination of 4:4'-dihydroxydiphenyl ( $\gamma$ -diphenol) in acetic acid solution.

Schmidt and Schultz (*Annalen*, 1881, 207, 334), by treating  $\gamma$ -diphenol with phosphorus pentachloride, obtained three substances, namely, (1) a chlorinated diphenol (m. p. 126°); (2) *p*-dichlorodiphenyl (m. p. 148°); (3) pentachlorodiphenyl (m. p. 179°).

I have already shown that the first product was most probably not

a trichlorodiphenol as suggested by Schmidt and Schultz, but was identical with 3 : 3'-dichloro-4 : 4'-dihydroxydiphenyl (*loc. cit.*) These chemists, assuming that the first product is a trichloro-derivative, explain the formation of the third compound from it by the replacement of hydroxyl by chlorine.

By chlorinating  $\gamma$ -diphenol with bleaching powder solution in presence of acids, a deep violet coloration is produced, which was noticed by Schmidt and Schultz. If this operation is carried out quantitatively, the interesting fact is demonstrated that three molecular proportions of chlorine are absorbed by one of  $\gamma$ -diphenol.

The diphenol (1 gram) was dissolved in caustic soda, dilute sulphuric acid added to the solution, and a solution of bleaching powder introduced from a burette until a reaction was obtained with starch-iodide paper. The amount of chlorine used was 1.14 grams, this quantity being identical with that corresponding with three molecules of chlorine.

The reaction does not appear to go quite smoothly, as a pure substance could not be isolated from the product of chlorination, but analyses indicated that a trichlorodiphenyl had been formed.

The object of these experiments being to find a method of obtaining the dichlorophenol, the direct chlorination in acetic acid solution was studied, and it was found that the mono-, di-, and tri-chloro-derivatives could be prepared by taking calculated quantities of chlorine obtained by oxidising hydrochloric acid with a weighed amount of potassium dichromate.

### *3-Chloro-4 : 4'-dihydroxydiphenyl.*

The diphenol (1.86 grams) was dissolved in glacial acetic acid, and a current of dry chlorine, obtained by warming 0.98 gram of potassium bichromate with hydrochloric acid, was passed into the solution at the ordinary temperature. The gas was at once absorbed, and at the conclusion of the experiment the solution was concentrated to a small bulk and poured into water. The monochloro-compound, which was obtained as a white precipitate, was recrystallised from dilute acetic acid; it forms white needles, soluble in ether, alcohol, or benzene, and melting at 215°.

0.1628 gave 0.10463 AgCl. Cl = 15.89.

$C_{12}H_9O_2Cl$  requires Cl = 16.08 per cent.

### *3 : 3'-Dichloro-4 : 4'-dihydroxydiphenyl.*

The chlorination of the diphenol was carried out exactly as in the preceding case, except that twice the quantity of potassium dichromate was used.

The crude dichloro-compound was recrystallised from hot water and obtained in fine, white needles melting at  $124^{\circ}$ . Its properties were identical with those of the 3:3'-dichloro-4:4'-dihydroxydiphenyl (m. p.  $124^{\circ}$ ), obtained by another method (*loc. cit.*), and a mixture of the two preparations melted exactly at  $124^{\circ}$ . This identity is, of course, a proof of the constitution of this and the preceding substance.

0.1827 gave 0.20763 AgCl. Cl = 28.09.

$C_{12}H_8O_2Cl_2$  requires Cl = 27.81 per cent.

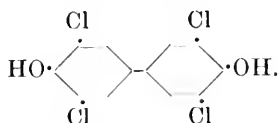

3:3':5(?)-Trichloro-4:4'-dihydroxydiphenyl.

This trichloro-derivative, produced by using the appropriate amount of potassium dichromate, was obtained from dilute acetic acid in white needles; it is soluble in ether, alcohol, or benzene, and melts at  $179^{\circ}$ .

0.0899 gave 0.13083 AgCl. Cl = 35.96.

$C_{12}H_7O_2Cl_3$  requires Cl = 36.75 per cent.

Although the orientation of the third atom of chlorine has not been absolutely demonstrated, yet there can be little doubt that the halogen occupies the position indicated by the notation used in naming the compound. The tetrachloro-compound, which was also prepared, and found to correspond exactly with the substance described by Magatti, has, in all probability, the following constitution:

My thanks are due to Messrs. Levinstein, Limited, Manchester, for a supply of the pure 3:3'-dichlorobenzidine, and to Messrs. K. Whitaker and J. Brothers, who assisted in carrying out certain portions of the practical work.

MUNICIPAL TECHNICAL SCHOOL,  
BURY, LANCASHIRE.

### III.—*Separation and Estimation of Silver Cyanide and Silver Chloride.*

By ROBERT HENRY ADERS PLIMMER, D.Sc. (Grocers' Company's Research Student).

ON boiling a mixture of silver chloride and cyanide with dilute nitric acid, I noticed that the latter salt was easily dissolved with the evolution of hydrogen cyanide, and on collecting this gas in a solution of silver nitrate it was found that the amount of silver cyanide produced was constant. Further experiments showed that silver cyanide was quantitatively decomposed by the action of dilute boiling nitric acid, so that by this means it can be easily separated from silver chloride and estimated.

The earliest and most complete investigations on silver cyanide were made in 1844 by Glassford and Napier (*Phil. Mag.*, 25, 66), who state that nitric acid has no effect on silver cyanide except when concentrated and boiling, and that sulphuric acid diluted with its own volume of water decomposes silver cyanide, liberating hydrogen cyanide and forming silver sulphate; by this means, the cyanide may be separated from silver chloride, which remains unchanged. These observers did not, however, collect the hydrogen cyanide and determine its amount. This observation, although cited in Gmelin's Handbook, has apparently been overlooked, for other treatises on analytical chemistry give only two methods of separation depending on the decomposition of silver cyanide by acids. These processes are (1) that of Kraut (*Zeit. anal. Chem.*, 1863, 2, 243), which consists in oxidising silver cyanide with nitric acid (sp. gr. 1.2) in sealed tubes for several hours at 100° or for one hour at 150°, and (2) that described in Sonnenschein's *Handbuch der Analytischen Chemie* (1871, p. 252), which depends on the action of hydrochloric acid, whereby the silver cyanide is converted into silver chloride, the difference in weight indicating the quantity of cyanogen.

#### EXPERIMENTAL.

The first experiments were carried out with silver cyanide prepared from potassium cyanide in the usual way and dried at 100°. A known weight was gently boiled in a small flask with 200 c.c. of dilute nitric acid, the strength of which was about twice normal, the flask being connected with a condenser placed in a vertical position, to the end of which was attached a Volhard's receiver containing excess of silver

nitrate solution acidified with dilute nitric acid. The hydrogen cyanide passing over with the steam produced a white precipitate in the silver nitrate solution, but although after one hour the silver cyanide was almost entirely decomposed, yet a small quantity remained which was dissolved completely only after boiling for about two hours. This decrease in the rate of decomposition is in all probability due to the resistance offered by the hard lumps which are formed in drying the silver cyanide. The silver cyanide obtained in the receiver was weighed and indicated a loss of 8—10 milligrams; this deficiency was attributed to a small residue of silver chloride, the presence of which was due to the potassium chloride originally contained in the potassium cyanide under examination.

Experiments were then performed with silver cyanide prepared from hydrogen cyanide obtained by the action of dilute sulphuric acid on potassium ferrocyanide. Here, again, a slight loss amounting to about 1 per cent. occurred, as will be seen from the following results:

AgCN taken.*	AgCN obtained.	Loss.
0.3524	0.3484	0.0040
0.5042	0.4994	0.0048
0.3778	0.3744	0.0034
0.2484	0.2446	0.0038
0.3328	0.3288	0.0040

In every case, the silver cyanide at the commencement was rapidly attacked, but the last portions required prolonged boiling for 1—2 hours in order to complete the decomposition. During this time, the nitric acid, which at first was of normal strength, or, in some cases, even weaker, became more concentrated, but although this might have caused a slight oxidation of the silver cyanide, yet it seemed as if this loss were in a great measure due to experimental error, since a deficiency of almost the same amount occurred when the silver cyanide was dissolved in warm ammonia and reprecipitated with dilute nitric acid. Heat was applied in this case because the salt dissolved very slowly in the cold. Two experiments were made.

AgCN taken.	AgCN obtained.	Loss.
0.2590	0.2572	0.0018
0.3996	0.3954	0.0042

The amount of silver in the silver cyanide produced from the hydrogen cyanide obtained in the foregoing distillation was estimated with the following results:

\* The tabulated weights throughout are expressed in grams.

0.2952 AgCN gave 0.2376 Ag. Ag = 80.49 per cent.

0.3948 AgCN „ 0.3174 Ag. Ag = 80.39 „

AgCN requires Ag = 80.56 per cent.

The amount of silver in the silver cyanide reprecipitated from the ammonia solution was also estimated.

0.2484 AgCN gave 0.1996 Ag. Ag = 80.35 per cent.

0.3874 AgCN „ 0.3120 Ag. Ag = 80.54 „

Although dry silver cyanide can in this way only be directly estimated with an accuracy of about 1 per cent., it can be completely separated from silver chloride and indirectly estimated by difference. The following two results were obtained with a mixture of these compounds :

AgCN taken.	AgCN obtained.	Loss.	AgCl taken.	AgCl obtained.
0.3594	0.3552	0.0042	0.6970	0.6974
0.2624	0.2584	0.0040	0.2288	0.2290

From these experiments, it will be seen that it is not necessary to heat the mixture of silver cyanide and silver chloride in a sealed tube with concentrated nitric acid when their estimation is required.

Silver cyanide, however, when freshly precipitated and not dried, is quantitatively decomposed into prussic acid by the action of dilute nitric acid.

In these experiments, a 2 per cent. solution of potassium cyanide was used; in each case, 10 c.c. were allowed to flow from a burette into a known quantity of water containing 5 c.c. of a 10 per cent. solution of silver nitrate. This solution was then acidified with nitric acid until its strength in some experiments was normal, in others semi-normal, and distilled. The distillate, as in the previous experiments, after passing through a condenser was collected in a Volhard's receiver containing 5 c.c. of the solution of silver nitrate acidified with dilute nitric acid. The time taken to completely decompose the silver cyanide was from  $\frac{1}{2}$ — $\frac{3}{4}$  hour, but the distillation was continued for an hour so as to ensure that all the hydrogen cyanide had passed over. The silver cyanide obtained was collected on a tared filter paper, washed with cold water, dried at  $100^{\circ}$ , and weighed.

Two determinations of the amount of silver cyanide (+ silver chloride) given by 10 c.c. of the 2 per cent. solution of potassium cyanide directly were previously made with the following results :

10 c.c. KCN solution gave 0.3892 AgCN	} mean = 0.3887.
10 c.c. „ „ 0.3882 „	

The small residue of silver chloride which remained behind and which, as already mentioned, was due to traces of potassium chloride in the potassium cyanide, was neglected in the first two experiments, but in the remaining six estimations its weight was also determined. Ten c.c. of the foregoing potassium cyanide solution were employed in each experiment, and the results were as follows:

AgCN obtained.	Residue of AgCl.	Total.	Error	
0.3830	—	—	—	
0.3844	—	—	—	
0.3874	0.0038	0.3912	+ 0.0025	} mean = - 0.0004
0.3864	0.0044	0.3908	+ 0.0021	
0.3832	0.0044	0.3876	- 0.0011	
0.3826	0.0052	0.3878	- 0.0009	
0.3846	0.0010	0.3856	- 0.0031	
0.3844	0.0022	0.3866	- 0.0021	

The variations in the amount of silver cyanide obtained are in all probability due to the experimental errors incurred in measuring out the 10 c.c. from a burette, or in drying the tared filter papers at 100°.

A series of six experiments was also carried out with a mixture of freshly precipitated silver cyanide and silver chloride obtained by mixing 10 c.c. of a 2 per cent. potassium chloride solution with the same amount of the 2 per cent. potassium cyanide solution and 10 c.c. of aqueous silver nitrate, then acidifying with nitric acid, and distilling in the manner already described.

The amount of silver chloride given by the potassium chloride solution was estimated separately; two experiments with 10 c.c. yielded 0.3918 and 0.3912 gram of precipitate, giving a mean of 0.3915 gram.

Hence the total amount of insoluble silver salts obtainable from 10 c.c. of potassium cyanide solution and 10 c.c. of potassium chloride solution is 0.7802 gram.

The following table contains the results obtained with the mixture (KCN = 10 c.c.; KCl = 10 c.c.):

AgCN obtained.	AgCl obtained.	Total.	Error.	
0.3840	0.3910	0.7750	- 0.0052	} mean = - 0.0013
0.3842	0.3954	0.7796	- 0.0006	
0.3854	0.3922	0.7776	- 0.0026	
0.3854	0.3940	0.7794	- 0.0008	
0.3866	0.3946	0.7812	+ 0.0010	
0.3832	0.3974	0.7806	+ 0.0004	

The foregoing experiments show that by the action of hot dilute

nitric acid on a mixture of silver chloride and cyanide the latter compound may be entirely removed from the former and its amount directly estimated.

#### IV.—*Action of Malt Diastase on Potato Starch Paste.*

By BERNARD F. DAVIS, B.Sc., and ARTHUR R. LING.

##### *Introductory.*

It is well known that when starch paste is hydrolysed by an aqueous solution of malt diastase, the speed of the reaction as indicated by the diminution of the specific rotatory power, and the increase of the cupric reducing power of the products in a given time becomes less the more the temperature of hydrolysis exceeds a certain point, which is termed the optimum temperature of diastatic action.

Brown and Heron (Trans., 1879, 35, 596) give numerous determinations of the specific rotatory power of the products of the hydrolysis of potato starch in the form of paste by malt extract at different temperatures after the lapse of definite intervals of time, and from their results it may be deduced that the optimum temperature of diastatic action lies between 50° and 60°. Kjeldahl, who, in the same year (*Compt. rend. labor. de Carlsberg, Copenhagen*, 2, 109), confirmed this conclusion by determinations of the cupric reducing powers of the products in question, found the optimum temperature to be 55°.

The velocity of the reaction between diastase and starch paste, if measured by the constants just referred to, becomes less, *pari passu*, at temperatures above 55° up to the point at which the activity of the enzyme is permanently destroyed. Moreover, if solutions of diastase are heated above 55° before mixing with starch paste, the same apparent slackening of the reaction or weakening of the enzyme is observed. The effect of heat on diastase is usually spoken of as restriction, a term we have adopted, it being understood that in all the experiments recorded in this paper the diastase was invariably previously heated in aqueous solution.

In a paper read before the Midland Counties Institute of Brewing (*J. Fed. Inst. Brewing*, 1902, 8, 475), we gave an account of a large number of experiments on the action of diastase (previously

heated in aqueous solution and in the dry state, at various temperatures for definite intervals of time) on potato starch paste.

In the case of previously heated diastase solutions, we found that when the temperature employed was not above the optimum point, the reaction with starch paste near the same temperature (not above it), provided a sufficient mass of the enzyme were employed, proceeded rapidly for the first 75 minutes, and then advanced steadily until, at the end of about 40 hours, the specific rotatory and cupric reducing powers of the product were approximately those of maltose. When, however, the diastase solution was previously heated above the optimum temperature, the reaction was not only slower, as has been observed by others, but the products were apparently different. Thus we found that by the action on starch paste of diastase solutions, restricted in this way at 70° (the hydrolysis being allowed to proceed at 55°), *d*-glucose could invariably be detected after the reaction had continued for several hours.

On the other hand, the products of the transformation of starch made with diastase solutions which had been previously heated for 30—60 minutes at temperatures not exceeding 55° were found by us not to contain *d*-glucose, even when the reaction was taken to its final stage. Nor could we detect *d*-glucose in the starch derivatives made with diastase, which had been previously heated in the dry state at temperatures as high as 125°. The only change in the enzyme observed in such cases was a weakening of its action.

It therefore appeared that the production of *d*-glucose was connected with the initial heating of the diastase solutions at temperatures above 55°, and since the publication of the earlier paper (*loc. cit.*) the work has been continued principally with the object of obtaining further information on this point.

The diastase used in the experiments was prepared by C. J. Lintner's method (*J. pr. Chem.*, 1886, ii, 34, 378), and, except where otherwise stated, from Odessa malt dried at a temperature not exceeding 33°.

We are indebted to Mr. R. E. Free, of Messrs. Free, Rodwell and Co., Mistley, for placing at our disposal several samples of this low-dried malt. The starch used was the purest potato farina. The temperature of hydrolysis never exceeded 55°, but in a few cases it was a degree or two lower than this.

The methods of analysis adopted are explained in our earlier paper (*loc. cit.*), with the exception of that used to estimate *d*-glucose, which consisted in weighing the phenylglucosazone produced under standard conditions, and calculating from the weight the percentage of the hexose on the total solid matter in the solution. The values obtained are denoted by the symbol  $G_{3-93}$ . The symbol  $R_{3-93}$  represents the

cupric reducing power, expressed as percentage of maltose on the total solid matter, calculated by the solution factor 3.93 from the specific gravity of the solution.

### EXPERIMENTAL.

In order to give some idea of the power of the diastase preparations employed, we may quote the following experiment from our earlier paper, in which unrestricted diastase from the same Odessa malt (0.08 gram) was allowed to act, at a temperature of 55°, on starch (10 grams) made into paste of about 3 per cent. concentration.

Time.	$[\alpha]_{D, 3.93}$	$R_{3.93}$
1 $\frac{1}{4}$ hours	150.0°	78.8
18 $\frac{1}{2}$ „	143.6	90.6
42 „	138.5	99.7
66 „	138.0	96.9
138 „	137.6	99.5

An experiment since carried out with diastase from the same source (0.5 gram) and starch (10 grams) made into a paste of about 2 per cent. concentration gave the following results, the hydrolysis being conducted at 47°:—

Time.	$[\alpha]_{D, 3.93}$	$R_{3.93}$
67 hours	135.5°	99.6
89 „	134.6	97.5

This solution, which gave well-defined maltosazone but no glucosazone on treatment with phenylhydrazine acetate, also yielded maltose in the crystalline form.

These experiments show that the reducing power attains a maximum and then undergoes diminution, a phenomenon which we have previously referred to as "reversion," but for which we have not at present found a satisfactory explanation. It is invariably exhibited in the case of conversions with both unrestricted and restricted diastase, and it may occur at any point of the reaction if the latter has stopped, because an insufficient amount of diastase is present to carry the hydrolysis to its final stage.

In addition to the cases already mentioned (*loc. cit.*), we have now obtained further evidence showing that not only does the reducing power diminish when the temperature of hydrolysis is maintained beyond a certain period, but that the rotatory power increases.

The following experiments were all made with diastase restricted by heating in aqueous solution at various temperatures.

## Series I.

A. Three separate amounts of diastase, (a) 1 gram, (b) 0.5 gram, (c) 0.2 gram, were restricted at 77.5—78° for an hour. They were then added to three 10 gram quantities of starch, each made into paste with 375 c.c. of water, and placed in a thermostat at 52—55°.

Time.	$[\alpha]_{D 3.93}$			$R_{3.93}$		
	(a).	(b).	(c).	(a).	(b).	(c).
43 hours	191.1°	190.9°	187.2°	6.7	2.6	1.7
91 „	184.5	191.4	189.7	15.3	4.4	5.8
187 „	181.7	191.1	189.4	18.7	4.5	5.4
259 „	183.2	—	—	20.8	—	—

(a), on fractionation, gave a dextrin insoluble in 46 per cent. alcohol having the constants  $[\alpha]_{D 3.93} = 184.0^\circ$ ,  $R_{3.93} = 2.36$ . A fraction soluble in 80 per cent. alcohol having a reducing power of  $R_{3.93} = 57.3$  was separated; but as this was contaminated with foreign matter from the diastase, and its amount was too small to attempt purification, it was not further examined; (b) and (c) were fractionated and found to contain no constituent capable of giving a crystalline phenylosazone:

B. An attempt was now made to carry this reaction further by employing a lower temperature of restriction. To this end, 0.5 gram of diastase was restricted for an hour at 75°, the solution being then added to 10 grams of starch made into paste with 375 c.c. of water. The temperature of hydrolysis was 52—55°.

Time.	$[\alpha]_{D 3.93}$	$R_{3.93}$
65 hours	171.8°	49.5
113 „	172.9	44.7
161 „	173.9	47.0
280 „	158.6	62.5

The reaction would have undoubtedly proceeded further if more diastase had been employed. The final solution, which gave no insoluble osazone, yielded a soluble osazone having the form of “iso-maltosazone” and melting below 150°. This result showed that *d*-glucose, if formed at all, had again disappeared (see pp. 25—27).

C. Diastase (2.25 grams) was restricted for 15 minutes at 74°, and subsequently for an hour at 75—75.5°. The solution was then added to a paste prepared from 30 grams of starch, and placed in a thermostat at 55°, the total volume of the liquid being 700 c.c.

Time.	$[\alpha]_{D 3.93}$	$R_{3.93}$
16 hours	191.0°	10.2
88 „	190.0	11.7
187 „	186.7	16.4

At the end of 187 hours, the solution still gave a blue coloration with iodine, and after adding 0.02 gram of unrestricted diastase it was again placed in the thermostat at 55°.

Time.	$[\alpha]_{D, 55^\circ}$	$R_{55^\circ}$
65 hours	138.9°	95.6
89   ,,	139.7	93.8

After 89 hours, the solution yielded a small amount of insoluble osazone, but the main portion of the product obtained by heating with phenylhydrazine was soluble in hot water, and had the form of "iso-maltosazone."

Subsequent experiments showed that the period of heating at 75° was too long, and that the unrestricted diastase subsequently added was not in sufficient quantity to complete the reaction. Any *d*-glucose which might have been formed would probably have disappeared again.

#### Series II.

The diastase (1.432 grams) was restricted at 75° for an hour, the solution filtered and added to 10 grams of starch made into a paste with water, the total volume being 400 c.c. After remaining in the thermostat at 55° for 115 hours, more of the same restricted diastase (1.305 grams) was added, and a further addition of 1.572 grams was made at the end of 238 hours.

Time.	Diastase added.	$[\alpha]_{D, 55^\circ}$	$R_{55^\circ}$
—	1.432 grams	—	—
65 hours	—   ,,	167.5°	39.2
89   ,,	—   ,,	162.5	38.8
115   ,,	1.305   ,,	—	—
161   ,,	—   ,,	141.8	56.5
238   ,,	1.572   ,,	—	—
281   ,,	—   ,,	137.5	70.5

The quantity of diastase used, which in the final solution corresponds with about 500 grams of malt, renders the constants (especially the specific rotatory powers) untrustworthy, although blank experiments and corrections were made for each addition of diastase.

No insoluble osazone was obtained from the final solution and only a small yield of soluble osazone. When the portion of this solution soluble in 90 per cent. alcohol was evaporated, even in alcoholic solution, it rapidly became brown. This phenomenon, which has been frequently observed by other workers in the case of the products of the hydrolysis of starch by restricted diastase, will be further dis-

cussed in a subsequent paper. The alcoholic solution of the final products of the conversion just described gave no evidence of the presence of maltose, and did not yield crystals even after a considerable lapse of time.

### Series III.

Attempts were now made to follow the reaction with lower temperatures of restriction.

A. Diastase (0.2 gram) was restricted for an hour at 63°, and the solution added to the paste prepared from 10 grams of starch. The solution, which contained rather more than 2 grams in 100 c.c., was placed in the thermostat at 52°.

Time.	$[\alpha]_{D, 52^\circ}$	$R_{3.93}$
43 hours.	150.3°	77.8
91   ,,	148.5	78.3
187   ,,	145.5	82.0

The final solution yielded a small amount of glucosazone when heated with phenylhydrazine acetate. As 0.2 gram of this diastase, if unrestricted, is more than sufficient to convert 10 grams of starch into maltose in 50 hours, it will be seen that apart from the production of glucose the heating at 63° has produced a great alteration. Subsequent experiments showed that by employing a larger amount of the restricted diastase it is possible to carry the reaction still further than the point attained in this experiment at the end of 187 hours.

B. Diastase (0.2 gram) was restricted for 1½ hours at 60°, and added to 10 grams of starch made into paste. The solution, which contained rather more than 2 grams of starch in 100 c.c., was placed in the thermostat at 55°.

Time.	$[\alpha]_{D, 55^\circ}$	$R_{3.93}$
65 hours	144.5°	88.7
113   ,,	145.5	87.9

The final solution was fractionated with alcohol, the portion soluble in 90 per cent. alcohol yielding, on treatment with phenylhydrazine acetate, an osazone (m. p. 150°), entirely soluble in boiling water and consisting of a mixture of the flat plates characteristic of maltosazone with the aggregates of "isomaltosazone."

If the evidence thus far adduced be taken in conjunction with the results published in our earlier paper (*loc. cit.*), it will be seen that when a solution of diastase is heated from 60° to 78°, the enzyme, besides being weakened, is modified, and, in virtue of this modification,

different products result from its action on starch paste. The nature of these products remains to be determined, but we have established the fact that *d*-glucose is formed when the heating of the diastase solution is carried out between 63° and 70°. Later experiments show that *d*-glucose is produced when the heating takes place at higher temperatures (for example, 78°, p. 29) if this is only maintained for a short time.

Having thus established the fact that this modification in the action of the enzyme is a result of its restriction in aqueous solution, it became interesting to ascertain whether this was due to a permanent alteration of the diastase molecule. The question also arose as to whether the *d*-glucose obtained when restricted diastase acts on starch owes its origin to the action of the modified enzyme on maltose, assuming this to be previously formed. As a result of several experiments, we stated (*ibid.*) that *d*-glucose is not produced by the action of restricted diastase on maltose, but the point is so important that it was again investigated.

#### Series IV.

Diastase (6 grams) was heated at 68° for 1½ hours with 100 c.c. of water, the solution filtered and made up to 250 c.c.

(a) Forty c.c. of the solution were added to 15 grams of starch made into paste with 300 c.c. of water.

(b) One hundred and fifty c.c. of the solution were precipitated with alcohol, the diastase collected, and 0.3 gram of the recovered substance dissolved in water at 52°, the solution being added to 15 grams of starch made into paste with 300 c.c. of water. A blank experiment with some of this reprecipitated diastase was carried out at the same time.

(c) Twenty c.c. of the original restricted diastase solution were added to 170 c.c. of a 4 per cent. solution ( $c_{3.93} = 4$ ) of maltose.

The remainder of the original restricted diastase solution was used for a blank experiment.

(a).			(b).		
Time.	$[\alpha]_{D 5.93}$	$R_{3.93}$	Time.	$[\alpha]_{D 5.93}$	$R_{3.93}$
19 hours	153.7°	71.4	17 hours	164.2°	59.3
43 „	151.8	79.1	41 „	154.1	72.2
67 „	150.0	79.4	113 „	153.0	72.3
139 „	147.6	82.0			

*d*-Glucose was produced in considerable amount in both these experiments. It is therefore proved that the alteration of the diastase by heating with water (in this case at 68°) is a permanent one, as it

retains the property of producing a certain amount of *d*-glucose from starch after being precipitated by alcohol and redissolved in water. It is conceivable that *d*-glucose may also result from the action of unrestricted diastase on starch paste, but that it is condensed to a polysaccharide by a secondary action of the enzyme. Experiments to test this point are now in progress.\*

*Experiment c.*—Action of restricted diastase on maltose (see p. 22).

Time.	$[\alpha]_{D 3.93}$	$R_{3.93}$	
19 hours	134.2°	99.96	100.12
139 „	134.0	99.12	99.18

There is no indication from these constants that *d*-glucose is formed by the action of restricted diastase on maltose, and this conclusion is confirmed by the fact that no insoluble osazone was obtainable from the solution. The constants (which, as in all other cases, were fully corrected for the effect of the diastase remaining in the boiled solution) differ from those of pure maltose to an extent beyond the limit of experimental error. To what this is due we cannot at present say.

The following experiment illustrates the action of unrestricted diastase on maltose, giving the constants  $[\alpha]_{D 3.93} = 137.8^\circ$ ,  $R_{3.93} = 100$ . About 3 grams were dissolved in water, a solution of diastase (0.1 gram) added, and the whole made up to 100 c.c. This solution was placed in a thermostat for 48 hours at  $55^\circ$ , and, on examination, gave the following values:  $[\alpha]_{D 3.93} = 131.5^\circ$ ,  $R_{3.93} = 99.5$ .

The solution yielded no glucosazone, but the soluble osazone obtained crystallised in stellate groups of needles and melted at  $169$ – $170^\circ$ . The maltose, after the above-described treatment, was completely fermentable by yeast.

It now became of interest to determine the amount of *d*-glucose formed by the action on starch paste of diastase, restricted for different lengths of time at various temperatures. For this purpose, the sugars in a known volume of the solution were converted into their phenylosazones under standard conditions, and the insoluble glucosazone collected and weighed. After about 50 determinations, the total mixed products were examined and identified as *d*-glucosazone. This result, taken in conjunction with the rotatory and reducing powers possessed by certain fractionated products which gave the insoluble osazone in large amount, proves conclusively that the osazone was derived from *d*-glucose, and that this sugar is one of the products of the action of restricted diastase on starch paste.

\* Compare Ling (*British Association Report*, 1903, and *J. Fed. Inst. Brewing*, 1903, 9, 450).

The osazone, as weighed, melted as a rule at  $198^{\circ}$ ; sometimes, however, the melting point was higher. After being twice recrystallised from alcohol, it melted constantly at  $204^{\circ}$ . When it was dissolved in glacial acetic acid, the solution had a lævorotation (compare E. Fischer, *Ber.*, 1890, 23, 2119).

Maquenne (*Compt. rend.*, 1891, 112, 799) and C. J. Lintner (*Zeit. ges. Brauw.*, 1895, 18, 153) have both devised methods for estimating various sugars as osazones. After numerous trials, we found that, for our purpose, exceedingly concordant results could be obtained in the estimation of *d*-glucose as osazone by working under the following conditions.

Twenty c.c. of the solution, containing 2—3 grams of starch products per 100 c.c., are mixed with 1 c.c. of phenylhydrazine and 1.5 c.c. of 50 per cent. acetic acid in a boiling tube, and heated for an hour in a bath of boiling water. At the end of this time, the liquid, which has evaporated to a small bulk, is carefully poured on to a tared Gooch crucible, and, after the mother liquor is removed, the crystalline glucosazone is transferred to the crucible and washed with a small quantity of boiling water (about 20—30 c.c.), so that the total filtrate does not exceed 50 c.c. It was found that the maximum amount of pure glucosazone could be obtained by one hour's heating. If the heating is continued for a longer time, decomposition of some of the soluble osazones ensues, and the products of this decomposition contaminate the glucosazone. Under these conditions, 0.1 gram of glucose mixed with various proportions of maltose gives 0.0505 gram of glucosazone. In filtering, care must be taken to allow the mother liquor to pass through the Gooch crucible before adding the washing water, otherwise the soluble osazone is precipitated and clogs the filter.

#### Series V.

These experiments were made in order to ascertain what effect the time of previous heating of the diastase solution has on the amount of *d*-glucose formed. The diastase used was prepared from malt germinated by ourselves in the laboratory (see Ling and Davis, *loc. cit.*, p. 484). Three portions of the diastase, amounting each to 0.3 gram, were restricted at  $64^{\circ}$  for 1 hour, 2 hours, and 4 hours respectively. They were then each added to three 15 gram portions of starch made into paste with 300 c.c. of water, the resulting solutions being placed in a thermostat at  $53^{\circ}$ . The following analytical results were obtained:

Time of restriction.	Time of hydrolysis.	$c_{3.93}$ (corr.).	$[\alpha]_{D 3.93}$	$R_{3.93}$	$G_{3.93}$
1 hour	117 hours	4.291	150.7°	78.9	6.5
2 hours	117 „	4.430	154.2	74.1	7.4
4 „	115 „	4.159	154.4	73.1	7.3

These results indicate that, when the time of restricting at 66° is more than an hour, there is no substantial increase in the amount of *d*-glucose formed.

### Series VI.

A freshly prepared active sample of diastase from Odessa malt was employed ; 0.3 gram was used in each experiment and 15 grams of starch. The temperature of restriction was 65—66°.

	Time of hydrolysis in hours.	Time of restriction in hours.			
		0.5.	1.	2.	4.
$c_{3.93}$ (corr.).	17	4.072	4.147	3.873	3.988
	41	4.345	4.384	4.034	4.079
	113	4.088	4.278	3.880	3.965
	209	4.081	4.175	3.829	3.878
$[\alpha]_{D 3.93}$	17	152.6°	154.0°	154.7°	158.4°
	41	144.6	143.5	147.8	153.2
	113	145.3	146.2	147.3	153.3
	209	145.3	147.8	148.8	153.1
$R_{3.93}$	17	74.4	72.6	71.9	66.3
	41	85.4	83.4	81.6	73.4
	113	87.6	85.1	—	73.4
	209	87.1	83.5	81.3	74.5
$G_{3.93}$	17	4.2	4.0	5.1	nil
	41	8.1	8.0	6.3	2.2
	113	9.9	9.2	7.5	8.0
	209	4.3	7.5	3.8	7.5

\* In this experiment, a distinct amount of matter insoluble in boiling water was obtained, but it was amorphous, and therefore not glucosazone.

It is seen by these experiments that for a restriction temperature of 66° the maximum amount of *d*-glucose is formed when the period of

heating was half an hour. It is interesting to note the marked diminution in the percentage of *d*-glucose, after the hydrolysis has proceeded for 209 hours, as compared with the values in the preceding columns (113 hours). This is possibly due to the condensing action of the enzyme.

*Series VII.*

The same diastase was used as in the last series, but the temperature of restriction was 69°. The temperature of hydrolysis was 55°.

	Time of hydrolysis in hours.	Time of restriction in hours.			
		0.25.	0.5.	1.	2.

### Series X.

In this series, solutions containing the weights of diastase given in the table were restricted at the temperatures mentioned, rapidly cooled, and added to paste prepared from 20 grams of starch and 400 c.c. of water at 55° in each case. The hydrolysis was allowed to proceed for 66 hours.

Amount of diastase.	Temperature of restriction.	Time of restriction.	G <sub>3-93</sub> .
0.3 gr.	59.5—60°	1 hour.	0.5
0.3 „	62°	0.25 „	0.4
0.3 „	62°	0.75 „	0.5
1.0 „	76.5—77.5°	5 min.	3.9

In the last experiment, water, at a temperature of 78°, was mixed with the dry diastase, the mixture having initially a temperature of 76.5°. The solution was raised to 77.5° in 5 minutes, after which it was rapidly cooled and added to the starch paste.

### *Conclusions.*

The effect of heating a solution of diastase is to cause a weakening of the action of the enzyme, and also to produce an alteration in the diastase molecule. The latter effect, which is the more important in the foregoing experiments, is a permanent one, for diastase solution which has been heated above 55° retains its altered properties when reprecipitated from a solution by alcohol and allowed to act on starch paste at a temperature of 55° or below.

The alteration of the diastase appears to commence when a solution is heated below 60°, although a complete change is not effected, inasmuch as the amount of *d*-glucose formed by the action on starch paste of diastase, previously heated for an hour at this temperature, is small.

As the temperature of restriction is increased, the amount of *d*-glucose formed by the action of the enzyme on starch is augmented, and the maximum amount of *d*-glucose is produced by diastase which has been previously heated in solution at 68—70°. Above this temperature, the weakening of the enzyme is so rapid that a much larger quantity of it has to be employed in order to attain the stage of the reaction at which *d*-glucose appears, especially if the heating is prolonged; nevertheless, this hexose is formed by diastase restricted at temperatures up to 78°, and probably above this.

It has invariably been observed that, when the solution is kept at the temperature of hydrolysis, usually 55°, after the maximum amount of *d*-glucose has been formed, this sugar diminishes in amount, and the occurrence of this apparently condensing action of the enzyme may probably explain the occasional failure to detect *d*-glucose among the products of hydrolysis (see Series I and II). In any case, the maximum amount of *d*-glucose formed does not exceed 12 per cent. of the total hydrolytic products.

## V.—*The Action of Halogens on Compounds containing the Carbonyl Group.*

By ARTHUR LAPWORTH.

THE question of the nature of the mechanism of substitution in carbon compounds has attracted much attention during recent years, more especially in certain cases where the compounds are benzenoid in character and in which the process of substitution in the aromatic nucleus appears to involve the initial formation of an additive product of the compounds with the agent used or of an intermediate substitution product in which the substituting atom or group is not found in its final position of attachment.

Considerably less is known of the mode in which substitution occurs in fatty compounds; and in what is possibly the simplest case of all, namely, that of direct substitution such as occurs among the paraffins, it may be said that there is no evidence which affords any real assistance in arriving at conclusions as to the mechanism of the process, and generally these cases have been avoided as being the most difficult to solve.

The case of substitution in the group of compounds containing the complex  $\text{:CH}\cdot\text{CO}$ , such as ketones, aldehydes, carboxylic acids and their derivatives, is one of considerable interest, and in certain aspects has aroused much discussion, for there is here a possibility that the characteristic replaceability of the  $\alpha$ -hydrogen atom may be not a direct process, but one due to the initial formation of the enolic form  $\text{:C:C(OH)}\cdot$ , and this view has appeared more probable since it has been shown that the nitro-paraffins, which in many respects resemble carbonyl compounds, are apparently not capable of being brominated directly, but are easily converted into monobromo-derivatives if they are first transformed into the isonitro-form which corresponds with the enolic forms of carbonyl compounds. It is a general rule, too, that those carbonyl compounds are the most easily attacked which are known to be capable of conversion into their enolic forms or one of the corresponding metallic derivatives.

The difficulty with which the paraffins are attacked by halogens renders this question of the mechanism of their substitution most difficult to investigate in a satisfactory way, and it seems desirable, therefore, that search should be made for some other class of more easily substituted compounds in which the process is direct, at least in the same sense as it probably is in the paraffin series, and the work described in the present paper was commenced in the hope that, after all, the bromination of simple ketones might prove to be mainly the

result of "direct" substitution. The results obtained, however, can only be interpreted on the opposite assumption; briefly stated, they were as follows.

The action of bromine on acetone in dilute aqueous solution is exceedingly slow, but becomes more rapid in presence of acids, the resulting accelerations being of the same order in the case of the more powerful mineral acids (sulphuric, hydrochloric, and nitric acids), and less obvious in the case of the weaker ones, such as acetic acid. The influence of hydrochloric acid on the velocity was not appreciably affected by the presence of an equivalent amount of potassium chloride or bromide. Neutral salts of strong bases and acids in general did not produce any marked influence on the speed of reaction. It was noticed, too, that the velocity observed in diffused daylight was not appreciably different from that in darkness.

The effect of the three mineral acids was nearly proportional to the amounts used, but in the case of sulphuric acid, between the concentrations 0.04- and 0.40-normal, the effect was proportionately slightly greater as the dilution increased. The velocity was nearly proportional to the concentration of acetone, but was practically independent of the concentration of the bromine.

Discussing these points in the reverse order, it may be observed that the independence of the velocity of reaction on the concentration of bromine shows clearly, first, that the reaction proceeds in at least two stages, in one or more of which the bromine is not involved, and, secondly, that in the stage or stages in which the bromine takes part, the velocity of reaction is so great that the time occupied is not measurable.

The approximate proportionality of the velocity to the concentration of the acetone indicates that in the reaction representing that stage, the velocity of which is measured, only one molecule of acetone takes part, whilst the observations as to the influence of acids of different concentration are best explained on the supposition that in this reaction one hydrogen ion is involved.

The increasing degree of dissociation of sulphuric acid due to dilution becomes apparent in the slight increase of the velocity constants representing the speed of absorption of bromine per equivalent of acid per litre.

The effects produced by sulphuric, nitric, and hydrochloric acids at the concentrations 0.40-normal were represented approximately by the numbers 1.19, 1.20, 1.36. These numbers, although of the same order of magnitude, are not proportional to the respective concentrations of the hydrogen ions. This discrepancy, however, is not without parallel, and does not militate seriously against the foregoing general conclusion.

It seems probable, then, that the bromination of acetone under the

conditions maintained is best regarded as the result of a slow, reversible change effected in the acetone by the hydrogen ions, followed by an almost instantaneous bromination of the product, a change which is not appreciably reversible. This intermediate product is perhaps the enolic form of the ketone, as it has been already shown that in many cases the rapid attainment of equilibrium between the tautomeric forms of carbonyl compounds is brought about by acids (Trans., 1902, 81, 1503, and 1903, 83, 1121), whilst there is ample reason for believing that the enolic forms are the more rapidly attacked by substituting agents.

It is clear, also, that the independence of the speed of reaction on the concentration of bromine shows that the velocity with which the second form of the acetone is brominated must be incomparably greater than that of the reverse change of the labile to the normal form, so that the observed velocity is a fairly precise measure of the speed with which acetone is converted from the normal into the less stable form.

In the case of the interaction of chlorine and acetone, the speed of reaction is more obviously dependent on the concentration of the halogen, but as that concentration diminishes, the velocity decreases until it approximates very nearly to that observed when bromine is used under similar conditions. This difference might be explained in at least two ways: (1) that chlorine acts directly on acetone, or (2) that the halogen is capable of existing in the initial change in the ketone which precedes the actual substitution. Of these, however, the first possibility is apparently disposed of by experiments on the action of chlorine on neutral solutions of acetone, as in this case the initial velocity of reaction is far too small to account for the difference in the speeds with which chlorine and bromine are absorbed by acetone in presence of acid: in both cases, the speed increases with lapse of time, owing, doubtless, to the increasing amount of acid present.

The last part of the paper contains an account of some experiments which were made for the purpose of ascertaining whether the action of chlorine and bromine on other carbonyl compounds is accelerated by acids, and the results show beyond question that the effect is a fairly general one and is well marked in the case of acetone and other ketones in solvents other than water, and also in those of carboxylic acids and their anhydrides and esters.

The ease with which dry acetic acid may be brominated in presence of halogen hydrides leads to a simple explanation of the part played by small quantities of phosphorus in promoting the action of halogens on carboxylic acids. The phosphorus chlorides and bromides which are produced in the first instance, will react so as to remove the water present, supplying at the same time the requisite hydrogen chloride or bromine; in the absence of water, the halogen hydrides

will be produced by the interaction of the phosphorus halogen compounds with some of the carboxylic acid itself. The usual explanation, namely, that the halogen only attacks the acid chloride or bromide is no longer necessary since it has been shown that the accelerating effect of powerful acids is not confined to substitutive changes in the series of carboxylic acids.

### EXPERIMENTAL.

#### *Bromination of Acetone.*

The action of bromine on acetone, either undiluted or dissolved in organic solvents, is difficult to control, and dilute aqueous solutions of the ketone were therefore employed, the experiments being made with the object of ascertaining, first, the effect of varying concentrations of acetone and bromine, and, secondly, the effects produced by foreign substances which might reasonably be expected to alter the velocity of reaction, either by their influence on the state of dissociation of the reacting substances or by retarding or accelerating the changes of structure which the ketone might undergo.

In the preliminary experiments, a dilute aqueous solution of acetone was rendered yellow by the addition of bromine water and then divided between a number of stoppered bottles, to each of which was then added varying quantities of a number of electrolytes. The results showed clearly that the effect of neutral salts, such as sodium sulphate, potassium bromide, &c., was very slight, but that acids caused a very marked increase in the speed with which the colour of the bromine disappeared, so that, instead of occupying some days or even weeks, the action was at an end in a few hours or minutes, according to the affinity and the amount of acid present. Thus with equivalent amounts of sulphuric acid, hydrochloric acid, and acetic acid, the first two acted very rapidly, and the last caused a marked acceleration; with acetic acid in presence of an excess of sodium acetate,\* the change was almost as slow as in the absence of acids.

In order to ascertain whether the product of the action of bromine on acetone in presence of dilute mineral acid was a simple substitution product, 30 grams of acetone were dissolved in a mixture of 200 c.c. of water and 50 c.c. of ordinary hydrochloric acid, the whole being allowed to remain for several weeks in a stoppered vessel with one molecular proportion of bromine. After the colour of the solution had entirely disappeared, the solution was filtered from a very small

\* In this instance it was found necessary to submit the sodium acetate to a preliminary treatment with a small quantity of bromine, the excess of which was afterwards removed by a stream of air, as the salt invariably absorbed a small quantity of halogen even after repeated crystallisation.

quantity of crystalline matter, cooled in ice, and saturated with calcium chloride, the oil which separated being removed, dried, and fractionally distilled.

The crystalline material was insoluble in water and crystallised from ethyl acetate in fine needles melting at  $75^{\circ}$ .

0.3112 gave 0.6483 AgBr. Br = 88.6.

$C_3H_5OBr_5$  requires Br = 88.5 per cent.

The compound appeared to agree in all its properties with the penta-bromoacetone melting at  $76^{\circ}$ .

The liquid portion of the product had the characteristic pungent odour of bromoacetone, and, when rapidly distilled under atmospheric pressure, passed over for the most part between  $130^{\circ}$  and  $142^{\circ}$ , a certain amount of a dark brown residue remaining in the flask. The fraction boiling at  $130$ — $142^{\circ}$  was washed with dilute sodium carbonate solution to remove the hydrogen bromide liberated during the distillation, dried over anhydrous sodium sulphate, and analysed.

0.1685 gave 0.2338 AgBr. Br = 59.0.

$C_3H_5OBr$  requires Br = 58.4 per cent.

There is therefore no reason to suppose that the reaction between acetone and bromine in presence of dilute acids is in any way abnormal. It may be mentioned that in the quantitative experiments described below the products invariably had the pungent odour of bromoacetone.

A series of quantitative experiments was made with a dilute aqueous solution of acetone at a constant temperature, the concentration of the bromine being determined from time to time by withdrawing aliquot portions of the solution by means of a pipette, and running these directly into a solution of potassium iodide; the amount of iodine liberated was ascertained by titration with a 0.05-normal solution of sodium thiosulphate, the exact value of which was checked from time to time.

The concentration of the acetone was kept somewhat low in order that its condition of hydration might be as nearly as possible the same in different experiments, which will only be the case in dilute solution. Moreover, the relative amount of bromine employed at first was always considerably less than one molecular proportion, so that the concentration of the unsubstituted portion of the acetone should not vary too widely; it was found, as a matter of fact, that within the limits adopted the relative initial concentrations of the bromine and acetone did not appreciably affect the nature of the results.

In every case in which a flask had to be opened several times during an operation, so that a measurable quantity of volatile materials might

have escaped, a second flask was prepared simultaneously, in precisely the same way, and opened for titration only at the beginning and at the end of the experiment; in the few cases in which the titres did not correspond, the results were rejected. Further, in order that the results should have at least a comparative value, the correct working of the thermostat and the concentration of the solutions were tested by another determination of the velocity of reaction in a solution of standard concentration, so that any material variation in the conditions could be readily detected and the necessary allowance made. These measurements were, however, made with the object of ascertaining the general character of the influence of the materials employed, and are to be regarded as approximations only, but it is probably safe to suppose them comparable.

The speed of removal of bromine by a dilute aqueous solution of acetone in the absence of free acid or alkali is very small; thus, in a solution containing 40 grams of acetone per litre, the free bromine at the commencement of the experiment corresponded with 9.25 c.c. of  $N/20$  thiosulphate per 25 c.c. of the solution, whilst at the end of three days, during which time it remained at the temperature of the laboratory, the titre had only diminished to 9.05, and at the end of a week it was 8.70.

In the presence of acid, the speed of disappearance of the bromine was nearly constant. The numbers obtained in the following experiments, in which the concentration of acetone and sulphuric acid, as well as the temperature, are those which were adopted throughout as the standard for comparison, prove clearly that the speed at the end of the operation is practically identical with that at the commencement. The temperature throughout the series of experiments was  $20.3^{\circ}$ , except where a statement to the contrary occurs. The titres are those for 25 c.c. of solution, and are given in terms of  $N/20$  thiosulphate; the initial and final numbers are expressed in the same terms, but were always determined by the titration of 50 c.c. of the solution, so that the numbers in these cases are one-half of those actually obtained, and were used throughout for the determination of the approximate value of the constant  $k$ , this term being found by the aid of the formula:

$$k = 10^4 \times V/c_1c_2,$$

where  $V$  is the velocity of disappearance of free bromine in gram-molecules per litre, and  $c_1$  and  $c_2$  are the concentrations of the ketone in gram-molecules, and of the acid in gram-equivalents per litre respectively.

The numbers in the third column of the following table are those calculated on the assumption that the reaction may be represented by a straight line between the initial and final points.

*Experiment A.*

Quantities employed : acetone = 40 grams ; normal  $\text{H}_2\text{SO}_4$  = 400 c.c. per litre.

Time.	Titre.	Calculated.
0	19.25	—
10 minutes	17.05	16.95
20    ,,	14.80	14.60
60    ,,	5.00	5.30
67    ,,	3.50	3.65
70    ,,	3.00	3.05
75    ,,	1.60	1.90
80    ,,	0.65	0.75
83    ,,	0.05	—
$k = 8.38$		

Two other experiments with the same concentrations of acid and ketone gave  $k = 8.52$  and  $8.57$ .

As these experiments indicated that the velocity of bromination was nearly independent of the amount of bromine present, two other experiments were made with small quantities of the halogens and these confirmed this conclusion, the same rectilinear character being evident and the constants found being (*B*)  $8.40$  and (*C*)  $8.55$ .

In Fig. I (p. 37), the results of the last two experiments are compared with those given in the foregoing table.

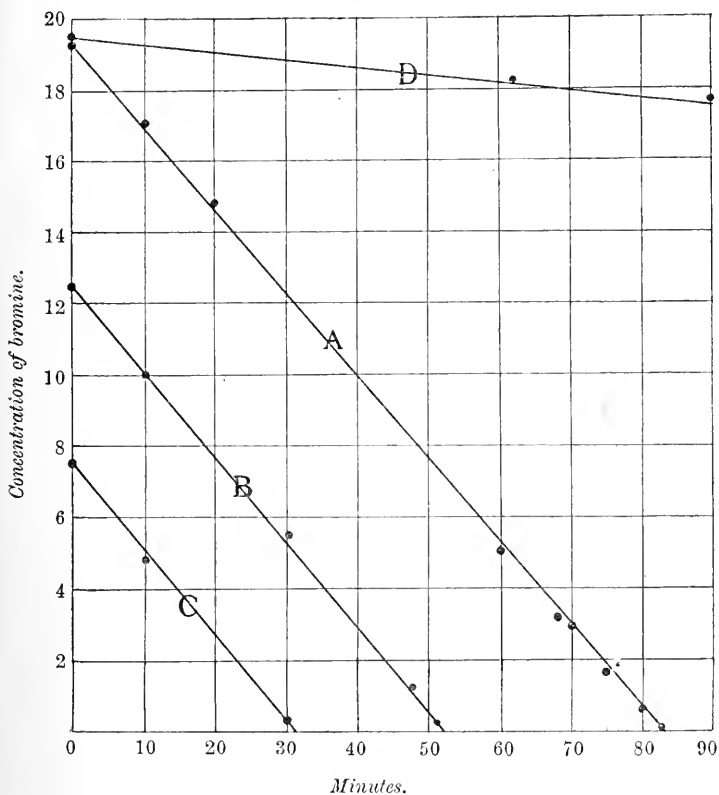

In order to determine whether the initial change produced in the ketone by the acid was a reversible one, a solution containing 40 grams of acetone and 400 c.c. of normal sulphuric acid was prepared and allowed to remain for four days, when a measured bulk of bromine water was added and the whole at once diluted to one litre with water at  $20.3^\circ$ , an exactly similar solution being made simultaneously in which the ketone and acid were brought into contact only at the last moment. It was found that the titres of 25 c.c. of these solutions, five minutes after making up, were 17.2 and 17.4 respectively, whilst the corresponding velocity constants were  $k = 8.31$  and  $8.43$  respectively ; it seems clear, therefore, that the initial change occurs only to a very minute extent and is of a reversible character.

*Effect of the Concentration of Ketone and Acid.*—The line *D* in Fig. I represents a portion of a line joining the points corresponding with the initial and final titres obtained in an experiment in which the concentration of the acetone is only one-tenth of that present in *A*, *B*, and *C* ; the reaction velocity was somewhat less than a tenth of that observed in the other three cases.

The mean results obtained in a number of experiments at  $20.3^{\circ}$  are given in the following table, and represent the variation of  $k = 10^4 \times V/c_1c_2$  with the concentration of ketone and acid.

Sulphuric acid.	Acetone (grams per litre)			
	4	10	20	40
0.40 gram-mols. per litre	8.07	8.24	8.38	8.49
0.20                    "	—	8.53	8.59	8.71
0.10                    "	—	—	8.81	8.93
0.04                    "	—	—	—	9.68

FIG. 1.

With hydrochloric and nitric acids at a concentration of 0.40 gram-molecules per litre and 40 grams of acetone per litre, the reaction was also rectilinear, the constants found being 11.56 and 10.21 respectively. In presence of potassium chloride and bromide with hydrochloric acid of the above concentration, the constants ( $k$ ) were 11.69 and 11.54 respectively, in both cases, an amount of

the salt equivalent to the acid present being employed. The results obtained with 0.40-normal acetic acid were very inconsistent, a rapid fall in the bromine concentration being observed at first and due perhaps to some impurity in the acetic acid, which was not readily removed, even by distillation over sodium acetate. With acetic acid in the presence of two equivalents of sodium acetate which had been purified by a preliminary treatment with bromine, a rapid initial fall in the titre from 16.80 to 14.25 occurred in the course of a quarter of an hour, whilst subsequently the action became so slow that after an additional period of five days the titre had fallen only to 13.90.

*Chlorine and Acetone.*

On the whole, it was found that when chlorine was allowed to act on acetone in dilute aqueous solution in presence of mineral acids, this halogen invariably disappeared somewhat more rapidly than bromine. The following details of two simultaneous series of measurements made with two solutions of identical concentration as to acetone and acid will serve to show what was the general nature of the difference observed in the two cases.

Quantities employed: acetone = 20 grams per litre; normal  $\text{H}_2\text{SO}_4$  = 400 c.c. per litre.

A. Bromine.		B. Chlorine.	
Time.	Titre.	Time.	Titre.
0	9.20 c.c.	0	(?)
12.5 minutes	7.75 "	11.0 minutes	11.00 c.c.
34.0 "	5.45 "	19.0 "	8.90 "
65.5 "	1.80 "	26.0 "	7.70 "
71.5 "	1.15 "	38.5 "	5.65 "
77.5 "	0.40 "	47.0 "	4.50 "
		55.5 "	3.40 "
		64.0 "	2.25 "
		74.0 "	1.10 "
		81.0 "	0.35 "

It will be noticed that the chlorine at first disappears with considerably the greater speed, but, as the concentration of the halogen diminishes, the velocity of chlorination approaches very nearly to that of bromination, so that it appears that the velocity of substitution is not so nearly independent of the concentration of the halogen in the former as in the latter case.

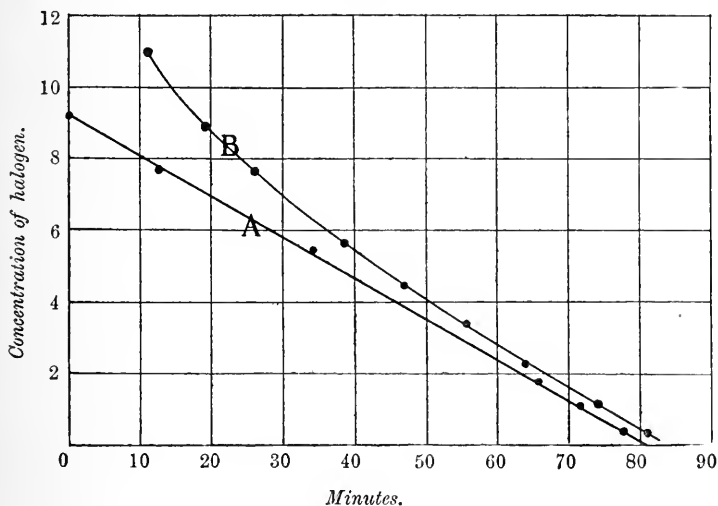

To test the question as to whether chlorine exerts an independent or direct influence on the speed of substitution, the effects of the two halogens on dilute, initially neutral, aqueous solutions of acetone were

directly compared and the following results obtained, the concentration of the acetone being 40 grams per litre.

A. Bromine.			B. Chlorine.		
Time.	Titre.		Time.	Titre.	
0	10.70	c.c.	0	9.95	c.c.
4 hrs. 5'	10.45	"	3 hrs. 6'	9.85	"
23 " 53'	10.70	"	23 " 6'	9.55	"
87 " 3'	10.30	"	87 " 0'	7.60	"
168 " 0'	9.10	"	168 " 0'	2.40	"

Thus the action of chlorine alone on acetone is very slow indeed and does not account for the very considerable difference between the initial velocities of chlorination and bromination in the presence of acid.

FIG. 2.

#### *Bromination of Acetone in Solvents other than Water.*

Specimens of purified light petroleum, benzene, and chloroform were allowed to remain in contact with bromine for some hours and were then washed repeatedly with dilute alkali and water and finally dried. This treatment was found to be necessary, as almost all specimens of these liquids were found to decolorise a small quantity of bromine, and the subsequent action of bromine on acetone dissolved in them was much too rapid for comparative experiments, owing, probably, to the production of free hydrogen bromide.

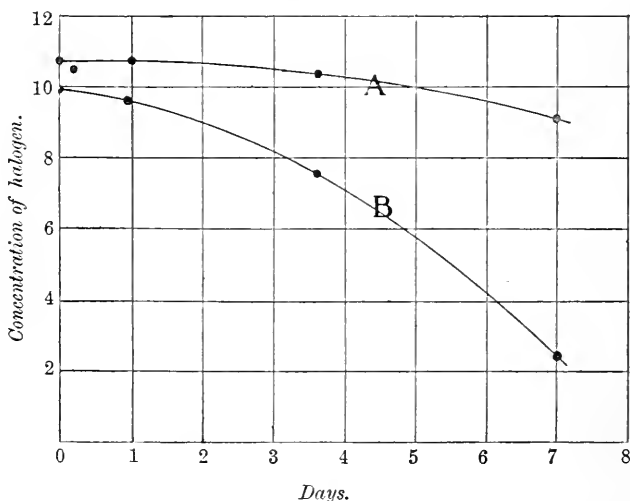

Highly dilute solutions of acetone, hydrogen chloride, and bromine

in the purified solvents were then prepared, and it was found on mixing the solutions of acetone and bromine that the disappearance of the colour of the latter was conveniently slow at first and that addition of the hydrogen chloride solution produced a very marked acceleration. It was also observed that, when no hydrogen chloride was added, the disappearance of successive small quantities of bromine occurred with increasing rapidity, owing, no doubt, to the hydrogen bromide formed.

*Effect of Acids on the Speed of Bromination and Chlorination of other Carbonyl Compounds.*

Many ketones are not, at first, easily attacked by bromine, but when once the reaction has begun it proceeds rapidly. This effect

FIG. 3.

may be noticed when, for example, methyl isopropyl ketone is treated with bromine in the cold or when  $\alpha$ -bromocamphor is prepared by adding bromine to camphor which is being heated on the water-bath.

Acetic anhydride, when mixed with bromine at the ordinary temperature, is only very slowly affected, but, if previously saturated with hydrogen chloride or if mixed with a few drops of sulphuric acid and subsequently cooled, is so readily attacked that on the addition of bromine the temperature rises appreciably and in the course of a few minutes the colour of the halogen may disappear.

Diethyl malonate was examined as a type of ester which is comparatively easily brominated. When this substance is mixed with purified bromine at the ordinary temperature, no marked effect is noticeable, often during the course of some hours; in presence of a small quantity of hydrogen chloride, however, the action proceeds very rapidly, even if the temperature is kept low. A striking experiment may be made by mixing a few grams of the ester with an approximately equal bulk of bromine in the cold; a few drops of the mixture are warmed in a test-tube over a Bunsen burner, and when the resulting action is complete the fuming product is cooled and added to the bulk of the mixture; a violent reaction soon occurs, hydrogen bromide is evolved in large quantities, and the colour of the liquid changes from a deep brown to a very pale yellow, the change being usually complete in less than a minute.

Acetic acid was chosen to illustrate the case of acids. As is well known, bromine scarcely acts on acetic acid even at its boiling point, and it was found that, even when saturated with hydrogen chloride or bromide, this acid, when containing 1 or 2 per cent. of water, is only slowly attacked by the halogen at the temperature of the water-bath. If, however, it is repeatedly purified by freezing, it becomes easy to prepare bromoacetic acid, first by saturating the dry product with hydrogen chloride, and then by warming it at 80—90° with a slight excess of bromine: thus, from 33 grams of 99 per cent. acetic acid saturated with hydrogen chloride, a yield of 54 grams of bromoacetic acid or 71 per cent. of the calculated amount was obtained after 9 hours' heating with bromine on the water-bath.

In another experiment, 100 grams of the acid containing 95 per cent. of pure acetic acid were mixed with 22 grams of acetyl chloride for the purpose of removing water and affording simultaneously the requisite hydrogen chloride. After 42 grams of this mixture had been heated for 5 hours on the water-bath, the product was treated with successive quantities of bromine and distilled at the end of 6 hours; a yield of 83 grams of crystalline bromoacetic acid was thus obtained corresponding with about 85 per cent. of the calculated amount.

The effect of chlorine on dry acetic acid is similar; in diffused daylight, acetic acid saturated with hydrogen chloride was only slowly chlorinated at 100°, but this is also the case when phosphorus is employed, and the speed in the two cases appears to be very similar. It is probable, therefore, that in direct sunlight the yield by this process might be as good and the action as rapid as in the ordinary method, but no opportunity was obtained of trying the reaction under these conditions.

The author is indebted to the Research Fund Committee of the Chemical Society for a Grant which defrayed some of the cost of the investigation.

## VI.—*Derivatives of Menthyl Cyanoacetate.*

By DOUGLAS ANDERSON BOWACK and ARTHUR LAPWORTH.

THE esters of acetoacetic, cyanoacetic, and malonic acids contain hydrogen atoms, which, although directly attached to carbon atoms, are easily replaced by sodium, and the resulting metallic derivatives, at least in the case of the first two classes, appear to be derived from the enolic modifications of the esters. The stability of the enolic forms of the free esters appears to vary considerably, and only in the case of the derivatives of the acetoacetates is there any direct evidence that a measurable amount of free enol is present when an equilibrium is attained. In the hope of obtaining further evidence on this point, some optically active derivatives of cyanoacetic acid were prepared, with the view of determining whether they exhibited any measurable mutarotation, as this phenomenon is apparently always associated with change in molecular structure, and, moreover, was well marked in the case of certain derivatives of menthyl acetoacetate (Trans., 1902, 81, 1502, and 1903, 83, 1117).

The following investigation had been practically completed when a paper by Tschugaeff appeared (*J. Russ. Phys. Chem. Soc.*, 1902, 34, 6069), in which the rotatory power of menthyl cyanoacetate was given, so that the first compound described in the present paper is not new.

We have not been able to consult the original paper, but the rotatory power of the ester as given in an abstract (Abstr., 1903, ii, 1) agrees satisfactorily with the number we had previously obtained.

Menthyl cyanoacetate does not appear to exhibit a trace of mutarotation, even in presence of traces of bases or acids, agents which have been found to accelerate this change whenever it occurs. The rotatory power of the monobromo-derivative in benzene, however, altered somewhat rapidly from  $[\alpha]_D - 23.42^\circ$  to  $[\alpha]_D - 32.97^\circ$ .

It was expected that if mutarotation occurred in any of the derivatives of this ester, it would probably be most readily detected in the azo-compounds, particularly as the azo-derivatives of menthyl aceto-

acetate exhibited this property in an extraordinary degree (compare Trans., 1903, 83, 1117). Moreover, Weissbach (*J. pr. Chem.*, 1903, [ii], 67, 395) has shown that ethyl phenylazocycanoacetate may be obtained in three different forms, two of which he regards as stereoisomeric azocycanoacetates, and the third as ethyl  $\alpha$ -phenylhydrazonocycanoacetate. No appreciable change in the rotatory powers of the menthyl esters, however, could be detected.

It is worthy of note that the rotatory powers of the azo-compounds described in the present paper, unlike those of menthyl acetoacetate (compare Trans., 1903, 83, 1117), are within the usual limits found for menthyl esters of ordinary carboxylic acids. Menthyl bromocycanoacetate, however, has initially an abnormally small rotatory power, which, as in similar cases, may perhaps be due to the presence of the asymmetric carbon atom present in the acyl residue.

#### EXPERIMENTAL.

##### *Menthyl Cyanoacetate*, $\text{CN} \cdot \text{CH}_2 \cdot \text{CO}_2 \cdot \text{C}_{10}\text{H}_{19}$ .

Menthol (43 grams) and ethyl cyanoacetate (30 grams), mixed in a distilling flask connected with a condenser, are gently heated over an Argand burner at such a temperature that about one drop of alcohol per minute is collected, and the heating is continued until the theoretical amount of liquid has thus been obtained. The product is then submitted to fractional distillation under a pressure of about 30 mm., so as to remove the considerable amount of menthene which is always formed; when the temperature of the vapour has risen to about  $150^\circ$ , the distillation is interrupted, and the residue, which partly solidifies on cooling, is triturated with alcohol and spread on porous earthenware, the solid being finally recrystallised from alcohol.

0.2018 gave 0.5167  $\text{CO}_2$  and 0.1726  $\text{H}_2\text{O}$ .  $\text{C} = 69.8$ ;  $\text{H} = 9.5$ .

$\text{C}_{13}\text{H}_{21}\text{O}_2\text{N}$  requires  $\text{C} = 70.0$ ;  $\text{H} = 9.4$  per cent.

The ester is somewhat readily soluble in most of the ordinary organic media, and crystallises from alcohol in well-defined, small prisms or flat needles melting at  $83-84^\circ$ .

In plane polarised light, the crystals show straight extinction, and the directions of greatest elasticity and length are coincident, the double refraction being strong.

When melted between glass slips, the compound solidifies readily in very long, flat needles, crystallographically identical with those obtained from alcohol; in these, the optic axial plane cuts the crystals longitudinally, and in some cases a bisectrix, probably the obtuse, of a figure of wide angle, emerges normally to the field, so that the acute

bisectrix is probably emergent at the apices of the crystals. For the determination of the rotatory power, a solution of 0.5000 gram of the ester in benzene (25 c.c.) was examined in a 2 dm. tube; the rotation observed was  $\alpha_D = -3.25^\circ$ , giving  $[\alpha]_D = -81.15^\circ$ ; no alteration of this value was noticed after the lapse of some days, and no change was effected by the introduction of traces of piperidine or trichloroacetic acid. The rotatory power of menthyl cyanoacetate was given by Tschugaeff as  $[\alpha]_D = -80.71^\circ$  (*loc. cit.*).

*Menthyl bromocyanoacetate*,  $\text{CN}\cdot\text{CHBr}\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_{19}$ , was made by adding the requisite quantity of bromine to a solution of menthyl cyanoacetate in chloroform, the product being allowed to remain until the reaction was complete, when it was shaken repeatedly with water, dried over calcium chloride and evaporated, the solid residue being then crystallised from alcohol.

0.1908 gave 0.1176 AgBr.  $\text{Br} = 26.4$ .

$\text{C}_{13}\text{H}_{20}\text{O}_2\text{NBr}$  requires  $\text{Br} = 26.5$  per cent.

The substance is somewhat readily soluble in chloroform, benzene, and glacial acetic acid, but more sparingly so in alcohol and light petroleum. It separates from alcohol in well-defined, small prisms, which in plane polarised light have straight extinction and strong double refraction, the directions of greatest length and elasticity being coincident; when melted between glass slips, it solidifies in masses of very small, ill-defined, flat needles.

For the determination of the optical activity, a solution of 0.4056 gram of the compound dissolved in benzene (25 c.c.) had an initial rotation in a 2 dm. tube of  $\alpha_D = 0.76^\circ$ , whence  $[\alpha]_D = -23.42^\circ$ . The value rose within half an hour to  $[\alpha]_D = -32.9^\circ$ , afterwards remaining constant at this point.

*Menthyl p-Tolylazocyanoacetate*,  $\text{CH}_3\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{CH}(\text{CN})\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_{19}$ .

It was not found possible to obtain menthyl phenylazoacetate in a crystalline form, but the preparation of the corresponding *p*-tolylazo-compound presented little difficulty. Menthyl cyanoacetate was dissolved in a large quantity of warm alcohol containing an excess of sodium acetate, and to the well-cooled liquid was slowly added one molecular proportion of *p*-tolyl diazonium sulphate dissolved in the smallest possible quantity of water. After some hours, during which the mixture remained at the temperature of the laboratory, the whole was poured into water and the deposited oil collected, washed repeatedly with water, and dissolved in an equal bulk of alcohol. After some weeks, the azo-compound was deposited in large crystals, which were freed from adherent oil and recrystallised from alcohol.

0.2120 gave 0.5467  $\text{CO}_2$  and 0.1509  $\text{H}_2\text{O}$ .  $\text{C} = 70.3$ ;  $\text{H} = 7.9$ .

$\text{C}_{20}\text{H}_{27}\text{O}_2\text{N}_3$  requires  $\text{C} = 70.4$ ;  $\text{H} = 7.9$  per cent.

The compound dissolves readily in ether, ethyl acetate, acetic acid, chloroform, and benzene, but is much more sparingly soluble in alcohol and light petroleum. It separates very slowly from warm supersaturated solutions in alcohol in the form of beautiful, large, transparent, yellow plates which melt at  $93-95^\circ$ . When crushed fragments of the crystals are examined in cedar-wood oil in convergent polarised light, a biaxial interference figure of wide angle is occasionally noticeable. If, as is probable, the figures observed were those surrounding the acute bisectrix, the double refraction is positive in sign and strong. After melting between glass slips, the substance could not be made to resolidify.

For the determination of the optical activity, a solution of 0.7543 gram of the compound in benzene (50 c.c.) was examined in a 2 dm. tube. The rotation observed as a mean of several concordant readings was  $\alpha_D = -1.62^\circ$ , whence  $[\alpha]_D = -53.7^\circ$ .

The rotatory power did not change after the solution had remained for several days; the addition of piperidine, however, caused an immediate alteration of the observed rotation by  $0.04^\circ$ , but this new value was also constant, so that the change was probably not due to mutarotation; no effect was produced by the addition of trichloroacetic acid.

The azo-compound does not appear to dissolve in cold 30 per cent. aqueous sodium hydroxide, even if very finely powdered, and it communicates no colour whatever to the liquid; even if the alkali is added to the alcoholic solution of the substance, when the liquid is poured into water, the latter is found to be colourless after the precipitate has settled. The corresponding ethyl ester dissolves somewhat readily in dilute alkali, and the difference in properties between the two esters is doubtless to be attributed to the very great relative difference between their solubilities in water rather than to any chemical dissimilarity (compare Trans., 1903, 83, 1117).

*Menthyl p-Bromophenylazocynoacetate,*

This compound was prepared by a method exactly similar to that used in making the foregoing compound. It crystallised readily when its alcoholic solution was sown with a trace of the crystals of the corresponding *p*-tolyl compound.

0.2005 gave 0.4155  $\text{CO}_2$  and 0.1092  $\text{H}_2\text{O}$ .  $\text{C} = 56.5$ ;  $\text{H} = 6.0$ .

$\text{C}_{19}\text{H}_{24}\text{O}_2\text{N}_3\text{Br}$  requires  $\text{C} = 56.15$ ;  $\text{H} = 5.9$  per cent.

The substance closely resembles that just described in regard to its solubility in various media, but appears to be somewhat less readily soluble. It separates from warm alcohol in the form of magnificent, transparent, yellow prisms or thick plates which melt at 97—98°. Crystallographically, the description given of the *p*-tolyl compound applies equally well to the present substance. Occasionally it was found that another form of the compound separated during the crystallisation from alcohol. This modification presented the appearance of very fine needles and melted somewhat indefinitely between 95° and 105°. The difference between the two forms, however, appears to be of a crystallographical and not a chemical character, as the rotatory powers in both cases are constant and identical, and by seeding the supersaturated solution of the acicular modification with a trace of the other the whole may be converted into the transparent tables characteristic of the form melting at 97—98°.

For the determination of the rotatory power, a solution containing 0.3450 gram dissolved in benzene (25 c.c.) was examined in a 2 dm. tube. The rotation observed was  $\alpha_D = -1.18^\circ$ , whence  $[\alpha]_D = -42.75^\circ$ .

The authors desire to express their thanks to the Research Fund Committee of the Chemical Society for a grant which defrayed part of the cost of the investigation.

## VII.—*Optically Active Esters of $\beta$ -Ketonic and $\beta$ -Aldehydic Acids. Part IV. Condensation of Aldehydes with Menthyl Acetoacetate.*

By ARCHIE CECIL OSBORN HANN and ARTHUR LAPWORTH.

THE only  $\alpha$ -substituted derivatives of menthyl acetoacetate which have yet been described are the azo-compounds (Trans., 1903, 83, 1114), which have been isolated in a solid condition and found to exhibit mutarotation in a very marked degree. All attempts to prepare the ordinary  $\alpha$ -alkyl substituted derivatives, on the other hand, have failed, probably because, as obtained by the ordinary methods, they are mixtures of fusible isomerides, that is to say, of the *l*-menthyl esters of the *d*- and *l*-alkylacetoacetates.

Many of the alkylidenediaceoacetates, however, may be isolated

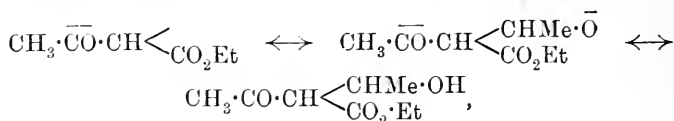

without difficulty in crystalline and apparently homogeneous forms. The method used in preparing them was usually that employed by Knoevenagel (*Annalen*, 1894, 281, 25; *Ber.*, 1894, 27, 2345, &c.), namely, by treating a mixture of the alkyl acetoacetate and an aldehyde with an organic base as a condensing agent. This synthesis has been shown by its discoverer to proceed in two stages, in the first of which condensation takes place between one molecule of the aldehyde and one of the ester, yielding the unsaturated alkylidenemonoacetoacetate,  $\text{CR}:\text{C}(\text{CO}_2\text{Alk})\cdot\text{CO}\cdot\text{CH}_3$ , whilst in the second stage the above product unites with another molecule of the original alkyl acetoacetate affording the alkylidenebisacetoacetate, having the constitution  $\text{CHR} \begin{smallmatrix} \text{CH}(\text{CO}_2\text{Alk})\cdot\text{CO}\cdot\text{CH}_3 \\ \text{CH}(\text{CO}_2\text{Alk})\cdot\text{CO}\cdot\text{CH}_3 \end{smallmatrix}$ . The mechanism of the process is generally supposed to consist in the initial formation of a compound of the aldehyde and the base which, it is usually stated, may be a primary or secondary but not a tertiary base; this initial compound then reacts with the ketonic ester, as, for example:

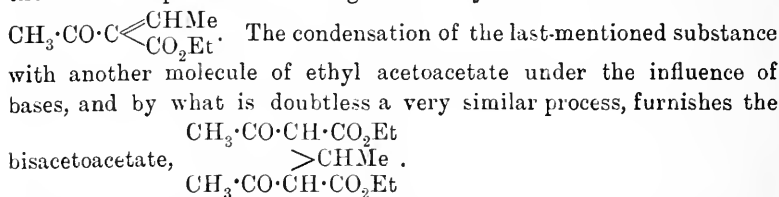

and Knoevenagel has isolated these supposed intermediate compounds and shown that they react with the acetoacetic esters in the manner represented in the foregoing equation (*Ber.*, 1898, 31, 2596).

The assumption that the condensation depends on the formation of such intermediate compounds is, however, entirely unnecessary, and the authors have found that, contrary to general belief, tertiary bases, if sufficiently powerful, are effective in bringing about the condensation, and there can be little or no doubt that the efficiency of a base depends mainly on its strength; thus, whilst pyridine scarcely acts at all, trimethylamine and tripropylamine in small quantities give good results, although they are not by any means so rapid in their action as the secondary bases, which are more powerful. In this and similar cases, the real effect of the bases is doubtless precisely similar to that which they exercise in bringing about the rapid attainment of equilibrium between the normal and *iso*-forms of tautomeric compounds, and in accelerating the union of hydrogen cyanide with carbonyl compounds, namely, by lowering the concentration of the hydrogen ions and thus increasing that of the negative ions of the acidic acetoacetic esters. The bases may be assumed to form small quantities of the ammonium derivatives exactly analogous to the metallic derivatives of the β-diketones or β-ketonic esters. The subsequent change may then be represented in the ordinary way as

the result of the addition of this ammonium compound to the carbonyl group of the aldehyde or more satisfactorily, we think, as the union of one of the ions\* of the acetoacetic ester with the carbonyl group of the aldehyde, to form a complex ion of the same type as that of the cyanohydrins (Trans., 1903, 83, 1000), followed by the union of these negative ions to form the hydroxyl compound (analogous to the cyanohydrins), which is generally recognised to be the first step in condensations of the type; thus with acetaldehyde and ethyl acetate,

the latter compound then losing water to yield the unsaturated ester

In the condensations of menthyl acetoacetate with aldehydes, the reactions appear to proceed more slowly than when the ethyl ester is used, and in many cases they are completed only after prolonged heating or by the addition of a small quantity of sodium hydroxide, which is very much more efficient than the comparatively weak organic bases.

\* We have previously suggested (Trans., 1902, 81, 1512) as a modification of an ionic view of tautomeric change which we supposed to have been advanced for the first time by Brühl (*Ber.*, 1899, 32, 2329), that the change of internal structure occurs only in the ions, as, for example, in the above case:

Brühl's paper, unfortunately, contained no reference to previous suggestions of a similar nature put forward by Knorr (*Annalen*, 1896, 293, 38) and by Wislicenus (*Tautomerie, Ahrens-Sammlung*, 897, *et seq.*). The latter had assumed, also, that ionisation might precede isomeric change, pointing out that when this was the case the change of internal structure would take place "more readily" than when an intramolecular atomic or group migration was also involved. Wislicenus thus anticipated a most important point in the views which we have put forward; he does not, however, appear to suggest that the change in the ion is a reversible one and tending towards an equilibrium (compare, in this respect, Lander, Trans., 1903, 83, 420), or that the ketonic form itself may undergo ionisation. The statement of the above view in terms of an hypothesis which does not postulate ionisation becomes virtually identical with Lander's suggestion (*loc. cit.*, p. 421) that the metallic derivatives exist in desmotropic forms.

The intermediate unsaturated esters, unlike those from the ethyl ester, may be occasionally produced in large amount by working at the ordinary temperature, and there is no difficulty in thus obtaining excellent yields of menthyl benzylideneacetoacetate,

whilst in the preparation of the corresponding ethyl ester the temperature must be maintained below  $-5^\circ$  for more than 20 hours. The same remark applies to the condensation with propaldehyde, which at the ordinary temperature yields first the crystalline menthyl propylideneacetoacetate,  $\text{CHEt}:\text{CAc}\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_9$ , although none of the corresponding derivatives of ethyl acetoacetate with fatty aldehydes appear to be obtainable in a similar way. The want of success experienced in attempting to prepare other examples of these intermediate compounds is probably attributable to the failure of the substances to crystallise in the absence of suitable nuclei before they undergo further condensation. It is noticeable with nearly all the compounds dealt with that they crystallise with extreme sluggishness, this being a characteristic of the derivatives of menthyl acetoacetate which has already been mentioned on more than one occasion (Trans., 1902, 81, 1500, and 1903, 83, 1117). To this property also is doubtless due the failure which has attended all efforts to prepare crystalline condensation products from menthyl acetoacetate and formaldehyde. It is not our intention to discuss the moot question of the propriety of representing some of the alkylidenebisacetoacetates as derivatives of cyclohexanone, a contention which appears to involve the improbable assumption that the esters are more stable under the influence of hydrazine hydrate than under that of the trace of weak base which is usually employed in preparing them (compare Rabe and Elze, *Annalen*, 1902, 323, 83, and Knoevenagel, *Ber.*, 1903, 36, 2118). Moreover, the point has no very direct bearing on the interpretation of any of our observations.

The menthyl esters of the alkylideneacetoacetic acids were not found to exhibit any very noteworthy mutarotation either in solvents or in the presence of traces of bases or acids. It is difficult to explain the reason for this apparent stability, more particularly as the specific rotatory powers of these esters are abnormally low, being in many cases not more than one-fourth of the value calculated from the observations of other workers on menthyl esters (Tschugaeff, *J. Russ. Phys. Chem. Soc.*, 1902, 34, 6069, and Cohen and Briggs, Trans., 1903, 83, 1213). In the absence of all other data, the abnormally low rotatory powers might have been reasonably attributed to the presence of an asymmetric carbon atom which originates in the acidic part of the molecule during the synthesis (compare Trans., 1903, 83, 1118), but the absence of any large amount of mutarotation,

such as was observed in the case of the azo-derivatives of menthyl acetoacetate, is difficult to reconcile with such a view.

Still more difficult to understand are the rotatory powers of the intermediate unsaturated alkylideneacetoacetates, which, if correctly represented by the formula  $\text{CHR}:\text{CAc}\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_{19}$ , contain no centre of asymmetry except that in the menthyl residue, nor, apart from the latter, is the molecule built up in an enantiomorphous way. Nevertheless, the rotatory powers of menthyl propylideneacetoacetate,  $\text{CHEt}:\text{CAc}\cdot\text{CO}_2\cdot\text{C}_{10}\text{H}_{19}$ , and benzylideneacetoacetate,

have the molecular rotations  $[\text{M}]_D - 97.70^\circ$  and  $-32.80^\circ$ , numbers which are respectively about two-thirds and one-fifth of the lowest usual values for the menthyl esters of monobasic acids, or, to look at the matter in another way, the latter of the two substances mentioned is apparently only the acetyl derivative of menthyl crotonate,

which has a rotatory power of about the normal value, namely,  $[\text{M}]_D - 203.1^\circ$  (*Annalen*, 1903, 327, 157). In view of these observations, Erlenmeyer may after all be correct in attributing an enantiomorphous character to one of the cinnamic acids (*Ber.*, 1903, 36, 2340. Compare also Sudborough and Thompson, *Trans.*, 1903, 83, 1167). The possibility still remains, however, that they may be re-

presented by the formula  $\begin{array}{c} \text{O} - \text{CMe} \\ | \quad | \\ \text{CHPh} \cdot \text{C} \cdot \text{CO}_2\text{Et} \end{array}$ , as, we believe, has already been suggested by Claisen.

## EXPERIMENTAL.

### *Methylene Derivatives.*

When molecular proportions of menthyl acetoacetate and formaldehyde, together with a few drops of piperidine, are allowed to remain for about twenty-four hours, condensation occurs with rise of temperature, water separates, and a colourless oil is obtained, which solidifies in the course of a few days. All attempts to obtain this substance in the crystalline form have been unsuccessful.

### *Ethylidene Derivatives.*

Numerous attempts were made to prepare *menthyl ethylideneacetoacetate* by condensing menthyl acetoacetate with aldehyde in alcoholic solution, but without success. The conditions were varied by using excess of the aldehyde and by keeping the mixture at  $0^\circ$  or  $-10^\circ$ ; in each case, however, the dimenthyl ester alone was formed.

This compound is best prepared by mixing two molecular proportions of the ester with one of acetaldehyde in alcoholic solution, a few drops of piperidine, diethylamine, or tripropylamine being added at intervals. The oily liquid is then warmed on the water-bath for two or three days, by which time it has assumed a jelly-like consistence, and contains the condensation product in the form of excessively slender needles. The mother liquors from these crystals on treatment with a drop of strong aqueous sodium hydroxide furnish an additional supply of material.

Some difficulty was experienced in obtaining the substance in a satisfactory condition; it was eventually found preferable to dry the compound thoroughly on a porous plate, then to dissolve it in cold dry benzene and precipitate with light petroleum.

0.1969 gave 0.5120 CO<sub>2</sub> and 0.1745 H<sub>2</sub>O. C = 70.9; H = 9.8.

C<sub>30</sub>H<sub>50</sub>O<sub>6</sub> requires C = 71.1; H = 9.8 per cent.

The compound is very readily soluble in all the usual media with the exception of water and light petroleum; it is obtained from a mixture of benzene and light petroleum in very slender, but well-formed, needles melting at 194—196°. The crystals have a weak double refraction; the extinction direction in polarised light is straight, and the directions of greatest elasticity and length are coincident. A solution of 0.4001 gram of the substance in 25 c.c. of benzene gave  $[\alpha]_D = -24.9^\circ$ , changing to  $-26.5^\circ$  on the third day.

Experiments were also made in order to determine whether the rotatory power was altered by the addition of a trace of a base as an accelerator. For this purpose, an approximately one per cent. benzene solution was divided between two 2-dcm. tubes, and a trace of piperidine added to one; the rotation in both cases, however, gave the same value, no mutarotation being observed during twenty-four hours.

### *Propylidene Derivatives.*

*Menthyl Propylideneacetoacetate*, CH<sub>3</sub>·CH<sub>2</sub>CH:C(CO·CH<sub>3</sub>)·CO<sub>2</sub>·C<sub>10</sub>H<sub>19</sub>

For the preparation of this compound, menthyl acetoacetate and propaldehyde in equivalent proportions were condensed with three or four drops of piperidine at the ordinary temperature. On the following day, the mixture formed a viscid, oily liquid containing drops of water, and was induced to solidify by the addition of a single drop of

concentrated aqueous sodium hydroxide, the flask containing the liquid being shaken vigorously from time to time. Condensation was also effected by allowing the reaction mixture to remain for some hours at  $0^{\circ}$ . In one experiment, two molecular proportions of menthyl acetoacetate were condensed with one of propaldehyde, the mono-menthyl ester being again formed. Another batch, prepared under the same conditions, yielded a compound melting at about  $200^{\circ}$ , which was subsequently shown to be the menthyl propylidenebisacetoacetate. Further condensations, however, whether effected with one or two molecular proportions of the menthyl ester only gave the unsaturated compound, the temperature at which the reaction proceeded being, apparently, immaterial.

0.2033 gave 0.5430  $\text{CO}_2$  and 0.1843  $\text{H}_2\text{O}$ .  $\text{C} = 72.8$ ;  $\text{H} = 10.0$ .

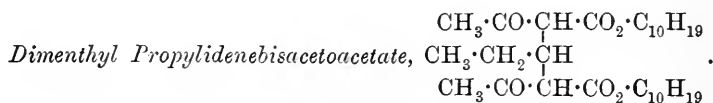

$\text{C}_{17}\text{H}_{28}\text{O}_3$  requires  $\text{C} = 72.8$ ;  $\text{H} = 10.0$  per cent.

The substance is easily soluble in benzene, chloroform, ether, or acetone, and when recrystallised from hot alcohol is obtained in the form of plates melting at  $84\text{--}88^{\circ}$ .

Conclusive evidence as to the nature of the compound under examination was afforded by its behaviour with warm sodium hydroxide solution, as a powerful odour of propaldehyde was evolved, and this decomposition is characteristic of the unsaturated alkylidene acetoacetates.

The crystals are rectangular, apparently orthorhombic plates which have straight extinction, the direction of greatest elasticity and length being coincident. The double refraction is strong. After melting between glass slips, this substance solidifies rapidly to fan-shaped masses which show aggregate extinction. Under the high power in convergent polarised light, the bisectrix of an interference figure of wide angle may be distinguished occasionally. The double refraction is positive, and the axial plane cuts the crystals in the directions of their greatest length.

The action of the substance on polarised light was investigated, 0.3980 gram being dissolved in benzene and made up to 25 c.c.; with this solution, a rotation corresponding with  $[\alpha]_D = -34.9^{\circ}$  was obtained, and no alteration of this value was observed.

This ester is obtained by condensing the monomenthyl derivative with about an equal weight of menthyl acetoacetate and a few drops of piperidine and alcohol. The reaction is considerably hastened by

warming on the water-bath, a viscid, oily liquid being obtained, which, on cooling, usually became almost solid in fifteen minutes.

0.1976 gave 0.5183  $\text{CO}_2$  and 0.1797  $\text{H}_2\text{O}$ .  $\text{C} = 71.5$ ;  $\text{H} = 10.0$ .

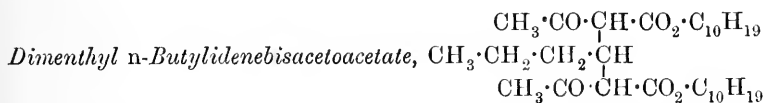

$\text{C}_{31}\text{H}_{52}\text{O}_6$  requires  $\text{C} = 71.5$ ;  $\text{H} = 10.0$  per cent.

The substance is easily soluble in benzene, chloroform, or hot ethyl acetate; very sparingly so in ether or light petroleum, and is almost insoluble in alcohol. On recrystallisation from acetone, it melts at  $201\text{--}207^\circ$ . The crystallographic characters of the compound are precisely similar to those of dimenthyl ethylidenebisacetoacetate.

A solution of 0.1301 gram in 25 c.c. of benzene had a constant rotation of  $[\alpha]_D = -26.9^\circ$ . Solutions in benzene in presence of a trace of piperidine were also observed in the polarimeter, but even here no mutarotation could be detected.

#### *Normal Butylidene Derivatives.*

All attempts to prepare menthyl *n*-butylideneacetoacetate were unsuccessful, the more complex ester being formed in each case.

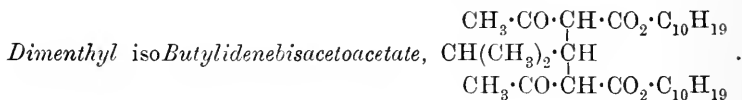

This substance is prepared by mixing *n*-butaldehyde with a molecular proportion of the menthyl ester in presence of a few drops of piperidine. The mixture soon forms an oily liquid at the ordinary temperature, and the product is obtained in the solid condition by the addition of alcohol and a small quantity of aqueous sodium hydroxide.

0.2023 gave 0.5339  $\text{CO}_2$  and 0.1853  $\text{H}_2\text{O}$ .  $\text{C} = 71.9$ ;  $\text{H} = 10.1$ .

$\text{C}_{32}\text{H}_{54}\text{O}_6$  requires  $\text{C} = 71.9$ ;  $\text{H} = 10.1$  per cent.

The compound separates from ethyl acetate in fine needles melting at  $184^\circ$ ; it is easily soluble in ether, benzene, and chloroform, less so in alcohol, acetone, and light petroleum. Crystallographically, it appears to be similar to the corresponding ethylidene derivative. A solution of 0.1857 gram in 25 c.c. of benzene gives  $[\alpha]_D = -16.8^\circ$ .

When this substance is treated in chloroform solution with hydrogen chloride, a viscid mass is obtained on evaporating the solvent; on triturating the substance with light petroleum and allowing the mixture to remain for some days, crystals are obtained melting at  $136.5\text{--}137.5^\circ$ , but this material was formed in such small quantity that it could not be subjected to detailed examination.

*isoButylidene Derivatives.*

This compound is obtained under conditions similar to those employed in the foregoing case, the addition of a drop of concentrated sodium hydroxide solution being used to hasten the condensation.

0.1647 gave 0.4331  $\text{CO}_2$  and 0.1500  $\text{H}_2\text{O}$ .  $\text{C} = 71.71$ ;  $\text{H} = 10.1$ .

$\text{C}_{32}\text{H}_{54}\text{O}_6$  requires  $\text{C} = 71.9$ ;  $\text{H} = 10.1$  per cent.

The substance crystallises from ethyl acetate in needles, which soften at  $193^\circ$  and melt completely at  $202^\circ$ . The ester is fairly soluble in the usual organic media; its crystals are slender needles, like those of the other alkylidenebisacetoacetates, but are always considerably larger and apparently somewhat better defined. A benzene solution of 0.2933 gram of the substance made up to 25 c.c. gave  $[\alpha]_D = -42.6^\circ$ ; here a slight mutarotation was observed, the rotatory power assuming a constant value of  $[\alpha]_D = -46.0^\circ$  at the end of a week.

*Benzylidene Derivatives.*

A mixture of menthyl acetoacetate and benzaldehyde in molecular proportion, together with a few drops of piperidine, was allowed to remain at the ordinary temperature for about 24 hours; a cloudiness, due to the separation of water, was noticed at the end of an hour, and a semi-solid mass was finally obtained. The crystalline substance which separated was freed from the remaining oil by filtration under pressure, and was then dried on a porous plate and recrystallised from hot spirit.

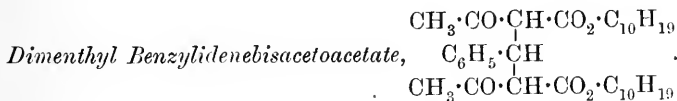

0.1960 gave 0.5491  $\text{CO}_2$  and 0.1487  $\text{H}_2\text{O}$ .  $\text{C} = 76.4$ ;  $\text{H} = 8.4$ .

$\text{C}_{21}\text{H}_{28}\text{O}_3$  requires  $\text{C} = 76.8$ ;  $\text{H} = 8.5$  per cent.

The compound is easily soluble in the usual organic media, although but sparingly so in light petroleum; it separates from alcohol in flattened, colourless needles, and melts sharply at  $133-134^\circ$ .

The crystals are well-formed, flat needles, or six-sided, elongated plates, which have straight extinction and are probably orthorhombic. The directions of greatest elasticity and length are coincident; the double refraction is moderate. When melted on a glass slip beneath

a cover-glass and then cooled, the compound solidifies fairly quickly in radiate masses of slender, flat needles, which are only distinguishable under a high power. A solution of 0.3995 gram of the substance in 25 c.c. of benzene gave  $[\alpha]_D = -10.0^\circ$ , no alteration in this value being noticed during three days.

This ester was obtained by condensing the benzyldene compound with one molecular proportion of menthyl acetoacetate in presence of a small quantity of alcohol and a few drops of piperidine; the mixture, when warmed on the water-bath, became considerably more viscous, and at the end of 12 hours was semi-solid and translucent. The product showed a great tendency to separate as a jelly from benzene, acetone, or ethyl acetate, but was obtained in the crystalline form by adding an equal bulk of light petroleum to its solution in cold chloroform; fine needles separated when the liquid evaporated at the ordinary temperature.

0.2077 gave 0.5612  $\text{CO}_2$  and 0.1720  $\text{H}_2\text{O}$ .  $\text{C} = 73.7$ ;  $\text{H} = 9.2$ .

$\text{C}_{35}\text{H}_{52}\text{O}_6$  requires  $\text{C} = 73.9$ ;  $\text{H} = 9.2$  per cent.

The compound is very sparingly soluble in alcohol, ether, and light petroleum, but dissolves fairly readily in benzene, acetone, or ethyl acetate. It softens at  $203^\circ$  and melts completely at  $206^\circ$ . Crystallographically, the substance resembles the corresponding ethylidene derivative. A solution of 0.1437 gram in benzene made up to 25 c.c. and observed in a 2-dm. tube gave a value for  $[\alpha]_D = -30.4^\circ$ .

*Addendum.*—It has been mentioned in the preceding pages that not only alkaline hydroxides and powerful primary and secondary organic bases, but also tertiary bases bring about the condensation of aldehydes with menthyl acetoacetate. This is found to be equally true with ethyl acetoacetate, as the following observations show.

When ethyl acetoacetate and 40 per cent. formaldehyde are mixed with pyridine even in fairly large quantity, no noticeable rise of temperature occurs, and condensation does not appear to take place even after some weeks at the ordinary temperature. If, however, two or three drops of concentrated trimethylamine solution or pure tripropylamine are added to 5 c.c. of the mixture, the temperature rises very rapidly, and in a few minutes water separates; in fact, these bases act much in the same way as does diethylamine, but considerably less rapidly weight for weight. As the products were liquid in the foregoing case,

a similar experiment was performed with a mixture of acetaldehyde (1 mol.) and ethyl acetoacetate (2 mols.); with 10 c.c. of such a mixture, 5 c.c. of pyridine produced no appreciable effect, but 20 drops of tripropylamine caused the separation of water within a few minutes at the ordinary temperature, and after three days the mixture solidified to a mass of crystals identical with those obtained by using piperidine or diethylamine in small quantities.

On adding 2 grams of tripropylamine to a mixture of 5.3 grams of benzaldehyde and 14 grams of ethyl acetoacetate, both freshly distilled, a marked rise in temperature occurred at once, and after five days at the ordinary temperature the whole had solidified to a crystalline mass of diethyl benzylidenebisacetoacetate.

We are indebted to the Research Fund Committee of the Chemical Society for a grant which defrayed a large part of the cost of this investigation.

### VIII.—*Notes on some Natural Colouring Matters.*

By ARTHUR GEORGE PERKIN, F.R.S., and SAMUEL PHIPPS.

THIS investigation contains an account of the yellow colouring matters which are present in the flowers of *Prunus spinosa* and the Japanese dyestuff "Fukugi," together with some results which have been obtained during the further study of morin, myricetin, hesperitin, and curcumin.

#### *The Colouring Matter of the Flowers of Prunus spinosa.*

Some years ago, while examining the dyeing properties of certain natural products, it was noted that some quantity of yellow colouring matter exists as a glucoside in the flowers of *Prunus spinosa* or common blackthorn. A cursory examination carried out at the time resulted in the isolation of a product which was apparently a mixture, because its acetyl derivative did not melt sharply, the melting point being

very low for this class of substance. The attempts then made to effect a separation were not successful, but more recently, in the hope that a new colouring matter might be present, the subject has been again investigated, and the difficulty overcome in an exceedingly simple manner. In order to facilitate the work, an extract of these flowers prepared by Merck of Darmstadt was chiefly employed.

Two hundred grams of the extract dissolved in 2 litres of water were treated with 50 c.c. of hydrochloric acid, boiled for three hours, and, after cooling, extracted with ether to remove the colouring matter, which was thus obtained as a brownish-yellow, crystalline mass (3.5 grams). This was purified by two or three crystallisations from dilute alcohol, and a portion then converted into the acetyl compound in order to determine whether its melting point coincided with that of the corresponding derivative of some known substance of this class. It was found to melt somewhat indefinitely at 133—134°, and gave on analysis  $C=60.09$ ;  $H=4.28$ , these figures indicating that it was most probably a mixture. The main bulk of the colouring matter was now dissolved in a small quantity of boiling acetic acid, and the crystals which separated on cooling were collected and recrystallised from the same solvent until no alteration in the melting point could be observed; the yield was 0.8 gram.

Found  $C=62.93$ ;  $H=3.89$ .

$C_{15}H_{10}O_6$  requires  $C=62.94$ ;  $H=3.49$  per cent.

The substance, which consisted of pale yellow, glistening leaflets melting at 276°, dissolved in dilute aqueous alkalis with a pale yellow coloration.

The *acetyl* compound crystallised from methyl alcohol in colourless needles which melted at about 116°, resolidified at a higher temperature, and melted again at 181—182°.

Found  $C=60.77$ ;  $H=3.97$ .

$C_{15}H_6O_6(C_2H_3O)_4$  requires  $C=60.79$ ;  $H=3.96$  per cent.

On fusing the colouring matter with caustic alkali, phloroglucinol (m. p. 210°) and *p*-hydroxybenzoic acid (m. p. 208—210°) were obtained.

These facts, together with an examination of its dyeing properties, indicated without doubt that this colouring matter was *kampherol*. As this dyestuff has recently been found in at least four other plants, it is likely to occur in many other vegetable species.

The acetic acid mother liquors from which the kampherol had separated were allowed to absorb moisture by exposure to the

atmosphere, which caused the deposition of a small quantity of a mixture of a kampherol and a second substance. This precipitate was removed, the filtrate treated with a small quantity of hot water, and the yellow precipitate, which slowly separated, was collected and purified by conversion into its *acetyl* derivative.

Found C = 58.67 ; H = 4.26.

$C_{15}H_5O_7(C_2H_3O)_5$  requires C = 58.59 ; H = 3.90 per cent.

This substance, which melted at  $191^\circ$ , was decomposed with acid in the usual manner, and the regenerated colouring matter crystallised from dilute alcohol.

Found C = 59.56 ; H = 3.61.

$C_{15}H_{10}O_7$  requires C = 59.60 ; H = 3.31 per cent.

It formed glistening yellow needles soluble in alkali solutions with a yellow coloration ; on fusion with caustic potash, it gave phloroglucinol (m. p.  $210^\circ$ ) and protocatechuic acid (m. p.  $193-195^\circ$ ). It was evidently *quercetin*, and to this colouring matter and kampherol the dyeing property of these flowers is evidently due.

A cursory examination of the flowers of the violet (*Viola odorata*) and the white clover (*Trifolium repens*) by a method similar to that employed above indicated in each case the presence of *quercetin* in the form of a glucoside. This colouring matter was recognised by the melting point of its acetyl derivative, and its decomposition products with caustic alkali, and in consequence of these observations a fuller investigation appeared unnecessary.

### *The Japanese Dyestuff "Fukugii."*

We are indebted to the kindness of Professor E. Yoshitake, of Tokio, for this material, which consists of the wood of a tree, and was obtained in the form of an almost colourless, coarse powder ; it appears, at least until recently, to have been employed to a considerable extent as a yellow mordant dyestuff, principally in the form of extract. A preparation of this kind was also procured and consisted of brittle, rectangular cakes ( $4'' \times 2\frac{1}{2}'' \times 1\frac{1}{2}''$ ) of a yellowish-brown colour, which weighed approximately 410 grams.

The coarsely powdered extract, dissolved in ten times its weight of water, was boiled with 100 c.c. of hydrochloric acid for two hours in order to decompose the glucoside. A somewhat viscous precipitate of the impure colouring matter thus separated, which, when cold, was washed by decantation, drained on a tile, and allowed to dry at the ordinary

temperature. The product was extracted with boiling alcohol, the extract evaporated and poured into a large bulk of ether, which caused the separation of a resinous impurity, and on evaporating the ethereal liquid the colouring matter now obtained was of a much lighter colour. For further purification, it was dissolved in boiling alcohol containing a trace of acetic acid, lead acetate solution added, the resulting yellow precipitate removed, the filtrate evaporated to a small bulk and poured into ether. The pale yellow, ethereal liquid was well washed with water, evaporated to dryness, and the viscid residue left for some days. Minute crystals slowly separated, which were collected, washed with a small amount of ether, and crystallised first from dilute ethyl alcohol and then from methyl alcohol until the melting point was constant. The product frequently contained a trace of the lead compound, which adhered somewhat tenaciously, and was best removed by means of ether, in which it dissolved with difficulty.

Found, (i) C = 65.03 ; H = 4.04. (ii) C = 65.17 ; H = 3.97.

$C_{17}H_{12}O_6$  requires C = 65.37 ; H = 3.84 per cent.

It consisted of a mass of minute, prismatic, canary-yellow needles, which melted at 288—290°. When crystallised from dilute alcohol, the air-dried product contains one and a half molecules of water of crystallisation.

Found,  $H_2O = 7.56$ .

$C_{34}H_{24}O_{12} \cdot 3H_2O$  requires  $H_2O = 7.35$  per cent.

This new colouring matter, for which the name *fukugetin* is proposed, is readily soluble in hot alcohol and dissolves in aqueous alkalis or in cold sulphuric acid with a pale yellow coloration. The solution in the latter solvent, on heating, becomes dull violet-red, and finally assumes an orange-brown tint, and, on dilution with water, now deposits a brown, amorphous precipitate soluble in aqueous alkalis to a dull red solution. With lead acetate in alcoholic solution, an orange-yellow precipitate is formed, whilst alcoholic ferric chloride develops a brownish-black coloration ; on the other hand, alcoholic potassium acetate gives no insoluble salt, and mineral acids do not react to form the usual compounds. When examined by Zeisel's method, it was found to contain no methoxyl groups.

Fukugetin readily dyes mordanted fabrics, and it was at once observed that the shades produced were almost identical, except as regards the iron mordanted portion, with those given by luteolin.

	Cr.	Al.	Sn.	Fe.
Fukugetin.	Dull orange-yellow.	Orange-yellow.	Bright ye'llow.	Olive-brown.
Luteolin.	Brown orange-yellow.	„	„	Olive-black.

Crystalline acetyl and benzoyl derivatives of this new colouring matter could unfortunately not be obtained either by the usual processes or by the pyridine method. Methylation also led to the formation of a viscous product, although it is possible that these difficulties might have been surmounted if a larger quantity of substance had been available for experiment.

*Bromine Compound.*—One gram of fukugetin was added to a solution of one gram of bromine in a little glacial acetic acid. After twenty-four hours, the product was drained on porous tile, ground up with a small amount of acetic acid, filtered at the pump, washed once or twice with acetic acid, and purified by crystallisation from nitrobenzene, two or three drops of acetic acid being added to the solution when cooling. Two distinct preparations were made.

Found, (i) C = 43.47; H = 2.43. (ii) C = 43.53; H = 1.95.

$C_{17}H_{10}O_6Br_2$  requires C = 43.22; H = 2.54.

*Dibromofukugetin* forms minute, flat needles melting at  $280^\circ$ , readily soluble in hot alcohol, more sparingly so in acetic acid.

On fusion with alkali in the usual manner, fukugetin gave protocatechuic acid (m. p.  $194-196^\circ$ ) and phloroglucinol (m. p.  $210^\circ$ ).

The above results are, unfortunately, too meagre to allow of the prediction of the constitution of this substance with any certainty, but the similarity of most of the general properties of the compound with those of luteolin, and the fact that it contains similar nuclei, point to the probable close relationship between these colouring matters. Interesting in this respect is the stability of alkaline solutions of fukugetin when exposed to the air, for these do not undergo oxidation even after many days. This property, as shown in former investigations, is somewhat characteristic of flavone compounds such as apigenin and luteolin, but is not possessed by flavanol derivatives, of which fisetin and quercetin may be quoted as examples. It is possible that the distinction between luteolin and fukugetin consists chiefly in the manner by which the catechol nucleus is connected with the pyrone ring, and one or two formulæ suggest themselves as very probable representatives of this colouring matter. It is intended, should a further supply of raw material be forthcoming, to continue these experiments in the hope of elucidating with certainty the constitution of this interesting substance.

An examination of the dyeing properties of "fukugi" showed, as was to be expected, that it behaved in this respect in an analogous manner to weld (*Reseda luteola*). The similarity in shade was so marked that, except in point of strength—for fukugi is a stronger dye than weld—

it is impossible to distinguish between them, and there can be little doubt that prior to the introduction of the synthetical colouring matters this dyestuff would have been a valuable addition to those already in use.

### *Ethylation of Morin.*

Although quercetin and other members of the flavanol class readily give, on alkylation, well-defined crystalline substances, morin has only yielded a methyl ether in a state of purity (Trans., 1896, 29, 192), for on ethylation in the usual manner, viscous products result which have hitherto refused to crystallise. As it seemed possible that the impurities might be more readily removed after acetylation, the residue from former experiments carried out some years ago was treated in the following manner.

The resinous mass was digested with boiling acetic anhydride for some hours, the solution evaporated to a small bulk, and diluted with about twice its volume of methylated spirit. After several days, a small quantity of crystalline matter separated, and the mixture was now set aside for some weeks; the product was then collected, crystallised two or three times from methyl alcohol, and thus obtained in colourless needles, readily soluble in hot alcohol and melting at 121—123°.

Found, C = 65.70; H = 6.22.

$C_{15}H_5O_3(OEt)_4 \cdot C_2H_3O$  requires C = 65.78; H = 6.06 per cent.

To prepare the free tetraethyl ether, the acetyl compound was digested with boiling alcoholic potassium acetate, the solution poured into a small quantity of dilute hydrochloric acid and the product crystallised from methyl alcohol.

Found, C = 66.50; H = 6.63.

$C_{15}H_6O_3(OEt)_4$  requires C = 66.65; H = 6.28 per cent.

*Morin tetraethyl ether* forms pale yellow, prismatic needles, sparingly soluble in cold methyl alcohol, and melting at 126—128°. In general properties, it closely resembles the tetramethyl ether previously described (*loc. cit.*).

*The Bromination of Myricetin in the presence of Alcohol.*

A most interesting property of morin,  $C_{15}H_{10}O_7$ , the colouring matter of old fustic, is that when brominated in the presence of alcohol it yields tetrabromomorin ethyl ether,  $C_{15}H_5O_6Br_4 \cdot OEt$ . This peculiar behaviour, which is apparently not possessed by other flavanol derivatives, is considered by Herzig (*Monatsh.*, 1897, 18, 700) to render doubtful the constitution assigned to it by one of the authors (*Trans.*, 1896, 29, 792).

Being in possession of a small quantity of myricetin, which is apparently a flavanol derivative capable of yielding a tetrabromocompound (*Trans.*, 1896, 69, 1287), the authors have studied its behaviour in these circumstances.

Myricetin (1.9 grams) in 20 c.c. of alcohol was treated with 3.4 grams of bromine and the mixture left for forty-eight hours, when on cautiously diluting with water a small quantity of crystalline precipitate gradually separated and was recognised as tetrabromomyricetin (*loc. cit.*); this was removed after some hours, the filtrate treated with a large volume of water, and a second deposit collected and crystallised two or three times from dilute alcohol.

Found, C = 31.29; H = 1.68; Et = 4.36.

$C_{15}H_5O_6Br_4Et$  requires C = 30.81; H = 1.51; Et = 4.38 per cent.

*Tetrabromomyricetin ethyl ether* formed colourless needles very soluble in alcohol; it becomes red at  $110^\circ$ , commences to sinter at  $132^\circ$ , and melts with decomposition at  $146^\circ$ . This melting point is given with reserve, owing to the possibility that a trace of tetrabromomyricetin itself may be associated with the product. The lack of raw material did not permit of further experiment, but the result indicates that in these circumstances myricetin behaves in an analogous manner to morin, though somewhat less readily.

*The Molecular Weights of Hesperitin and Curcumin.*

In a previous communication (*Trans.*, 1898, 31, 1031), it was shown that the properties of hesperitin were in accord with the constitution  $OH \cdot C_6H_3(OCH_3) \cdot CH : CH \cdot CO \cdot O \cdot C_6H_3(OH)_2$ , previously indicated by Hoffmann (*Ber.*, 1876, 9, 685) and Tiemann and Will (*ibid.*, 1881, 14, 848). The fact, however, that this substance gave well-defined crystalline salts having the formulæ  $(C_{16}H_{14}O_6)_2C_2H_3O_2K$  and

$C_{32}H_{27}O_{12}K$  suggested that its molecular weight was  $C_{32}H_{28}O_{12}$ , or twice that assigned to it by these authors.

More recently it was shown (Trans., 1903, 88, 127) that certain substances, the molecular weights of which were well known, also gave somewhat peculiar salts by similar methods. Thus from gallacetophenone,  $C_8H_8O_4$ , the salt  $C_{24}H_{23}O_{12}K$ , and from daphnetin,  $C_9H_6O_4$ , the salt  $C_{18}H_{11}O_8K$  resulted, and other cases might be cited. It was accordingly evident that these salts do not in all cases furnish trustworthy indications of the molecular weight, and cryoscopic experiments were therefore carried out, advantage being taken of the ready solubility of acetylhesperitin in naphthalene.

0.3351 in 13.90 naphthalene gave  $\Delta t - 0.375^\circ$ . Found,  $M = 449$ .

0.4310 ,, 13.87 naphthalene gave  $\Delta t - 0.490^\circ$ . Found,  $M = 443$ .

$C_{16}H_{11}O_6(C_2H_5O)_3$  requires  $M = 428$ .

It is consequently evident that the molecular weight of hesperitin is represented by the formula  $C_{16}H_{14}O_6$ , and that the above-mentioned potassium and sodium salts belong to the class of "semi-substituted" compounds (*loc. cit.*).

It has been shown by Ciamician and Silber (*Ber.*, 1897, 30, 192) that the molecular weight of curcumin is most probably represented as  $C_{21}H_{20}O_6$  rather than  $C_{14}H_{14}O_4$ , the formula originally assigned to it by Jackson and Menke (*Amer. Chem. J.*, 1882, 4, 77). Analyses of its mono-potassium salt (*loc. cit.*), although agreeing approximately with the formula  $C_{21}H_{19}O_6K$ , were not completely satisfactory, owing to the difficulty of purifying this somewhat soluble compound. It therefore appeared interesting to confirm these results, if possible, by the cryoscopic method, for which purpose a benzoylcurcumin would probably be suitable.

This derivative was readily prepared by treating 2 grams of curcumin dissolved in 30 grams of pyridine with 23 grams of benzoyl chloride. The product was washed with water, the viscous residue dissolved in alcohol, and the crystals, which gradually separated, were purified by crystallisation from a mixture of this solvent and benzene.

Found,  $C = 73.87$ ;  $H = 4.48$ .

$C_{21}H_{17}O_6(C_7H_5O)_3$  requires  $C = 74.11$ ;  $H = 4.70$  per cent.

*Benzoylcurcumin* consists of fine, lemon-yellow needles melting at  $176-178^\circ$ .

0.3256 in 13.23 naphthalene gave  $\Delta t - 0.25^\circ$ . Found,  $M = 688$ .

$C_{21}H_{17}O_6(C_7H_5O)_3$  requires  $M = 680$ .

These results therefore indicate that the molecular weight assigned

to curcumin by Ciamician and Silber is correct, and point to the fact that this colouring matter contains three hydroxyl groups, although only two have hitherto been suspected.

Curcumin itself is somewhat soluble in naphthalene, but apparently not sufficiently so for molecular weight determination; the cryoscopic experiments gave  $M=429$ , whereas the formula  $C_{21}H_{20}O_6$  requires  $M=368$ .

The isolation of curcumin from turmeric is at best a tedious operation, and as the yields obtained by the published methods were not satisfactory, the following process was adopted.

An alcoholic extract of turmeric was treated with lead acetate solution (Daube, *Ber.*, 1870, 3, 709), and the precipitated lead compound of the colouring matter collected, thoroughly washed with alcohol, and then with water. The product suspended in warm water was decomposed with dilute sulphuric acid, and the resulting mixture of curcumin and lead sulphate well washed, drained on porous tile, and extracted with boiling alcohol. After concentration, the extract was poured into ether, the solution decanted from tarry matter, evaporated to a small bulk, and diluted with carbon disulphide. The mixture, when left exposed to the air at the ordinary temperature, gradually deposited crystals, which were collected from time to time, and in this way a yield of approximately 0.56 per cent. of curcumin was isolated from the sample of root employed. Little or no loss should occur by this process, and the mother liquors contain only a trace of the so-called turmeric resin.

The authors express their thanks to the Research Fund Committee of the Chemical Society for a grant, which has been partly employed to cover the expenses of this research.

IX.—*The Four Optically Isomeric l-Menthylamines and their Salts.*

By FRANK TUTIN and FREDERIC STANLEY KIPPING.

IN the course of the investigation of the isomeric salts derived from hydrindamine (Kipping, Trans., 1903, 83, 873) and methylhydrindamine (Tattersall and Kipping, Trans., 1903, 83, 918), it seemed particularly important to try and obtain corresponding isomerides from some optically active base of a totally different type, and among such bases which are moderately accessible, menthylamine seemed to be the most suitable.

Two compounds, distinguished as *l*- and *d*-menthylamines, have been known for some time: *l*-menthylamine was obtained by reducing nitromenthene with zinc and sulphuric acid (Moriya, Trans., 1881, 39, 77), and also by reducing the oxime of *l*-menthone with sodium and alcohol (Andres and Andreef, Ber., 1892, 25, 609); *d*-menthylamine was prepared from the oxime of *d*-menthone (Andres and Andreef, loc. cit.), and was also obtained, together with the *l*-base, by heating *l*-menthone with ammonium formate (Wallach and Kuthe, Annalen, 1893, 276, 306); in the latter case, the two bases were separated by fractionally crystallising their formyl derivatives, which are the original products of the reaction.

These *l*- and *d*-bases, which are liquids, have been characterised by preparing from them a number of simple derivatives, and the specific rotations of many of the latter have been determined by Binz (Zeit. physikal. Chem., 1893, 12, 727).

Our investigations show that the base produced by the reduction of the oxime of "*l*-menthone" is a mixture of four optically isomeric menthylamines, in which, however, three of the bases are present in relatively very small quantities. The base obtained by the action of ammonium formate on *l*-menthone is likewise a mixture of these four optical isomerides, but apparently in proportions different from those in which they occur in the reduction product of the *l*-oxime.

The explanation of these facts is to be found in the origin and in the methods of formation of the basic mixtures. Leaving out of consideration the reduction of nitromenthene, the other methods for the preparation of the base start from menthone, a ketone which contains two asymmetric groups and which, in its turn, is produced by the oxidation of menthol with sulphuric acid and dichromate.

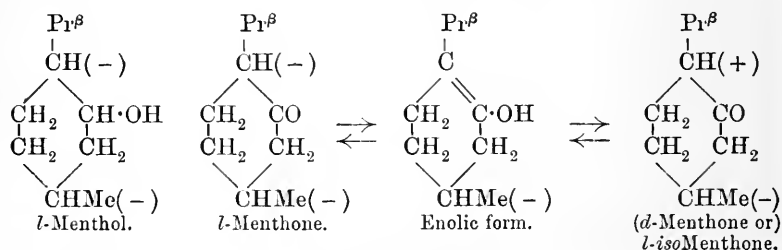

The menthone obtained by carrying out this oxidation with dilute sulphuric acid and dichromate at 30° has a specific rotation  $[\alpha]_D - 26^\circ$  to  $- 28^\circ$  and is called *l*-menthone; when, however, oxidation is accom-

plished with the aid of concentrated acid at  $30^{\circ}$ , the product has a specific rotation  $[\alpha]_D +26^{\circ}$  to  $+28^{\circ}$  and is called *d*-menthone, the "inversion" being due to the action of the concentrated acid (Beckmann, *Annalen*, 1889, 250, 322).

The application of the terms *laevo*- and *dextro*- to these two products and the observation that they have approximately equal but opposite specific rotations seem to have caused some confusion as to the relationship between these two ketones (compare Richter, *Organ. Chem.*, 1898, p. 340; Vorländer, *Ber.*, 1903, 36, 268). That they are not enantiomorphously related is indicated by the differences in physical properties and more especially by the values of the specific rotations of their oximes, both of which compounds are levorotatory, having specific rotations of  $[\alpha]_D -40.7^{\circ}$  to  $-42.5^{\circ}$  and  $-4.85^{\circ}$  to  $-6.67^{\circ}$  respectively.

That the conversion of "*l*-menthone" into "*d*-menthone" by the action of acids or of alcoholic solutions of alkalis is not an optical "inversion" but a partial racemisation is also rendered highly probable, even if not proved, by the fact that the product, "*d*-menthone," is optically active.

A consideration of the constitution of menthone leads to the same conclusion: assuming that the oxidation of menthol with dilute acid and dichromate gives one product only, then of the two asymmetric groups in this ketone which may be represented by — —, one only would probably undergo change under the influence of acids or alkalis, namely, that which is capable of keto-enolic tautomerism; the result would be a mixture, probably of unequal quantities, of the — — and — + isomerides, the formation of which may be indicated as follows:—

The values of the specific rotations of the partially racemised ketonic mixture would depend, therefore, on those of its two components and on the proportions in which they are present, and since it is quite possible that partial racemisation occurs to some extent even in the oxidation with dilute sulphuric acid and dichromate, ordinary "*l*-menthone" itself may be a mixture of the two optical isomerides.

Whether "*l*-menthone" is one definite compound or not, the oxime repared from it in the usual way in alkaline solution is doubtless a

mixture of the oximes derived respectively from the -- and - + ketones, and consequently, on reduction, since a third asymmetric group is produced, four optically isomeric menthylamines will be formed, as experiment shows, however, in very unequal quantities: these four isomerides would be the forms --- and - + - derived from the -- ketone, and -- + and - + + derived from the - + ketone.

Similar arguments hold good in the case of the formation of the base by heating menthone with ammonium formate; although there is here no free alkali, the high temperature would, no doubt, tend to give in the first place a mixture of two menthones, from each of which two menthylamines would then be produced; these four compounds would be identical respectively with those obtained from the oxime, provided that in both cases the asymmetric group containing the methyl radicle undergoes no change; were this group also to undergo inversion, then obviously four additional isomerides (+ - -, + + -, + - +, + + +) would be formed, and an optically inactive mixture of four externally compensated bases would be the final result. As we show later that all the four bases obtained in these reactions are optically active, it is proved that throughout all the changes involved in the production of menthylamine from menthol one of the asymmetric groups escapes racemisation.

*Nomenclature.*—If we assign to *l*-menthone the configuration --, then *d*-menthone would have the ++ configuration, and the ketone obtained from *l*-menthone by the action of acids or of alkalis would have the - + configuration, and might be named *l*-isomenthone. The two menthylamines derived from *l*-menthone may then be distinguished as *l*-menthylamine (---) and *l*-neomenthylamine (- + -); respectively (compare Forster, *Trans.*, 1898, 63, 391; Tattersall and Kipping, *ibid.*, 1903, 83, 919), those derived from the isoketone being named *l*-isomenthylamine and *l*-isoneomenthylamine respectively. The four isomerides derived from the true *d*-menthone (+ +) and from *d*-isomenthone (+ -) could then be distinguished in a similar manner.

We have adopted this system in dealing with the four bases described in this paper, and as the choice of the configuration originally assigned to any one isomeride is, of course, purely arbitrary, we retain the name *l*-menthylamine for the base produced in the largest quantity by the reduction of the oxime of "*l*-menthone" and assign to it the configuration ---.

One of the other three compounds undergoes partial racemisation, giving a base which is not *l*-menthylamine, and as the latter and the other two isomerides are stable, we infer that this partial racemisation takes place in the group  $>\text{CH}\cdot\text{NH}_2$ , which is known to change very

readily in some cases; if this is so, the base which undergoes change and that into which it is partially transformed would have the configurations  $--+$  and  $-++$ , since the  $-+-$  compound would give *l*-menthylamine. The two isomerides in question are therefore named the *l*-iso-bases, the unstable one being distinguished as *l*-isoneomenthylamine; the remaining compound is called *l*-neomenthylamine.

*Isomeric l-Menthylamine d-Bromocamphorsulphonates*.—Having obtained an optically pure *l*-menthylamine in sufficient quantity and having satisfied ourselves that the base did not undergo partial racemisation under the conditions of our experiments, we were able to study the question of the existence of isomeric salts; it was thus proved that *l*-menthylamine gives with the bromo-acid, isomeric salts corresponding with those obtained from hydrindamine and methylhydrindamine, but, as in some earlier cases, it seemed impossible to obtain the compound of lower molecular rotation in a pure condition, that is to say, free from its isomeride.

The separation of the four isomeric menthylamines already mentioned was accomplished by fractionally crystallising the hydrochlorides, *d*-bromocamphorsulphonates, *d*-camphorsulphonates, formyl and benzoyl derivatives in the manner indicated in the experimental part of this paper.

*l*-Menthylamine is isolated from the reduction product of menthone-oxime without much difficulty by either of the first two processes, but in order to separate the remaining mixture of isomerides none of the first four methods is sufficient, and it is necessary to convert the bases into their benzoyl derivatives, which are then submitted to a prolonged and troublesome process of fractional crystallisation. The bases are regenerated by hydrolysing their benzoyl derivatives with dilute sulphuric acid, but, unfortunately, in this process one of the isomerides (*l*-isoneomenthylamine) undergoes partial racemisation, giving the *l*-iso-base, so that we have been unable to obtain it, except in the form of its benzoyl derivative.

The following table shows the principal compounds which have been prepared:

	<i>l</i> -Base.		<i>l</i> -neo-Base.		<i>l</i> -iso-Base.		<i>l</i> -isoneo-Base.
	M. p.	$[\alpha]_D$ .	M. p.	$[\alpha]_D$ .	M. p.	$[\alpha]_D$ .	M. p. $[\alpha]_D$ .
<i>d</i> -Bromocamphorsulphonate	226° + 43·2°		70—75(?)	—	166° + 65°		—
<i>d</i> -Camphorsulphonate .....	158 - 5·3		188 + 11·8°		177 + 21·7°		—
Benzoyl derivative.....	156 - 61·9		128 - 17·4		121 + 22·7		104° - 3·8°

The specific rotations of the salts were determined in aqueous solutions, those of the benzoyl derivatives in chloroform.

## EXPERIMENTAL.

*Isolation of l-Menthylamine Hydrochloride.*

The base obtained by the reduction of the oxime of "*l*-menthone" with sodium and alcohol was distilled in steam, neutralised with hydrochloric acid, and the salt systematically crystallised from water; the most sparingly soluble portion consisted of coarse needles of *l*-menthylamine hydrochloride, the more readily soluble fractions, which were apparently mixtures, separated in more slender needles.

The specific rotation of the pure salt and those of the two most readily soluble fractions were determined with the following result: \*

<i>l</i> -Menthylamine hydrochloride.		Mixture of hydrochlorides.	
	$[\alpha]_D$ .		$[\alpha]_D$ .
Solvent, chloroform	-45.4°	-41.9°	} different samples.
" "	-45.6	-39.6	
" water.....	-36.6	-28.0	
	$[M]_D$ .		$[M]_D$ .
" " .....	-70.1	-53.5	

The value obtained in aqueous solution for the pure salt is rather higher than that obtained by Binz (*loc. cit.*), whose sample possibly contained an isomeride, the existence of which in the original reduction product is indicated by the lower specific rotations of the more readily soluble fractions.

*l*-Menthylamine *d*-Bromocamphorsulphonate,  
 $C_{10}H_{19} \cdot NH_2, C_{10}H_{14}OBr \cdot SO_3H$ .

The base from the most sparingly soluble hydrochloride (see above) gives, with *d*-bromocamphorsulphonic acid, a salt which crystallises readily in well-defined prisms melting at about 225°. When crystallised two or three times, this substance appears to be homogeneous and its melting point hardly changes appreciably, but, as will be shown later, it really consists of a mixture of salts, both, however, derived from pure *l*-menthylamine.

*l*-Menthylamine *d*-bromocamphorsulphonate is very sparingly soluble in ethyl acetate, sparingly so in water; it dissolves readily in alcohol or chloroform, but is practically insoluble in light petroleum.

The specific rotation of a sample which had been crystallised fifteen times from dilute alcohol was determined: in chloroform,  $[\alpha]_D + 48.5^\circ$ ; in water,  $[\alpha]_D + 43.25^\circ$ ,  $[M]_D$  being 201.5°.

\* In these and in all future optical determinations, unless otherwise stated, 20 c.c. of solution contained 0.5 gram of the substance.

Taking the molecular rotation of the bromocamphorsulphonic acid as  $[M]_D + 270$ , that of the base would be  $[M]_D - 68.5$ , a result which agrees closely with that deduced from the specific rotation of the hydrochloride.

*l*-Menthylamine *d*-Camphorsulphonate,  $C_{10}H_{19} \cdot NH_2 \cdot C_{10}H_{15}O \cdot SO_3H$ .

This compound, when prepared from the base contained in the pure *d*-bromocamphorsulphonate, crystallised in large needles melting at  $158^\circ$ ; it was moderately soluble in water, readily so in alcohol, and very soluble in chloroform; when deposited from aqueous solution, it contained water of crystallisation.

The specific rotation was determined with a sample of the dried salt: in chloroform,  $[\alpha]_D + 9.5^\circ$ ; in water,  $[\alpha]_D - 5.3^\circ$ ,  $[M]_D$  in the latter case being  $-20.5^\circ$ .

Taking the molecular rotation of the acid as  $[M]_D + 51^\circ$ , that of the basic ion would be  $[M]_D - 71.5^\circ$ , which is somewhat higher than the values previously obtained.

*Benzoyl-l*-Menthylamine,  $C_{10}H_{19}NH \cdot CO \cdot C_6H_5$ .

The benzoyl derivative, prepared from the pure bromocamphorsulphonate by the Schotten-Baumann method, crystallised from alcohol in large needles melting at  $156^\circ$ ; in chloroform,  $[\alpha]_D = 61.9^\circ$ .

*The Existence of Isomeric Menthylamines in the Reduction Product of "l-Menthoneoxime."*

Fractional crystallisation of the hydrochloride of the crude base, obtained by reducing *l*-menthoneoxime, gave, as already stated, products differing in specific rotation; the *d*-bromocamphorsulphonate, prepared from all the more readily soluble fractions of the hydrochloride, or from the original basic reduction product, proved to be a mixture, from which, by repeated crystallisation from dilute alcohol, we isolated (*a*) a salt melting at  $225^\circ$ , identical with pure *l*-menthylamine *d*-bromocamphorsulphonate; (*b*) a salt melting very indefinitely at  $170$ — $176^\circ$ , which was obviously a mixture, and the further treatment of which is described later.

The salt melting at  $225^\circ$  formed by far the greater proportion of the whole product, even when the *d*-bromocamphorsulphonate was prepared from the more readily soluble portions of the fractionated hydrochloride.

*The Formation of Isomeric l-Menthylamine d-Bromocamphorsulphonates.*

A considerable quantity of *l*-menthylamine *d*-bromocamphorsulphonate was prepared partly by the fractional crystallisation from dilute alcohol of the salt obtained from the pure hydrochloride, and partly in a similar manner from the crude *d*-bromocamphorsulphonate; when, judging by the melting point and crystalline form, it seemed that we had obtained a definite compound, the whole of the pure material was separated into six fractions, and the first and last were examined polarimetrically in chloroform solution; the first fraction gave  $[\alpha]_D + 48.5^\circ$ , whilst the last fraction had  $[\alpha]_D + 48.0^\circ$ .

As these two extreme fractions had practically the same specific rotation and melted simultaneously at  $224\text{--}225.5^\circ$ , it seemed that the salt was homogeneous; nevertheless, we rejected the last fraction and its mother liquors. The remaining salt was then decomposed with barium hydroxide, regenerated from its component acid and base in the usual way (compare *Trans.*, 1903, 83, 906), and the product systematically crystallised from dilute alcohol; after thus obtaining nine fractions, each of which had been crystallised several times, and all of which seemed identical, the melting points and optical properties of the first and last fractions were determined.

	M. p.	In water.		In chloroform,
		$[\alpha]_D$ .	$[M]_D$ .	$[\alpha]_D$ .
First.....	226°	+43.75°	203.8°	48.75°
Last.....	221	+38.8	180.8	42.8

These experiments afforded almost conclusive evidence of the existence of isomeric salts, but in order to establish this fact beyond all question the first fraction only was decomposed and regenerated from its components; the salt thus obtained, when repeatedly crystallised from aqueous alcohol, gave extreme fractions having the same melting points as before ( $226^\circ$  and  $221^\circ$ ), and the specific rotation  $[\alpha]_D$  of the last fraction was found to be  $+39.5^\circ$  in water and  $+43.1^\circ$  in chloroform, these results agreeing closely with those previously obtained. The last fractions (m. p.  $221^\circ$ ) from the two preparations were added together and the mixture crystallised six times from dilute alcohol; the first fraction then melted moderately sharply at  $222^\circ$ , and its specific rotation in chloroform was  $[\alpha]_D + 44.4^\circ$ .

In these results we have a complete analogy between the case of *l*-menthylamine and that of *d*-hydrindamine (*loc. cit.*) or *l*-methylhydrindamine (*loc. cit.*); in spite of its apparent purity, the salt melting at about  $221^\circ$  is undoubtedly a mixture and contains a considerable quantity of the isomeride melting at  $226^\circ$ , although it does not seem

probable that a complete separation of the two components could be accomplished even by further crystallisation of very large quantities of material.

*Attempts to Isolate other Isomeric Menthylamines.*

The salt melting indefinitely at 170—176°, which is obtained on crystallising from dilute alcohol the *d*-bromocamphorsulphonate of the base prepared by the reduction of "*l*-menthoneoxime," forms tufts of short, slender needles and has a specific rotation of  $[\alpha]_D + 50^\circ$  (approximately) corresponding with a molecular rotation of  $[M]_D + 233^\circ$  in aqueous solution. This substance had the characteristics of a mixture, and all attempts to isolate a pure compound by crystallisation from dilute alcohol were unavailing.

As the salt of *l*-menthylamine with Reychler's *d*-camphorsulphonic acid was found to crystallise very readily from water, a separation of the bases in this crude *d*-bromocamphorsulphonate was attempted with the aid of this acid. We therefore liberated the basic mixture and prepared the *d*-camphorsulphonate, which crystallised from water in needles; after several crystallisations, the most sparingly soluble fraction, when dried in the air, melted at 144—147°, but when dried at 100° for several hours it melted at 164—165°, this difference indicating water of crystallisation. As this fraction of the salt appeared to be pure, its specific rotation in water was determined with the following result:  $[\alpha]_D + 5.8^\circ$ ,  $[M]_D + 22.4^\circ$ . The molecular rotation of the base in this salt would therefore be  $[M]_D - 29^\circ$ , that of the acid being  $[M]_D + 51.0^\circ$ .

As we expected that the base would be "*d*-menthylamine," it appeared probable that this salt, in spite of its having been repeatedly crystallised, was really a mixture containing a considerable proportion of the salt of the *l*-base; it was therefore converted again into the *d*-bromocamphorsulphonate. On crystallising this salt from ethyl acetate containing a little chloroform, a further quantity of *l*-menthylamine *d*-bromocamphorsulphonate, melting at 225°, was separated. The residue then crystallised from aqueous alcohol in very slender, bulky needles melting at 164—167°, but after many further crystallisations it melted sharply and constantly at 170°, and appeared to be homogeneous. A sample thus prepared, when examined polarimetrically, gave  $[\alpha]_D + 63.5^\circ$  in aqueous solution, whence  $[M]_D + 295.9^\circ$ ; this value indicating the presence of a dextrorotatory base having the molecular rotation  $[M]_D + 26^\circ$ , whereas the value for "*d*-menthylamine," calculated from that of the hydrochloride examined by Binz, is  $[M]_D + 33^\circ$ .

Not feeling satisfied that this salt was derived from pure "*d*-menthylamine," and the quantity being too small for further crystallisation, we

prepared some base by heating *l*-menthone with ammonium formate, and hydrolysed the crude mixture of formyl derivatives directly with hydrochloric acid.

The base thus obtained was converted into the *d*-bromocamphorsulphonate, and this salt, although showing a great tendency to separate as an oil from its solution in dilute alcohol, was finally obtained in tufts of fine needles, which, after recrystallisation, melted at  $168^{\circ}$ , the melting point not being raised by further crystallisation. The specific rotation of this salt was determined with the following result: in chloroform,  $[\alpha]_D + 54.5^{\circ}$ ; in water,  $[\alpha]_D + 63.9^{\circ}$ ,  $[M]_D$  being  $297.7^{\circ}$ .

As the specific rotation of the salt melting at  $170^{\circ}$  obtained from the products of the reduction of the oxime was  $[\alpha]_D + 63.5^{\circ}$  in aqueous solution, it seemed as if this substance was a pure salt of a *d*-base, but when a sample was converted into the hydrochloride, which crystallised from water in needles melting at  $230$ – $232^{\circ}$ , and a fraction of this product was examined in aqueous solution, it was found to be optically inactive, whilst another fraction gave  $[\alpha]_D + 6.8^{\circ}$  in aqueous solution, and a third was levorotatory. A solution of the base in dilute alcohol prepared from a portion of the inactive hydrochloride was also examined and found to be inactive.

#### *Isolation of Four Benzoylmenthylamines.*

The base in the *d*-bromocamphorsulphonate melting at  $170^{\circ}$  is therefore a mixture, even after the exhaustive purification which it has undergone; this was proved in the following manner: the benzoyl derivative was prepared by the Schotten-Baumann method from both the samples of *d*-bromocamphorsulphonates melting at  $168$ – $170^{\circ}$  and having specific rotations of  $63.5^{\circ}$  and  $63.9^{\circ}$  respectively. When crystallised from alcohol, both preparations were found to be mixtures, and as the result of a prolonged and very troublesome process of fractional crystallisation four benzoyl derivatives were ultimately isolated in a pure condition.

(1) The most sparingly soluble fraction, which crystallised in long needles, melted at  $156^{\circ}$ , had  $[\alpha]_D - 61.9^{\circ}$  in chloroform solution, and was identical with the benzoyl derivative of *l*-menthylamine.

(2) A compound which crystallised in long, glistening leaf-like plates, melted at  $128^{\circ}$ , and had  $[\alpha]_D - 17.4^{\circ}$  in chloroform solution.

(3) A compound which crystallised in thick tufts of short, fine needles, melted at  $104^{\circ}$ , and had  $[\alpha]_D - 3.8^{\circ}$  in chloroform solution.

As this derivative was the most fusible isomeride and might therefore have been a mixture, it was recrystallised three times from

alcohol, and the specific rotation again determined in chloroform solution, was  $[\alpha]_D - 3.9^\circ$ , indicating that the substance is pure.

(4) The most readily soluble fractions gave a benzoyl derivative which crystallised in very long, slender needles, melted at  $121^\circ$ , and had  $[\alpha]_D + 22.7^\circ$  in chloroform solution.

During the fractional crystallisation of the benzoyl derivatives, it was observed that when the original solutions were allowed to evaporate spontaneously, short, thick prisms were obtained, together with needles; when, however, these apparently homogeneous prisms were recrystallised, they gave needles and the glistening plates of the benzoyl derivative melting at  $128^\circ$ . The proportions of these four benzoyl derivatives actually isolated from the crude mixture were approximately equal, but the compound melting at  $104^\circ$  was perhaps obtained in rather the largest quantity. The various mother liquors contained a very considerable fraction of the total material.

#### *Attempts to separate the Isomeric Formylmenthylamines.*

Having proved that the basic product of the reduction of "l-menthoneoxime," as well as that obtained by heating "l-menthone" with ammonium formate, is a mixture of at least four menthylamines, not easily separated through the agency of their benzoyl derivatives, and, moreover, having found that these benzoyl derivatives are hydrolysed only with great difficulty, it seemed desirable to try and isolate the four amines in the form of their formyl derivatives, especially as the latter were known to undergo hydrolysis with moderate ease, and could therefore serve for the preparation of the bases themselves with less chance of partial racemisation. A considerable quantity of formylmenthylamine was therefore prepared, and, instead of hydrolysing directly, the crude product was crystallised first from ether and then from ethyl acetate, from which it finally separated in well-defined, four-sided prisms melting at  $112-113^\circ$ . The melting point of this, the principal crystalline product, was constant, but the mother liquors deposited a small quantity of crystals melting at  $117^\circ$ ; when these two preparations were mixed together, the mixture melted at  $115^\circ$ . The two specimens were, therefore, not different substances, but the more sparingly soluble fractions (m. p.  $112-113^\circ$ ) probably contained a small quantity of another formyl derivative not easily removed by crystallisation.

#### *l-iso-Menthylamine.*

The solid formyl derivative (m. p.  $112-113^\circ$ ) was then hydrolysed with strong hydrochloric acid; the hydrochloride thus obtained, after crystallisation from water, melted at  $186-187^\circ$ . The base in this salt

was then combined with *d*-bromocamphorsulphonic acid, and the compound thus obtained crystallised from dilute alcohol in well-defined needles melting at 166°. The specific rotation of this salt was determined in aqueous solution and found to be  $[\alpha]_D + 65^\circ$ , whence  $[M]_D + 303^\circ$ ; this gives a molecular rotation of the base  $[M]_D + 33^\circ$ , a value which is identical with that calculated from the molecular rotation of the "*d*-menthylamine" hydrochloride described by Binz (*loc. cit.*).

The base from this most sparingly soluble fraction of the *d*-bromocamphorsulphonate gave a pure benzoyl derivative melting at 121°, but the most soluble portions of the *d*-bromocamphorsulphonate seemed impure, and when the base contained in them was converted into the benzoyl derivative, the latter on fractional crystallisation gave, in addition to the compound melting at 121°, a small quantity of the benzoyl derivative melting at 128°. The formyl derivative melting at 112—113° is, therefore, impure in spite of repeated fractional crystallisation, and apparently the best way of obtaining a pure base is to hydrolyse the formyl derivative and crystallise a salt prepared from the basic mixture. The salt of this base, *l*-isomenthylamine, with Reyhler's *d*-camphorsulphonic acid, was prepared for the purpose of comparison with the *d*-camphorsulphonate of the base obtained on hydrolysing the benzoyl derivative melting at 128° (p. 77). It was moderately soluble in water, crystallising in needles which, when dried at 100°, melted at 177°. The specific rotation of this salt in aqueous solution was determined and found to be  $[\alpha]_D + 21.7^\circ$ , whence  $[M]_D + 83.9^\circ$ , so that the calculated value for the base is  $[M]_D + 33^\circ$ .

#### *Further Examination of Formyl Derivatives.*

The ethereal mother liquors from the crystallisation of the formyl derivative were evaporated, and the brown, syrupy residue distilled under 12 mm. pressure. After some unchanged menthone had passed over, about two-thirds of the remaining liquid distilled at 208—215°, giving an almost colourless, highly refractive, viscous liquid, to which a small quantity of ethyl acetate was added, when a larger quantity of the formyl derivative, melting at 112—113°, was obtained than that which crystallised from the ethereal solution of the original substance. This product, when separated from an uncrystallisable residue, was hydrolysed with strong hydrochloric acid and the base converted into the *d*-bromocamphorsulphonate. This salt, which appeared highly impure, and only crystallised partially when kept for some time in a vacuum, was therefore converted into the benzoyl derivative, the latter being fractionally crystallised from alcohol.

Probably about 75 per cent. of this product consisted of the derivative melting at  $128^{\circ}$ , this being identical with that obtained in small quantity from the formyl derivative melting at  $112$ — $113^{\circ}$ , but some of the benzoyl derivative melting at  $121^{\circ}$  was also isolated, together with a small quantity of the isomeride melting at  $156^{\circ}$ .

The distillation was stopped when the temperature reached  $238^{\circ}$ ; the residue in the flask was hydrolysed and converted into the benzoyl derivative, which, on fractional crystallisation from alcohol, was found to consist chiefly of the derivative melting at  $156^{\circ}$ , and a smaller amount of the derivative melting at  $104^{\circ}$ , although the proportion of the latter was not nearly so large as that obtained before in the fractional crystallisation of the benzoyl derivatives from the crude mixture of formyl derivatives; this fact, and further evidence obtained later, seemed to show that the formyl derivative corresponding with this benzoyl derivative had partially racemised on distillation.

In all the experiments in which the bases obtained from the formyl derivatives were separated by means of their benzoyl compounds, the proportion of the benzoyl derivative melting at  $156^{\circ}$  was always less than that of the isomerides melting at  $128^{\circ}$  and  $121^{\circ}$ .

#### *Hydrolysis of the Benzoyl Derivatives.*

The preceding experiments show that it is practically impossible, or at least very difficult, to separate the four formyl derivatives present in the original mixture; the compound melting at  $112$ — $113^{\circ}$ , which is the only crystalline substance obtained in any quantity, serves for the preparation of one base only, namely, *l*-isomenthylamine.

We were therefore obliged to make use of the benzoyl derivatives for the preparation of the two remaining bases, and as it was necessary to prove that the bases did not racemise during hydrolysis, we reconverted them either into the benzoyl derivative or into some salt which had been previously shown to be homogeneous.

The benzoylmenthylamines do not hydrolyse appreciably when boiled for many hours with strong hydrochloric acid, and when dilute sulphuric acid (1 : 1) is used, the only basic product obtained is a small quantity of ammonia.

A sample of the benzoyl derivative of *l*-menthylamine was heated for 6—8 hours in a sealed tube at  $140$ — $160^{\circ}$  with strong hydrochloric acid and a small quantity of glacial acetic acid; at the end of this time, the benzoyl derivative was completely decomposed into benzoic acid and a quantity of tarry matter mixed with menthene and menthylamine. The base was combined with *d*-bromocamphorsulphonic acid, and as the salt thus obtained melted at  $224^{\circ}$  after recrystallisation, the base seemed not to have racemised.

Some of the pure benzoyl derivative of *l*-isomenthylamine (m. p.  $121^{\circ}$ ) was hydrolysed in a similar manner, and the base again converted into the benzoyl derivative, which still melted at  $121^{\circ}$ , thus indicating that racemisation had not taken place to any appreciable extent.

*l*-Neomenthylamine.

As the benzoyl derivative melting at  $128^{\circ}$  appeared to be derived from a base which had not hitherto been isolated, it was analysed to prove that it really was a menthylamine derivative.

Found, C = 78.80 ; H = 9.67.

$C_{17}H_{25}ON$  requires C = 78.76 ; H = 9.65 per cent.

This benzoyl derivative was then hydrolysed in the manner already described, but the base, which was isolated by distillation in steam, was obtained in very poor yield. The *d*-bromocamphorsulphonate prepared from the distillate was dissolved in dilute alcohol and the solvent allowed to evaporate, but the salt separated as an oil, although, when slowly evaporated in a vacuum desiccator, the solution deposited nodular masses, which, when dried at the ordinary temperature, melted at  $70-75^{\circ}$ . Since this salt could not be obtained in well-defined crystals from the ordinary solvents, it was decomposed with caustic potash, and the base, when distilled in steam and combined with Reychler's *d*-camphorsulphonic acid, yielded a salt crystallising from the concentrated aqueous solution in well-defined needles, which, after recrystallisation, melted constantly at  $188^{\circ}$ . This salt had the appearance of a pure substance, and as it was less fusible than the *d*-camphorsulphonates of either of the other two bases we concluded that racemisation had not taken place to any appreciable extent.

*l*-Neomenthylamine *d*-camphorsulphonate is moderately soluble in water, alcohol, or ethyl acetate, and dissolves very readily in chloroform ; it crystallises from water in a hydrated state. The specific rotation of this salt in aqueous solution was determined and found to be  $[\alpha]_D + 11.8^{\circ}$ , whence  $[M]_D + 45.7^{\circ}$ . This gives  $[M]_D - 6^{\circ}$  (approximately) for the molecular rotation of the base, the constant for the acid being  $[M]_D + 51.0^{\circ}$ .

*l*-isoNeomenthylamine.

The benzoyl derivative of *l*-isoneomenthylamine, melting at  $104^{\circ}$ , was hydrolysed in a similar manner, and the *d*-bromocamphorsulphonate of the base dissolved in dilute alcohol ; the salt crystallised in fine needles, but had the characteristics of a mixture, and after three recrystallisations melted at about  $169^{\circ}$  ; from the mother liquors,

tufts of needles were obtained, which, after recrystallisation, appeared less impure than the more sparingly soluble fraction and melted at about 157°.

The base contained in this apparently impure *d*-bromocamphor-sulphonate was again benzoylated; the product, after fractional crystallisation from alcohol, consisted principally of the original benzoyl derivative melting at 104°, but a certain amount of benzoyl *l*-isomenthylamine (m. p. 121°) was contained in the more readily soluble fractions. It therefore appeared highly probable that *l*-isoneomenthylamine had undergone change to a certain extent, and this evidence confirms that obtained previously in examining the distillation products of the formyl derivatives, but with the quantity of material at our disposal we were unable to obtain salts of the base free from its closely related isomeride.

The authors desire to record their thanks to the Government Grant Committee of the Royal Society for financial assistance in carrying out this work.

## X.—*Peroxyaminesulphonates and Hydroxylaminetrisulphonates (Sulphazilates and Metasulphazilates).*

By TAMEMASA HAGA, D.Sc.

PERHAPS the most interesting of the sulphazotised salts discovered by Fremy (*Ann. Chim. Phys.*, 1845, [iii], 15, 408) are the two which result from the oxidation of one or other of the potassium hydroximino-sulphates (hydroxylaminedisulphonates) in aqueous solution by either silver oxide or lead peroxide or some other reagent. One of these products is the very unstable salt which he named *sulphazilate*. This substance is remarkable for crystallising from its aqueous solution, which is of an intense bluish-violet colour, in brilliant golden-yellow needles, very slightly soluble in ice-cold water, but dissolving easily in hot water. It can seldom be preserved for any length of time, and gives a disagreeable odour to the skin, like that caused by manganates and ferrates. According to Fremy, it is easily fusible, but that is a mistake; it is the products of its decomposition which melt. The other salt, his *metasulphazilate*, is also sparingly soluble in cold water, but is colourless and has considerable stability. It crystallises in

rhombic prisms which are so well defined that Fremy describes the compound as being the most beautiful of all the sulphazotised salts. These crystals appear to be isomorphous with those of potassium 5/6-normal hydroximosulphate and the two salts can hardly be separated by crystallisation. Its solution is quite neutral and gives a precipitate with basic lead acetate only. Fremy expressed the composition of the sulphazilate by the formula  $\text{HO}_7\text{NS}_2\text{K}_2$  (here written with the atomic proportions now in use), which is only incorrect in including hydrogen (Claus). He gave the composition of the meta-sulphazilate correctly as  $\text{H}_6\text{O}_{23}\text{N}_2\text{S}_6\text{K}_6$ .

Claus (*Annalen*, 1871, 158, 205), who gave details for the preparation of the coloured salt by lead peroxide, proved that in its production from potassium 5/6-normal hydroximosulphate it is not necessarily accompanied by sulphate; he also demonstrated with tolerable certainty that it is the sole product of the oxidation; and found that it passed spontaneously into the colourless salt, together with a fixed quantity of sulphate and a gas which is apparently nitrous oxide (compare page 89 of this paper). He recognised the sulphonate constitution of both salts and gave to the coloured salt the name and formula 'oxysulph-

azotate,'  $(\text{SO}_3\text{K})_3\text{N} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{N}(\text{SO}_3\text{K})$ , and to the white salt the name and

formula, 'trisulphoxyazoate,'  $\text{O}:\text{N}(\text{SO}_3\text{K})_3 \cdot \text{H}_2\text{O}$ , that is, with the nitrogen quinquevalent in both formulæ. It will be seen that, even empirically, these formulæ differ a little from Fremy's. Claus also sought for, and, as he believed, obtained, the primordial sulphazotised salt which he formulated at first as  $\text{SO}_2\text{NO}_2\text{K}$  (*op. cit.*, 213), and afterwards as  $\text{O}:\text{N}(\text{SO}_3\text{K})$  (*Ber.*, 1871, 4, 508). This would be the analogue of the 'trisulphoxyazoate,' with the nitrogen only trivalent; but the existence of this salt has since been disproved (*Trans.*, 1900, 77, 437).

Raschig (*Annalen*, 1887, 241, 223) having found that the white salt, in a boiling and feebly acid solution, may yield sulphate to the extent of two-thirds of its sulphur, along with, apparently, hydroxyaminosulphuric (hydroxylaminemonosulphonic) acid, has recognised that it behaves as a derivative of hydroxylamine. But because it does not decompose when in strongly alkaline solution, he will not allow that it is that base trisulphonated. He modifies Claus's two formulæ, writing that

for the coloured salt as  $(\text{SO}_3\text{K})_2\text{N} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{N}(\text{SO}_3\text{K})_2$ , and that for the white salt as  $(\text{SO}_3\text{K})_3\text{N} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{N}(\text{SO}_3\text{K})_3 \cdot 2\text{H}_2\text{O}$ .

Hantzsch and Semple have found (*Ber.*, 1895, 28, 2744) that, when crystals of potassium 2/3-normal hydroximosulphate form in a bluish-

violet solution of potassium sulphazilate, they may contain 1—4 per cent. of this salt, apparently in solid solution, and consequently show a bluish-violet colour. These chemists have therefore advanced the view that Fremy's coloured salt, which they have renamed 'nitroxydisulphonate,' is sulphonated nitric peroxide, the yellow crystals of which have double the molecular magnitude of the dissolved bluish-violet form, in analogy with the two forms of nitric peroxide itself. The formula for the bluish-violet modification is given in a foot-note as  $\text{O}\cdot\text{N}\cdot(\text{SO}_3\text{K})_2$ , in which, therefore, the nitrogen is represented as being trivalent and the oxygen as univalent. A structural formula for the yellow modification is not given, but Raschig's is rejected, as having two quinquevalent nitrogen atoms in union with each other, a mode of combination which is without parallel. Raschig's formula for the white salt is also rejected, but as the simpler one proposed by Claus is adopted in its place, the quinquevalency of the nitrogen is maintained. On the authority of Schatzman, and as a result of their own experiments in the case of hydriodic acid, these chemists state that, in acting as an oxidising agent, the coloured salt reverts to hydroximinisulphate.

In 1896, Sabatier (*Compt. rend.*, 122, 1417, 1479, and 1537 ; 123, 255) published the results of an investigation of the violet solutions produced by the action of reducing agents on a sulphuric acid solution of nitrososulphuric acid, and suggested that the colour is due to the formation of the acid of Fremy's potassium sulphazilate. His suggestion is discussed on page 93 of this paper.

In the detailed examination of Fremy's sulphazotised salts made by Dr. Divers and the author, the results of which have been described from time to time in the Transactions, the sulphazilate and metasulphazilate were purposely reserved for separate treatment, because they are distinguished from the other salts in being products of oxidation. In the present paper, the author endeavours to prove (1) that the sulphazilate is an *oxime-peroxide* (Scholl), or a *peroxime*,

the first and only inorganic peroxime yet known ; (2) that the metasulphazilate is a *triacylated hydroxylamine*,  $(\text{SO}_3\text{K})_2\text{NO}(\text{SO}_3\text{K})$ , being the only compound of this type having an established normal constitution (all others, such as tribenzhydroxylamine, being apparently of more complex constitution) ; and (3) that, consequently, the nitrogen in both these sulphazotised salts is only trivalent, instead of being quinquevalent.

From among the several constitutional names which suggest themselves for Fremy's provisional 'sulphazilate' and 'metasulphazilate,' that of *peroxylaminesulphonate* for the former, and of *hydroxylamine-trisulphonate* for the latter, have been adopted as preferable. In

consequence, it has been found advantageous in this connection to call the parent salt *hydroxylaminedisulphonate*, instead of the alternative *hydroximinisulphate*, the name usually employed by Divers and the author. It has also been found convenient to treat of the hydroxylaminetrisulphonates before the peroxyaminesulphonates, from which they are apparently always derived.

*Hydroxylaminetrisulphonates (Metasulphazitates; Trisulphoxyazoutes).*

Potassium hydroxylaminetrisulphonate is most readily prepared by Fremy's method, in which there is no intermediate separation of its parent salt, the peroxyaminesulphonate. Somewhat alkaline potassium hydroxylaminedisulphonate is gently boiled and shaken with silver oxide or lead peroxide, until the solution, which at first becomes intensely bluish-violet, just loses its colour. Then, by evaporation and cooling, the filtered solution can be made to yield nearly all its hydroxylaminetrisulphonate. Theoretically, all the hydroxylaminedisulphonate should be converted into hydroxylaminetrisulphonate and nitrite,

but sulphate and nitrous oxide are always produced, usually accompanied by very small quantities of nitrogen and aminemonosulphonate (aminosulphate). Nevertheless, 86 and 87·8 per cent. yields of the indicated quantity of the salt have been obtained, together with 78 and 85 per cent. of the full amount of nitrite as indicated by the urea method (p. 94). The production of such large quantities of the hydroxylaminetrisulphonate shows the inaccuracy of Claus's description of the changes concerned. According to that account, which is endorsed by Raschig, no nitrite is formed, and the utmost yield of hydroxylaminetrisulphonate would be equivalent to only 75 per cent. of the sulphur of the hydroxylaminedisulphonate.

*Constitution.*—Strictly speaking, the product of the triacylation of hydroxylamine with sulphonate radicles can only be a disulphonate, the third sulphonate radicle becoming sulphatic by its union with oxygen. But the name of hydroxylaminetrisulphonate is sufficiently appropriate for such a compound, since, although a sulphatic salt, it is not actually a sulphate, but a mixed anhydride of acid salts, one being the 2/3-normal hydroxylaminedisulphonate and the other the acid sulphate:  $(\text{SO}_3\text{K})\text{OH} + \text{HON}(\text{SO}_3\text{K})_2 = \text{H}_2\text{O} + (\text{SO}_3\text{K})\cdot\text{O}\cdot\text{N}(\text{SO}_3\text{K})_2$ . Lossen (*Ber.*, 1892, 25, 440) has already pointed out that dibenzhydroxamic acid may be regarded as the mixed anhydride of benzhydroxamic acid and benzoic acid, and similarly in the case of other diacylhydroxyl-

amines.\* Nitrososulphuric acid (nitrosyl hydrogen sulphate), the mixed anhydride of nitrous and sulphuric acids, is an example of a mixed inorganic anhydride. But the present salt, as the anhydride of two different acid salts, finds its close analogue in potassium hyponitrosulphate,  $(\text{SO}_3\text{K})\text{O}(\text{N}_2\text{OK})$  (Pelouze's "nitrosulphate," *Trans.*, 1895, **67**, 1098; 1896, **69**, 1610), which is the anhydride of an acid hyponitrite and an acid sulphate. The two mixed anhydrides agree in being stable in alkaline solution and unstable in acid solution, and in not giving barium sulphate with barium hydroxide or chloride.

The evidence that the metasulphazilates have the constitution of hydroxylaminetrisulphonates is simple and direct, and similar to that as to the constitution of the hyponitrosulphates. In the first place, sodium amalgam decomposes them, apparently quantitatively (p. 96), into sulphate and normal aminedisulphonate (iminosulphate):

no sulphite being formed. Instead of sodium amalgam, the zinc-copper couple may be used to reduce hydroxylaminetrisulphonates in boiling solutions (p. 97), but in this case the aminedisulphonate is apt to hydrolyse during the heating. The result of this reduction of the salts not only proves their sulphatic constitution but shows also that neither the formula  $\text{ON}(\text{SO}_3\text{K})_2$  (Claus, Hantzsch) nor this formula doubled (Raschig) can possibly be right, because its acceptance would require that the sodium should act as a "carrier" of oxygen to the sulphonate radicle. Dunstan and Goulding (*Trans.*, 1899, **75**, 792) have found that trialkyloxamines, such as  $(\text{CH}_3)_3\text{N}:\text{O}$ , are reduced to trialkylamines by zinc and acid. Were metasulphazilates also oxaminic in constitution, they too should be reduced to aminetrisulphonates (nitrilosulphates). Sulphites, and even sulphur dioxide, have no action on the hydroxylaminetrisulphonates (p. 98).

In the second place, the metasulphazilates behave as sulphonated hydroxylamine. They reduce acidified permanganate; they give up one-third of their nitrogen in the form of ammonia when they are heated with soda-lime (Claus); and they can be hydrolysed ultimately into hydroxylamine and acid sulphate. Although very stable salts in other respects, they cannot, indeed, remain in solution very long or be

\* Twenty-six years ago, Koenigs (*Ber.*, 1878, **11**, 615 and 1588) found that benzenesulphinic and nitrous acids react to form hydroxylaminedibenzsulphinic (dibenzsulphydroxamic) acid, and that this with more nitrous acid becomes a tribenzsulphinic compound. Preliminary experiments made for the author seem to show that the latter will almost certainly prove to be hydroxylaminetribenzsulphinic acid. Its production may probably be expressed by the following equation:

kept for many months in the solid state without beginning to hydrolyse. But if a small amount of potassium or sodium hydroxide or, much more conveniently, of ammonia is added to their solution, they are permanent even for years in closed vessels. The other less sulphonated hydroxylamines have no such stability, but always revert more or less to sulphite and either nitrite or nitrous oxide. The hydrolysis is expressed by the equation :

Taking into consideration their water of crystallisation, the potassium and the ammonium hydroxylaminetrisulphonates can only be written with doubled formulæ, thus in some degree supporting Raschig's action in doubling Claus's formula for the former salt. But a cryoscopic measurement (p. 100) of the molecular magnitude of the sodium salt has shown that the simple formula is correct.

*Potassium hydroxylaminetrisulphonate*,  $2(\text{SO}_3\text{K})\text{ON}(\text{SO}_3\text{K})_2, 3\text{H}_2\text{O}$ , hitherto the only known salt, occurs in flattened, monosymmetric prisms, measurements of which have been made by Fock (Raschig). Its solubility in water at  $18^\circ$  is one in 25·37 parts. It is neutral to phenolphthalein, litmus, methyl-orange, and other indicators. When slowly heated to  $100$ — $120^\circ$  in the air, it loses some of its water of crystallisation, and is then hydrolysed by the remainder, acting together with the moisture of the atmosphere, so that at first it loses in weight and then gains. The residual mass is strongly acid, owing to the presence of acid sulphate. It has not been found possible to avoid hydrolysis and to obtain the anhydrous salt, even when the compound is very gradually heated in a current of dried air, after having already been exposed in a desiccator at the ordinary temperature. Its water, therefore, could only be determined by difference. As expressed by the foregoing formula, which agrees with Fremy's empirical formula, it is certainly  $3/2\text{H}_2\text{O}$ , although Claus made it out to be  $1\text{H}_2\text{O}$  only. In his paper, five concordant analyses of the anhydrous salt, besides four analyses of the hydrated salt, are given ; and so far from reference being made to any difficulty being experienced in rendering the salt anhydrous, it is stated that the water of crystallisation easily escapes at  $100^\circ$ . But it is important to note that his four determinations of the water give numbers which are all somewhat higher than those required by his calculation, although the salt occurs in large, clear, non-deliquescent crystals, and that the figures thus calculated are but little if any higher than those obtained by the author in two direct determinations of the loss of water by heating, in which the residues were always acid and therefore contained water. The salt has also been analysed by Raschig, but his results are not decisive (p. 99).

*Sodium Hydroxylaminetrisulphonate*,  $(\text{SO}_3\text{Na})\text{ON}(\text{SO}_3\text{Na})_2, 2\text{H}_2\text{O}$ .—This salt, now prepared for the first time, is obtained by boiling solution of 2/3-normal sodium hydroxylaminedisulphonate and its equivalent half-molecule of sodium hydroxide with lead peroxide. It is more difficult to purify from accompanying salts than the potassium salt, but by very cautious addition of sulphuric acid, these salts may be converted into sulphate, which can be easily separated from the hydroxylaminetrisulphonate by freezing. It crystallises in aggregates of small, tabular, monoclinic crystals (p. 99). The solubility of the salt is considerable, one part requiring only 2.83—2.85 parts of water at 21.5°. Like the potassium salt, it is neutral to indicators, and, when heated, hydrolyses in its water of crystallisation.

*Ammonium Hydroxylaminetrisulphonate*,  $\text{H}_{30}\text{O}_{23}\text{N}_5\text{S}_6$  or  
 $2(\text{SO}_3\text{NH}_4)\text{ON}(\text{SO}_3\text{NH}_4)_2, 3\text{H}_2\text{O}$ .

—The analysis of this salt confirms the view that the amount of water present in the potassium salt is greater than that found by Claus. The ammonium salt forms thick, rhombic plates and prisms, similar to those of the potassium salt and probably isomorphous with them. But goniometric examination was impracticable, for although some faces were 7—9 mm. long, others were too imperfectly developed for determination. The salt is neutral to litmus and methyl-orange, and generally like the potassium salt, but it is exceedingly soluble in water, one part dissolving in 0.61 part at 16°. The salt examined was prepared by digesting the basic lead salt with ammonium carbonate and evaporating the solution on the water-bath until it had almost lost its alkalinity, and then concentrating it further under reduced pressure over solid potassium hydroxide. Its nitrogen and sulphur were found to be in much closer agreement with the formula showing 3/2 molecules of water; but here again the difference between the numbers for the two formulæ is not very great (p. 100).

*Hydroxy-lead Hydroxylaminetrisulphonate*,  
 $\text{ON}(\text{SO}_3\text{PbO} \cdot \text{PbOH})_3, 3\text{H}_2\text{O}$ .

—This tetrabasic and very insoluble lead salt, which appears to be the only insoluble hydroxylaminetrisulphonate, was prepared by pouring a warm solution of the potassium salt into excess of carefully prepared basic lead acetate solution. It is a chalky powder readily decomposed by a solution of an alkali carbonate (p. 100).

*Peroxylaminesulphonates* (*Sulphazilates*; *Oxysulphazotates*; *Nitroxydisulphonates*).

Only silver oxide and lead peroxide have, as yet, been used in the preparation of a peroxylaminesulphonate, but many other oxidising agents produce the violet coloration, thus indicating the conversion of

a hydroxylaminedisulphonate into a peroxyaminesulphonate, as was pointed out by Fremy; even chlorine when used in limited quantity is able to produce this change. Ozone is an excellent reagent, rapidly producing a strong solution of the peroxyaminesulphonate when it is passed into a faintly alkaline solution of the hydroxylaminedisulphonate. Nitrous fumes are absorbed by an ice-cold solution of this salt, which assumes a dark-brown colour, and this solution, when rendered alkaline, slowly acquires the violet colour of the peroxyaminesulphonate. Also, when an ice-cold solution of potassium hydroxylaminedisulphonate and nitrite is barely acidified (preferably with sulphur dioxide), similar effects are produced. The temporary production of a violet colour is frequently observed in experiments made with the compounds of potassium nitrite and potassium hydroxylaminedisulphonates (Trans., 1900, 77, 432). Hydrogen peroxide, potassium ferricyanide, potassium permanganate, and alkaline cupric solutions do not interact with a hydroxylaminedisulphonate. Even freshly precipitated mercuric oxide has no action on it, although the oxide is more quickly affected by light when suspended in a solution of the salt.

In preparing potassium peroxyaminesulphonate, Fremy showed a preference for the use of silver oxide, whilst Claus, who assumed that the action of silver oxide was apt to proceed too far, preferred lead peroxide. Silver oxide gives a somewhat better yield and none of the silver goes into solution, whereas a little of the reduced lead peroxide dissolves and renders the salt impure. But the dissolved lead is readily removed, and the lead peroxide presents the advantage of being at hand when wanted, whilst the silver oxide has to be prepared each time and the metal afterwards recovered. Lead peroxide has therefore been used in the present research.

Fremy used either the  $2/3$ - or the  $5/6$ -normal potassium hydroxylaminedisulphonate as the source of the peroxyaminesulphonate; Claus used only the latter, and Raschig chose the former. The advantage lies with the  $5/6$ -normal salt, for, when prepared from a less alkaline salt, the peroxyaminesulphonate proves to be less easily purified and consequently less stable. The  $5/6$ -normal salt is always so far hydrolysed in dissolving that it is converted into the  $2/3$ -normal salt, the potassium hydroxide being left in solution, as noticed by Claus. The presence of free alkali, however, moderates the action of the oxidising agent, and to such an extent that a sufficiently concentrated solution of the very soluble normal sodium hydroxylamine-disulphonate is not attacked at all by lead peroxide. Apparently, therefore, lead peroxide acts as an acid oxidiser, in the form of plumbic anhydride, as suggested by Fremy.

The salt, which must be prepared just when it is wanted, is produced by mixing about 6 grams of the  $5/6$ -normal hydroxylaminedisulphon-

ate (or the same amount of the 2/3-normal salt together with a small quantity of potassium hydroxide) and a little more than the same weight of lead peroxide (or of the silver oxide precipitated from a little less than the same weight of silver nitrate) and making up with water to 25 c.c. The mixture is agitated for 15 minutes in water near to, but not above, 40°. Then the solution is decanted without delay, treated with carbon dioxide (when lead peroxide has been used), and filtered, before crystallisation sets in. The solution should therefore be kept warm up to this point. When it has remained some hours in an ice-box, almost the whole of the peroxyaminesulphonate will have separated as a crust of minute, yellow needles. These can be recrystallised, but not without material loss, from hot water made slightly alkaline with potassium hydroxide. When, as appears to have been the case with Fremy, much hydroxylaminedisulphonate has been left unoxidised, some of this will be found with the peroxyaminesulphonate, from which it can hardly be wholly separated by recrystallisation, its crystals remaining coloured by the peroxyaminesulphonate, as observed by Hantzsch and Semple.

Any close determination of the yield cannot be made directly, since the salt can rarely even be roughly weighed before decomposition sets in. Its amount has therefore to be estimated by letting it decompose, igniting the residue with ammonium carbonate, and weighing the potassium sulphate. In this way, the yield of separated salt was found to be a very little over three-fourths of the calculated quantity when silver oxide was used; and a little less than two-thirds when lead peroxide was taken. But by indirect means the amount of the salt actually produced can be shown to be much higher than this. As already mentioned (p. 81), the exhaustive oxidation by lead peroxide of a hot solution of hydroxylaminedisulphonate has given nearly 88 per cent. of the calculated quantity of hydroxylaminetrisulphonate, a fact which signifies that at least as much peroxyaminesulphonate as is equivalent to this percentage of the total sulphur must have been formed, since its production is intermediate to that of the hydroxylaminetrisulphonate.

Potassium peroxyaminesulphonate is very unstable in water and very slightly soluble in the cold. In *N*/10-solution of potassium hydroxide, which fairly represents its usual mother liquor, it is more stable, but still not very soluble; 100 parts at 3° dissolve only 0.62 part of the salt, and at 29° only 6.6 parts (p. 101). It interacts in solution with normal potassium sulphite and then produces hydroxylaminetrisulphonate and hydroxylaminedisulphonate, evidently in molecular proportions (p. 101), this change being a fact of great theoretical importance. Its chemical activity is manifested in oxidising certain easily oxidisable substances and being thereby reduced to its parent

salt, hydroxylaminedisulphonate. Although it liberates iodine from hydriodic acid, it fails to oxidise hydrochloric acid. When the latter acid in concentrated solution is poured on the solid salt, it sets up the same decomposition as that which occurs spontaneously (p. 88). But here, as the rise of temperature is moderated, definite although minute quantities of aminemonosulphonate and of hydroxylamine (not its sulphonate) can be found. The salt has practically no action on alcohol; nitrous and sulphurous acids rapidly reduce it, so also does sodium amalgam, first to hydroxylaminedisulphonate (as already observed by Schatzman), and then this salt passes slowly but completely into aminedisulphonate (iminosulphate). Clean granulated zinc slowly reduces the salt, but copper does not. The spontaneous decomposition of the salt may, however, easily be mistaken for its slow reduction by a reducing agent, since in this case also, as will be presently described (p. 89), hydroxylaminedisulphonate is produced. The difference is readily detected by testing for nitrite, which is produced only in the spontaneous decomposition of the salt. Manganese dioxide very slowly decomposes it, causing a minute effervescence; lead peroxide is inactive. Potassium permanganate is reduced to green manganate. Clean filter-paper, unlike the paper in use in Fremy's time, does not affect it.

Part of the instability of peroxyaminesulphonates must be attributed to the presence of oxidisable impurities. Thus, Fremy noticed the decomposing action of atmospheric dust; whilst nitrite, another impurity liable to be found in the salt, also greatly increases its instability. Acids hasten the decomposition of the salt; alkalis retard it. When drained on the tile from an alkaline solution, the salt may, under cover, remain undecomposed for two hours or more; but if washed on the tile and thus deprived of the traces of its adherent alkaline mother liquor, it will decompose in a very few minutes. Nevertheless, on one occasion some of the salt thus purified was kept on a tile for 11 months in a desiccator, and only then decomposed through an accident. This, however, must be regarded as a very uncommon experience. The sensitiveness of potassium peroxyamine-sulphonate to acids has been recorded by others, but has been somewhat exaggerated. When the salt is free from every trace of nitrite, its cold acidified solution may remain coloured for 40 minutes. An alkaline solution may not lose all its colour when kept in a closed vessel for more than a month. If sufficiently pure, the solid salt may be preserved for a day or so under water rendered slightly alkaline with potassium hydroxide.

The nature of the decomposition of potassium peroxyaminesulphonate occurring in the absence of alkali has already been examined, although in all cases very imperfectly, by Fremy and by Claus, and in

the presence of alkali by Raschig. According to Fremy, the solid salt decomposes explosively when heated; when exposed to the air, it becomes strongly acid; and when heated in solution, it yields sulphate and a gas mistaken by him for oxygen, but which was really nitrous oxide. He was also mistaken in stating that it melts readily and that when left in a closed bottle it evolves nitric oxide. Claus found that, whether in the solid state or in solution, whether when cold or moderately heated, the decomposing salt yields hydroxylaminetrisulphonate and nitrous oxide, together with acid sulphate equivalent to one-fourth of its sulphur, according to the equation  $2K_4N_2S_4O_{14} + H_2O = 2KHSO_4 + 2K_3NS_3O_{10} + N_2O$ . Raschig has confirmed Claus's statements and also states that the solid salt or its solution also decomposes in this way even when left in contact with alkali. He also adds that its solution when acidified is decolorised in a few minutes, whilst in the presence of alkali it can in some cases be heated to boiling without change. All these statements by Claus and Raschig require to be modified in order that they may accurately describe the behaviour of the salt, and even then they fail to indicate the primary change which the decomposing salt undergoes. Thus the acid sulphate produced is seldom equal to one-fourth of the total sulphur, although it may be so, as twice found by Claus, and indeed also in the present investigation, but only when the salt had been used with too small a quantity of water to dissolve it all on warming. Owing to this fact, only a part of the nitrogen, which does not become hydroxylaminetrisulphonate, appears as nitrous oxide, along with a small amount of free nitrogen.

Solid potassium peroxyaminesulphonate is too unstable when dry and free from alkali to exist many minutes without rapidly and almost explosively decomposing. In this decomposition, slight white fumes of ammonium salt (probably pyrosulphite and pyrosulphate), nitrogen and nitrous oxide, and a small quantity of sulphur dioxide are given off, whilst the residue, when the mass of the salt has been at all considerable, gets very hot (above  $300^\circ$ ?) and melts. This residue consists of potassium sulphate (principally pyrosulphate) with a very little ammonium salt. Sometimes a trace of amine-monosulphonate can be detected by the mercuric nitrate test; also a trace of hydroxylamine (or other substance reducing alkaline cupric solution), but none of the other sulphonates, the temperature having been too high to leave these substances undecomposed.

The true products of the spontaneous decomposition of a peroxyaminesulphonate are only found (in company with small quantities of apparently secondary products) when the salt is heated to boiling with enough water to dissolve it, and in presence of sufficient alkali to prevent both the acidification of the solution during the decomposition

of the salt and also the secondary changes which would result from acidification. The alkali does not appear to modify the nature of the primary change, although it distinctly increases the stability of the salt, as already mentioned (p. 87). When carried out in the foregoing manner, the decomposition of a peroxyaminesulphonate proceeds largely in such a way that not only do three-fourths of the sulphur of the salt, as suggested by Claus and by Raschig, together with one-half of its nitrogen, come out as hydroxylaminetrisulphonate, but the rest of the sulphur and one-fourth of the nitrogen become hydroxylaminedisulphonate again, whilst the remaining one-fourth of the nitrogen appears as nitrite,

although some nitrous oxide and sulphate, besides minute and uncertain quantities of other substances, are always produced (p. 92).

This result explains the production of the large quantities of acid sulphate and nitrous oxide observed by Claus and Raschig, for the nitrous acid when not neutralised by alkali interacts with the hydroxylaminedisulphonate and yields acid sulphate and nitrous oxide (Trans., 1900, 77, 433).

The regeneration of hydroxylaminedisulphonate in the spontaneous decomposition of a peroxyaminesulphonate accounts for the fact, met with in the present investigation, that much more hydroxylaminetrisulphonate is obtainable by heating hydroxylaminedisulphonate in solution with excess of lead peroxide than can be derived from the decomposition (out of contact with lead peroxide) of the peroxyaminesulphonate equivalent to that quantity of hydroxylaminedisulphonate (p. 81). For in the presence of lead peroxide, that hydroxylaminedisulphonate which is regenerated by the independent decomposition of the peroxyaminesulphonate is oxidised again to more of this salt, to be again decomposed in the same way, until the whole of the disulphonate has become trisulphonate and nitrite, except that part of it which is lost as sulphate and nitrous oxide. Remembering that  $4(\text{SO}_3\text{K})_2\text{NOH}$  gives  $2(\text{SO}_3\text{K})_4\text{N}_2\text{O}_2$ , the larger yield of hydroxylaminetrisulphonate which should result will be seen, on comparing the equation on page 81 with that just given, to be theoretically in the ratio 4:3. It will now, too, be evident, on reference to Claus's memoir, that his incomplete knowledge of the nature of the decomposition of the peroxyaminesulphonate led him to object too much to Fremy's account of the action of the oxidising agent in producing hydroxylaminetrisulphonate.

*Constitution.*—The constitution of a peroxyaminesulphonate as a sulphonate was recognised by Claus, and is deducible from the fact that it is formed by the dehydrogenation of hydroxylaminedi-

sulphonate. The problem of its constitution as a nitroso-compound remains to be solved, and the description just given of the potassium salt amounts to a demonstration, first, that its constitution is that of a peroxide and therefore of a peroximide; and, secondly, that its nitrogen is trivalent.

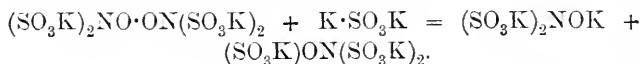

Among the facts bearing on its constitution as a peroxyamine, that is, as a derivative of  $\text{H}_2\text{NO}\cdot\text{ONH}_2$ , are, first, those of its mode of formation. The 2/3-normal hydroxylaminedisulphonate loses its two hydrogen atoms, at the ordinary temperature and when it is in aqueous solution, by the action of ozone, lead peroxide, silver oxide, and a variety of other substances:

but not, however, by oxygen itself; for Raschig's observation, that a solution of hydroxylaminedisulphonate when exposed to the air may assume a slight violet colour, applies in reality only to the case where the 2/3-normal salt is contaminated with nitrite, the pure salt never oxidising nor colouring in this way. The interaction with lead peroxide points clearly either to the peroxide constitution or, but with much less probability, to a rise in the combining power of the nitrogen to quadrivalency.

The fact of the ready reversion, at the common temperature and in solution, of a peroxyaminesulphonate to a hydroxylaminedisulphonate by acting as an oxidising agent is equally strong evidence of the same constitution. This reversion is also quantitative to an extent that admits of its being used to estimate the amount of the salt present in a solution (Schatzmann, Hantzsch and Semple).

Its combination with a molecule of normal sulphite (p. 86) affords convincing evidence to the same effect, since it is effected through the oxygen atoms of the peroxyaminesulphonate:

This interaction will be again discussed on page 91. Inferentially in favour of the peroxide constitution are also the odour which the peroxyaminesulphonates impart to the skin, their colour, and their decomposition into nitrous acid and sulphonated hydroxylamines.

So soon as it is recognised that peroxyaminesulphonates are peroxides, all doubt is removed as to the valency of their nitrogen, which then can be only that of a triad. Contrariwise, when such a constitution is not admitted, the nitrogen of a peroxyaminesulphonate, with equal certainty, cannot be trivalent. In order, therefore, to strengthen the conviction that the peroxyaminesulphonates are indeed peroxides and peroximides, it becomes important to state the

reasons against admitting the nitrogen of these salts to be quadrivalent or more than trivalent.

To begin with, it is extremely improbable that oxidation by lead peroxide, silver oxide, or ozone should raise the valency of the nitrogen to only quadrivalency and not to quinquevalency, and that it should raise it at all without converting the sulphonate to sulphate radicles. Neither Claus nor Raschig assumes that it does, for according to them the nitrogen of the hydroxylaminedisulphonate is itself quinquevalent. But there are also two strong reasons for rejecting the assumption that the valency of the nitrogen is raised by the oxidation of hydroxylaminedisulphonates to peroxyaminesulphonates. One of these is the nature of the products of the spontaneous decomposition of a peroxyaminesulphonate. These products, in so far as they contain nitrogen, are all trivalent nitrogen compounds, namely and in the main, hydroxylaminetrisulphonate, hydroxylaminedisulphonate, and nitrite; if nitrous oxide is also recognised, that fact will not affect the argument. No nitrate can be found among these products (p. 102). It is, of course, the establishment of the trivalency of the nitrogen of the first-named product which has really settled the matter. But as it is only as yet on the chemical work of Divers and the author (*Trans.*, 1894, 65, 523), that the adoption of the trivalency of the nitrogen in hydroxylaminedisulphonates can be based, the result of a determination by a cryoscopic method (p. 100) of the molecular magnitude of the normal sodium hydroxylaminedisulphonate may be adduced in support of it. This result shows that the molecule of the salt contains but one atom of nitrogen (necessarily, therefore, trivalent), and not two atoms as had been represented by Claus and by Raschig. Now, the spontaneous decomposition of a peroxyaminesulphonate can only be hydrolytic, and is therefore one not affecting the valency of the nitrogen; or, should this be contested, it can still be asserted that at least this decomposition cannot be interpreted as a change involving a diminution in the valency of the nitrogen.

The other reason against the belief that the valency of the nitrogen changes when a hydroxylaminedisulphonate is oxidised to a peroxyaminesulphonate is that of the production of the two compounds of trivalent nitrogen, the hydroxylaminedisulphonate and hydroxylaminetrisulphonate, by the union of a peroxyaminesulphonate with a normal sulphite (p. 86). These two reasons for regarding the nitrogen of a peroxyaminesulphonate as trivalent seem to be conclusive, and therefore support the view that these salts are constituted as peroxides or peroximides.

Since the sodium salt is even more unstable than the potassium salt, the determination of the molecular weight of a peroxyaminesulphonate has not been possible. It would seem better to modify

Hantzsch and Semple's suggestion concerning the molecular weights of the two forms of the potassium salt (p. 80), to the extent of giving the simple formula,  $(\text{SO}_3\text{K})_4\text{N}_2\text{O}_2$ , to the violet form, and reserving the double formula, or even a higher multiple of this, for the yellow form.

*Products of Decomposition.*—Without further experiments than those described on pages 94 and 106, the number of the products and the great variations in their proportions are such that the nature of the spontaneous decomposition of a peroxyaminesulphonate cannot yet be fully determined. But its general character can be indicated, now that the constitution of both peroxyaminesulphonates and hydroxylaminetrisulphonates has been determined.

It can hardly be doubted that the molecule of peroxyaminesulphonate becomes halved by hydrolysis and converted into the hydroxylaminedisulphonate, always found in abundance, and the *hydroperoxyaminesulphonate*, as yet undiscovered because incapable of continued existence, thus :

It is already known (Trans., 1889, 55, 765 ; 1894, 65, 539) that, in the presence of alkali, the nitroxy-radicles of a hydroxylaminesulphonate tend to separate from the sulphonate radicles. Such a tendency, exercised in the presence of undecomposed peroxyaminesulphonate, will lead to the production of hydroxylaminetrisulphonate and nitrite in the case of hydroperoxyaminesulphonate, and of the former salt and hypouitrite in the case of hydroxylaminedisulphonate, thus :

When the three equations are combined, the intermediate products disappear and the following equation is left,

or, leaving the comparatively stable hydroxylaminedisulphonate unchanged,

It is fairly certain that the sulphate which, in greatly varying although never very large quantity, is always produced, does not come from the hydrolysis of the salt itself or from that of either the hydroxylaminetrisulphonate or hydroxylaminedisulphonate derived from it. For the trisulphonate is remarkably stable in the presence of alkali, and the disulphonate, although unstable in its presence,

yields not sulphate but sulphite. As this is also true of hydroxylaminemonosulphonate, it may be assumed to be so in the case of peroxylaminesulphonate. The sulphate should therefore have another origin, which may well be taken to be the decomposition of the hydroperoxylaminesulphonate in circumstances in which it fails to interact with peroxylaminesulphonate, perhaps because the temperature of the solution is too low. In that case, it will naturally hydrolyse, one half becoming hydroxylaminedisulphonate by oxidising the other half into sulphate and nitrous acid,

Or, it may well hydrolyse wholly into sulphate and nitrous oxide,

These equations combined with the primary equation give,

An equation to account for the production of nitrogen, and another for that of aminemonosulphonate are easily framed :

A justification of the lower of these equations and an illustration of the nature of the change expressed by it are to be found in the production of aminemonosulphonate from hydroxylaminedisulphonate when decomposing in presence of copper sulphate (Trans., 1900, 77, 978).

By combining these six equations in different ways, the various results obtained can be explained (p. 107), although the conditions for the occurrence of one mode of decomposition more than another are not yet ascertained.

*Sabatier's Bluish-violet Acid.*—Sabatier has studied the nature of the bluish-violet colour produced in a solution of nitrososulphuric acid (nitrosyl hydrogen sulphate) in the monohydrate of sulphuric acid by sulphur dioxide, and in other ways (p. 80), and has found this colour to be more closely like that of a solution of potassium sulphazilate than the colour of the latter is like that of a solution of potassium permanganate. On this ground and from a consideration of the circumstances which give rise to the colour, he has suggested that it is due to the presence in the solution of the acid of Fremy's salt, constituted according to the formula  $\text{ON}(\text{SO}_3\text{H})_2$ . Sabatier may be right, but there is much to be said against this opinion. Firstly, the tints of the two coloured solutions are not so similar as he asserts.

Secondly, certain striking contrasts may be observed in the chemical character of the two solutions. Potassium peroxyaminesulphonate is produced by the action of lead peroxide and is not attacked by it, whereas the coloured acid solution is at once oxidised by lead peroxide. Conversely, whilst this acid solution is indifferent towards sulphur dioxide and produced by it, potassium peroxyaminesulphonate is at once changed by this reagent.

Then, again, it has not proved to be possible either to convert potassium peroxyaminesulphonate into this violet acid solution or to effect the opposite change. Mr. S. Sekiguchi, a Post-graduate of this University, has kindly carried out some experiments in this direction. Making the mixtures very gradually and keeping them cold by ice and salt, he has poured the solution, prepared from nitrososulphuric acid and sulphur dioxide in sulphuric acid, into a solution of potassium hydroxide; and, on the other hand, an aqueous solution of potassium peroxyaminesulphonate into some concentrated sulphuric acid; in both cases, an almost immediate disappearance of the violet colour results. In the former case, too, the alkaline solution was evaporated and crystallised, without finding any of the hydroxylaminetrisulphonate which would result from the decomposition of peroxyaminesulphonic acid and might, to some extent, in accordance with its usual stability, escape decomposition.

#### *Details of Experiments.*

*The Exhaustive Action of Lead Peroxide on Hydroxylaminedisulphonates.*—Potassium  $2/3$ -normal hydroxylaminedisulphonate was boiled with excess of lead peroxide in about 15 times its weight of water, containing from  $1/5$  to  $2/5$  of a molecule of potassium hydroxide, until the solution had again become colourless. To the cold filtrate, just enough barium acetate was added to precipitate all sulphate present; the filtrate was then evaporated, and the hydroxylaminetrisulphonate crystallised out, as far as possible, and weighed. Potassium nitrite, produced in large quantity, was estimated in the mother liquor and alcoholic washings of the crystals of the hydroxylaminetrisulphonate by the urea method. Sulphate was found partly in solution and partly in the lead residue, which was extracted alternately with dilute nitric acid and potassium hydroxide. The sulphate, both in solution and residue, was estimated, and, in two cases, the soluble lead also, as a measure of the lead peroxide consumed.

In one experiment, 73.2 grams of salt gave 58.2 grams of trisulphonate in crystals, that is, 58.5 mol. of trisulphonate from 100 mol. of disulphonate, or 87.75 per cent. of the theoretical quantity. Nothing else was determined, and so high a yield of hydroxylaminetrisulph-

onate was only reached by adding alcohol to separate the last portions of the salt from the very concentrated nitrite mother liquor.

In another experiment, 125 grams of the disulphonate gave 97.33 grams of trisulphonate, equal to 57.33 mol. of trisulphonate to 100 mol. of disulphonate, or 86 per cent. of the calculated quantity. The amount of potassium sulphate was 21.5 mol. per 100 mol. of salt taken, which leaves sulphur for the trisulphonate equivalent to 59.5 mol., as against the 57.33 mol. of crystallised salt. Very much nitrite was found (37.5 mol. per 100 mol. of disulphonate taken), indicating the production of very little nitrous oxide. The only way to interpret this large production of nitrite is to assume that, whilst 89.25 per cent. of the salt was oxidised into trisulphonate and nitrite, and only 3 per cent. into sulphate and nitrous oxide, 7.75 per cent. was oxidised into sulphate and nitrite, an assumption which cannot be easily justified.

In an earlier experiment, in which the crystallisation of the trisulphonate was only imperfectly carried out, 136.33 grams of the disulphonate gave 84.33 grams of the crystalline product, that is, 100 mol. gave 45.56 mol., or 68.33 per cent. of the theoretical quantity. But since the quantity of sulphate, almost if not actually the only other sulphur compound produced, amounted to only 19 mol. per 100 of disulphonate, the actual yield of trisulphonate can have been little short of 60.33 mol. per 100. The nitrite, as determined by the urea method, was 28.4 mol. per 100 of disulphonate taken. But the lead peroxide consumed was in this case determined, and made out to be 71.5 mol. per 100 mol. of disulphonate, and this indicates the production of 31.8 mol. of nitrite. Accepting the mean of these numbers for the nitrite, it results that about 90 per cent. of the hydroxylamine-disulphonate was converted into trisulphonate and nitrite, and the rest into sulphate and nitrous oxide.

In an experiment with 35 grams of potassium hydroxylaminedisulphonate, in which the crystals of hydroxylaminetrisulphonate were not weighed, 100 mol. yielded 13 mol. of sulphate and 26 mol. of nitrite. Calculating from these quantities, 78 per cent. of the salt was oxidised into trisulphonate and nitrite, 15.5 into trisulphonate and nitrous oxide, and 6.5 into sulphate and nitrous oxide. The trisulphonate produced will therefore have been about 93.5 per cent. of the calculated quantity, or 62.33 mol. per 100 mol. of disulphonate.

Another experiment was made on the normal sodium hydroxylaminedisulphonate (*Trans.*, 1894, 65, 546) in dilute solution, 11.33 grams being taken without any addition of sodium hydroxide, because the alkalinity of the salt was sufficient to protect it. But in this experiment, only the quantities of lead peroxide consumed and of sulphate formed were estimated. Exactly as happened in the experi-

ment with the potassium salt, 71.5 mol. of lead peroxide were consumed per 100 mol. of sodium salt. The sulphate amounted to 34 mol. per 100 mol. of salt used, more, that is, than in the experiments with the potassium salt. The calculated quantity of sodium hydroxylamine-trisulphonate was correspondingly lower, 55 mol. per 100 mol. or 82.75 per cent. of the theoretically possible quantity.

*Reduction of Potassium Hydroxylaminetrisulphonate by Sodium Amalgam.*—In the interaction between sodium amalgam and potassium hydroxylaminetrisulphonate in aqueous solution, the two liquids become warm, and the action is soon over if the two are well shaken together. No gas is evolved, and nothing is left in solution but the two salts, sulphate and aminedisulphonate (iminosulphate). The latter is easily recognisable by its separating as the very sparingly soluble  $2/3$ -normal potassium salt when the solution is nearly neutralised with an acid, and also by its nearly insoluble normal mercury-potassium salt (Trans. 1892, 61, 976; 1896, 69, 1629). But the salt was also analysed quantitatively (p. 97) in order to demonstrate its nature beyond question. By cautiously adding hydrochloric acid to the cold solution until it has become almost neutral to methyl-orange, and then precipitating with barium chloride, the sulphate is partially separated from the aminedisulphonate; the latter may then be estimated as sulphate in the filtrate after hydrolysis at  $150^{\circ}$ . In an experiment carried out in this way on 2.447 grams of potassium hydroxylamine-trisulphonate, the barium sulphate precipitate was washed with cold, and then with hot, water, ignited, and weighed. The sulphate from the hydrolysed aminedisulphonate was treated as in an ordinary sulphate determination. In this way determined, 34.79 per cent. of the sulphur came out as sulphate and 64.88 per cent. as aminedisulphonate, leaving 0.33 per cent. unaccounted for. In accordance with the equation, the actual numbers should have been 33.33 and 66.67 per cent. respectively. By other experiments, it was, however, established that some of the aminedisulphonate was precipitated with the sulphate. No doubt, also, some barium chloride was carried down.

Potassium hydroxylaminetrisulphonate, 1.441 grams, was reduced by sodium amalgam, and the solution neutralised and precipitated in the cold by barium chloride as above described. The washed precipitate was then heated for 4 hours at  $150^{\circ}$  with dilute hydrochloric acid in a sealed tube. The acid was nearly neutralised, and the barium sulphate collected, washed, and weighed as usual. The filtrate from this yielded a fresh precipitate with barium chloride, for the barium aminedisulphonate, which was precipitated with the sulphate, had been hydrolysed into barium sulphate and ammonium hydrogen sulphate. Therefore, from the weight of the main precipitate of sulphate was deducted that of the small quantity last

obtained, and the remainder taken as sulphate actually produced by the sodium reduction. It amounted to the equivalent of 34.20 per cent. of the total sulphur. The aminedisulphonate in the original filtrate from crude sulphate was determined by hydrolysing and weighing its sulphur as sulphate. To the weight of this was added twice that of the barium sulphate obtained, as just described, from the soluble sulphate extracted by hydrolysing the crude barium sulphate, because twice that quantity represented the total sulphur of the aminedisulphonate precipitated along with the actual sulphate. This sum was equivalent to 65.75 per cent. of the total sulphur. That these data still deviate from the calculated numbers is no doubt due to the adhesion of a little barium chloride to the sulphate when precipitated in the cold. The barium of this chloride will have rendered insoluble some of the sulphate which should have dissolved out through the hydrolysis of the aminedisulphonate simultaneously precipitated. There seems, therefore, to be no reason for doubting the quantitative accuracy of the equation given on p. 82.

An experiment was then tried to see whether closer results could not be got by removing as much as possible of the aminedisulphonate from the solution before precipitating the sulphate, first crystallising out most of it from the nearly neutralised solution, and then removing some of the remainder as the mercury-potassium salt, by digesting the solution with mercuric oxide. This method, however, did not give better results than the preceding.

*Reduction of Potassium Hydroxylaminetrisulphonate by the Zinc-copper Couple.*—The reduction of the trisulphonate was successfully effected by boiling its solution (to which a few drops of sodium acetate solution had been added in order to protect the salt from hydrolysis) with some zinc-copper couple. But in consequence of the necessity of boiling the solution, hydrolysis of the aminedisulphonate is apt to set in.

Some aminedisulphonate prepared by the sodium amalgam method, and another sample, prepared by the zinc-copper couple, were analysed with the following results:

	By sodium.	By zinc-copper.	Calc.
Potassium.....	30.68	30.72 —	30.89
Sulphur.....	25.09	24.85 25.94	25.30
Nitrogen .....	5.32	6.16	5.54

*Hydrolysis of a Hydroxylaminetrisulphonate.*—The complete hydrolysis of the hydroxylaminetrisulphonates is more difficult to effect than that of any other of Fremy's salts. In the quantitative analysis of the salts, it was found necessary to keep the acidified solution for 5 hours at 180—200°. In the case of the potassium salt, the mean

percentage of sulphur then came out as 23.18; at 150° only, for 4 hours, it was 22.85; and at 90—100° for 5 hours, and then 3 hours at 130°, it gave only 22.64. In this case, the nitrogen of the hydroxylamine obtained (as measured by the iodine method) amounted only to 2.5 per cent. In another case, where the hydrolysis was allowed to go on for 48 hours at 90—95°, and then 2 hours at 130—134°, the nitrogen obtained as hydroxylamine was 2.71 per cent. (79.75 per cent. of total nitrogen).

*Inactivity of Sulphites towards Hydroxylaminetrisulphonates.*—Potassium hydroxylaminetrisulphonate weighing 2 grams, in sufficient water to keep the salt in solution, was left for 3 days with 3 grams of potassium metasulphite, rendered slightly alkaline to lacmoid paper (whilst strongly acid to litmus). The sulphite was then precipitated by barium hydroxide and the filtrate evaporated. In this way 1.98 grams of the hydroxylaminetrisulphonate crystallised out. The analysis of the salt thus recovered is given as that of II among the analyses of the salt below.

*Analysis of Potassium Hydroxylaminetrisulphonate.*—Although this has been analysed by previous workers, it was necessary to make several careful and full analyses in order to establish the fact that it contains more water of crystallisation than the proportion stated by Claus and by Raschig. Four separate preparations were analysed.

I. 0.4954 substance gave 0.3117 potassium sulphate; 0.5088 gave 0.8581 barium sulphate; 0.3387 gave 0.5680 barium sulphate; 0.2821 substance, finely powdered and heated in a current of dried air, first at 95° and then up to 110°, lost 0.0138; 0.2174 lost in this way 0.0101.

II. 0.2272 substance gave 0.1429 potassium sulphate; 1.0676 treated with sodium amalgam for 24 hours and then hydrolysed at 150° for 3 hours, gave 1.7918 barium sulphate and ammonia = 25.59 c.c. *N*/10 acid.

III. 0.2288 substance gave 0.1451 potassium sulphate; 0.1003 gave 0.1710 barium sulphate.

IV. 0.8505 substance gave 0.5347 potassium sulphate; 0.34475 gave 0.5799 barium sulphate; 2.4425, by sodium amalgam treatment and hydrolysis at 150° for 3 hours, gave ammonia = 51.38 c.c. *N*/10 acid; 0.7650, by the Dumas method, gave 22.3 c.c. moist nitrogen at 16° and 758 mm.

	Potassium.	Sulphur.	Nitrogen.	Water.

Claus has also given the results of five closely concordant analyses of the anhydrous salt, and should therefore have experienced no difficulty in rendering it anhydrous. In the attempts to determine total water, recorded above, the residue was always acid in consequence of the unavoidable hydrolysis and fixation of some of the water of crystallisation. A discussion of this matter is given on page 83.

*Analysis of the Sodium Salt.*—Two distinct preparations of the sodium salt were analysed :

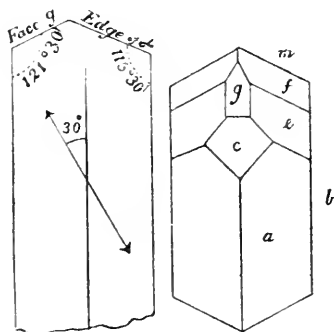

I. 0·4910 substance gave 0·2801 sodium sulphate ; 0·3845 gave 0·7174 barium sulphate, after hydrolysis at  $200^\circ$  for 3 hours. Hydrolysed at only  $160^\circ$  for 5 hours, 0·4548 gave 0·8378 barium sulphate, = sulphur 25·30 per cent. only.

II. 0·6097 substance gave 0·3455 sodium sulphate ; 0·1750 gave 0·3268 barium sulphate, after hydrolysis at  $210^\circ$  for 3 hours ; 0·7533 gave 24·0 c.c. moist nitrogen at 760·8 mm. and  $17^\circ$ , = 0·027 nitrogen.

	Sodium.	Sulphur.	Nitrogen.

*Crystallography of Sodium Hydroxylaminetrisulphonate.*—Professor Jinbo has kindly given me the following description of the crystals of this salt, which were examined under his directions by Mr. M. Yōtsuki, University Post-graduate. Thick, tabular, monoclinic crystals, about 3 mm. long and 2 mm. wide, elongated in the direction of the vertical axis. The observed faces are of seven kinds, of which *b* is the largest

and apparently the plane of symmetry.  $m$ , making with  $b$  an angle of about  $115^\circ$ , may be taken as a prism;  $d$ ,  $e$ , and  $f$  as pyramids;  $c$  as the base, and  $g$  as a positive orthodome. Two other faces in the zone

of the orthodiagonal are sometimes observed. A crystal laid flat on the clinopinacoid shows an extinction angle of  $30^\circ$  to the vertical axis, in the acute angle between this and the clinodiagonal.

*Analysis of the Ammonium Salt.*—The total nitrogen of the ammonium salt was determined by the Dumas method.

	Found.	$2\text{H}_{12}\text{O}_{10}\text{N}_4\text{S}_3 \cdot 3\text{H}_2\text{O}$	$\text{H}_{12}\text{O}_{10}\text{N}_4\text{S}_3 \cdot \text{H}_2\text{O}$
Sulphur .....	27.63	27.36	28.08
Nitrogen .....	16.06	15.98	16.40

*Analysis of the Basic Lead Salt.*—The salt was dried for analysis in a current of dry air at  $100^\circ$  in the case of preparation I, and at  $110^\circ$  in that of II. The salt was quite free from potassium but contained a trace of acetate.

	Found.	Found.	$\text{H}_9\text{O}_{19}\text{NS}_3\text{Pb}_6$
Lead .....	74.41	74.14	74.71
Sulphur .....	5.99	—	5.79

*Determination of the Molecular Magnitude of Sodium Hydroxylaminetrisulphonate.*—This was carried out by Löwenherz's method with melted sodium sulphate crystals (*Zeit. physikal. Chem.*, 1896, 18, 70).

Hydrated salt.	Anhydrous salt.	Fused sodium sulphate.	$\Delta t.$	M.W.
2.479	= 2.2411	59.411	$-0.369^\circ$	332.20
3.478	= 3.0210	57.520	$-0.510$	335.56

$\text{O}_{10}\text{N}_3\text{S}_3\text{Na}_3$  requires 339.37

*Molecular Magnitude of Normal Sodium Hydroxylaminedisulphonate.*—

Crystallised salt.	Fused sodium sulphate.	$\Delta t.$	M.W.
1.220	36.8180	- 0.39°	233
2.023	37.1980	- 0.74	239.6
$O_7NS_2Na_3$ requires 239.3			

With this molecular weight the nitrogen is necessarily trivalent.

*Solubility of Peroxylaminesulphonate in N/10 Solution of Potassium Hydroxide.*—The purified salt, previously washed on the porous tile with some of the solvent, was shaken with it for from 15 to 20 minutes, the temperature of the solution being 29°. After some time, 5 c.c. of the clear solution were withdrawn with a pipette. The rest of the solution, along with the undissolved salt, was left for some hours in ice, when again 5 c.c. were taken out, the temperature being 3°. The two portions were each weighed and the amount of dissolved salt ascertained by a sulphur determination. It was thus found that 0.163 gram of salt was dissolved in 5.03 grams of its alkaline solution at 29°, and that 0.027 gram was dissolved in 4.980 grams of its solution at 3°.

*Interaction of Potassium Peroxylaminesulphonate and Normal Potassium Sulphite.*—To a solution of 3.6 grams of potassium peroxylaminesulphonate, containing only a very small quantity of potassium hydroxide, a solution of normal potassium sulphite (neutral to phenolphthalein) was added from a burette, with constant stirring, until the violet colour of the solution was entirely discharged. The change took place quickly but not instantly. The quantity of sulphite required was only a little more than that indicated by theory. After a short interval, baryta water was added to precipitate the excess of sulphite and the hydroxylaminedisulphonate. The excess of baryta was removed from the filtered solution by carbon dioxide and the filtered solution evaporated so as to get out as much as possible of the sparingly soluble potassium hydroxylaminetrisulphonate. Some more of this salt was precipitated by adding twice the volume of alcohol and leaving the mixture for some time. The total trisulphonate thus separated weighed 2.268 grams, or 81.5 per cent. of the calculated quantity.

The barium precipitate was triturated in a mortar with very dilute acetic acid, added very slowly so as to avoid as far as possible having any local excess of acid. When the solution had become neutral to phenolphthalein, the undissolved barium sulphite was filtered off. Potassium carbonate in slight excess was added and the whole left for a day. Then, the solution, filtered from the barium carbonate and neutralised with acetic acid, was concentrated in a vacuum over sulphuric acid and mixed with twice its volume of alcohol. In 12 hours, the quantity of precipitated crystalline 2/3-normal hydroxylamine-disulphonate weighed 1.55 grams, this being equal to 76 per cent. of the

calculated quantity. It was pure, except for a trace of aminetrisulphonate (nitrilosulphate), doubtless due to the action of the sulphurous acid unavoidably liberated in the process of separating the barium sulphite from its own barium salt by acetic acid. It was identified by hydrolysis into sulphate and hydroxylaminemonosulphonate, and above all by its producing the bluish-violet peroxyamine-sulphonate when warmed with lead peroxide and a small amount of alkali. No nitrite was found in the mother liquor of the hydroxylaminetrisulphonate, showing that the production of the latter salt had not been due to spontaneous decomposition of the peroxylaminesulphonate. Hydroxylaminetrisulphonate and disulphonate are, in fact, the only substances which could be detected among the products of the interaction of the peroxylaminesulphonate and sulphite. Since, therefore, the separated quantities of these products were found to be in approximately molecular proportions, and as these salts are not insoluble, even in their alcoholic mother liquors, it may be regarded as proved that the interaction which takes place is exclusively that represented by the equation on p. 90.

*Spontaneous Decomposition of Potassium Peroxylaminesulphonate.*—The principal products of the spontaneous decomposition of a peroxyaminedisulphonate in hot alkaline solution are easy to recognise. Unless very dilute, the solution yields crystals on cooling and more on evaporation. At first the sparingly soluble hydroxylaminetrisulphonate alone crystallises, and later on both this and the equally sparingly soluble hydroxylaminedisulphonate. In each case the crystals are characteristic and easily distinguished. The presence of the disulphonate in the solution is quickly and distinctively indicated, as has just been mentioned, by warming with a small quantity of lead peroxide, which gives it again the bluish-violet colour of peroxyamine-sulphonate. By removing sulphate and hydroxylaminedisulphonate from the solution by barium hydroxide, nearly all the hydroxylaminetrisulphonate can be crystallised out; the mother liquor containing the nitrite may then be tested in any of the usual ways for this salt.

It was important to know whether any nitrate is formed by the decomposition, and therefore necessary first to get rid of all the nitrite present by a process that does not convert any of it into nitrate. The nitrite was accordingly changed into aminetrisulphonate (nitrilosulphate) by adding enough potassium carbonate and then passing in sulphur dioxide until the solution became acid, at which point the aminetrisulphonate that had been produced at once hydrolysed (Trans., 1892, 61, 954). Lastly, by blowing in air until all the remaining sulphur dioxide had been expelled, the acid solution was left free from either nitrite or sulphite, and, therefore, ready for testing for nitrate. None of this salt was found. The application of the

process of sulphonating the nitrite to the determination of total nitrogen in solution, is described on p. 104.

The testing for aminemonosulphonate (aminosulphate) among the products of decomposition of a peroxyaminesulphonate is not an easy matter. The method adopted was to oxidise all the hydroxylaminedisulphonate by boiling the solution with lead peroxide until it was again colourless. The nitrite was then oxidised by pouring the solution into potassium permanganate solution to which sulphuric acid had been added. Mercuric nitrate solution then precipitated from it a little oxymereuric aminemonosulphonate (*Trans.*, 1896, 69, 1649), which, when treated with hydrogen sulphide, left the acid again in solution. By evaporation and addition of strong sulphuric acid, the acid was obtained in characteristic crystals (*loc. cit.*, 1642), which were sometimes weighed.

The quantitative examination of the solution is a troublesome and less satisfactory operation. The peroxyaminesulphonate can hardly be obtained for weighing in the dry and pure state, because of its instability. Therefore, after its composition had been found, from concordant analyses of four different preparations, to be that ascertained by previous workers, the preparation of the solution and its analysis after the salt had all decomposed were carried out in the following way. The peroxyaminesulphonate, recrystallised two or three times from hot water made alkaline with potassium hydroxide, was drained for a short time on a tile from its mother liquor, and at once dissolved in suitable quantity in water to which had been added a measured quantity of potassium hydroxide. The solution was maintained at the boiling temperature until colourless through the complete decomposition of the salt. The cold solution was then weighed off into four portions: one of 5 per cent. of the whole, for estimating the amount of peroxyaminesulphonate that had been dissolved; another of 15 per cent., for estimating the quantity of hydroxylaminetrisulphonate produced; a third and a fourth portion, each of 40 per cent., for estimating in one the quantity of sulphate, and in the other that of nitrite produced. The quantity of peroxyaminesulphonate taken was determined by weighing as barium sulphate the total sulphur in the solution. To ensure the hydrolysis of all the sulphonate, the solution was heated with hydrochloric acid in sealed tubes for 4—5 hours at 180—200°.

To determine the quantity of sulphate which had been produced, very dilute hydrochloric acid was added with constant stirring until the solution was only barely alkaline to phenolphthalein, then much ammonium chloride was added before precipitating with barium chloride, in order to keep the hydroxylaminedisulphonate in solution as far as possible. The impure sulphate, washed with ammonium

chloride solution on the filter, was transferred to a beaker, and digested in the cold with very dilute hydrochloric acid, washed again on the filter with boiling water, and then ignited in the usual way.

The hydroxylaminetrisulphonate was estimated by leaving the solution with sodium amalgam for two days, occasionally shaking the two together so as to convert this salt into hydroxylaminedisulphonate, and then all the hydroxylaminedisulphonate in the solution into aminedisulphonate (iminosulphate). The mercury having been filtered off and washed, hydrochloric acid was added to the solution until it was only just alkaline to methyl-orange, and then an excess of ammonium chloride was introduced. The sulphate was finally precipitated and treated as before described. Deducting from this quantity of sulphate that which was present before the treatment with sodium amalgam, there remained the sulphate equivalent to one-third of the sulphur of the hydroxylaminetrisulphonate, from which the quantity of this salt was calculated. Assuming hydroxylaminedisulphonate to be the only other sulphur compound produced in the decomposition of the peroxyaminesulphonate—an assumption which is nearly exact—the amount of this salt was then calculated as being equivalent to the sulphur not found either as sulphate or hydroxylaminetrisulphonate. The slight error in this assumption is caused by the production of very small quantities of aminemonosulphonate (aminosulphate). As to the last-named salt, it has not been possible to do more than ascertain that its quantity is usually quite small, although 2 mol. of the crystalline acid (p. 103) per 100 mol. of hydroxylaminedisulphonate oxidised by the lead peroxide were once actually obtained. In other words, the amount of sulphur found as aminemonosulphonate was in this instance 1.03 per cent. of that of the hydroxylaminedisulphonate used.

To determine the total nitrogen in the solution, the nitrite was completely sulphonated to aminetrisulphonate (nitrilosulphate) by adding enough potassium carbonate for the purpose and then passing in sulphur dioxide until a piece of lacmoid-paper was just reddened (Trans., 1892, 61, 954). Next, the hydroxylaminetrisulphonate in the solution was reduced by sodium amalgam, as above described, to sulphate and aminedisulphonate. Having thus brought all the nitrogen into aminesulphonates, the hydrolysis of these substances by hydrochloric acid was effected by heating, first, on the water-bath until all the sulphur dioxide had been expelled, and then for some hours in a pressure-tube at 150°. The solution distilled with alkali gave up all its nitrogen as ammonia. The difference between this and that originally present as peroxyaminesulphonate gives, indirectly, the quantity of nitrogen in the gases, whilst the difference, again, between the total nitrogen in the solution

and the sum of the quantities found as disulphonate and trisulphonate is the nitrogen which was present as nitrite.

Although the experimental work in estimating sulphate and hydroxylaminetrisulphonate was performed with great care, no high degree of accuracy in the results could be expected. A test experiment was made to see to what extent the method was imperfect. A solution was prepared by dissolving potassium sulphate, potassium hydroxylaminetrisulphonate, potassium hydroxylaminedisulphonate, and sodium nitrite in water to every 100 c.c. of which 5 c.c. of *N*/10 solution of potassium hydroxide had been added. The solution was twice analysed for sulphate and trisulphonate in the way described above. The quantities, taken and found, are here given in grams per 100 c.c.

	Taken.	Found.	
Trisulphonate.....	2.580	2.547	2.624
Sulphate .....	0.347	0.380	0.373
Disulphonate .....	0.622	0.629	0.551
Nitrite .....	0.208	0.212	0.217

From this experiment, it seems that the sulphate may come out nearly 10 per cent. too high, no doubt for two reasons; one that being precipitated in the cold, the barium sulphate retained other salts with it; the other and principal reason being that, in the process of neutralising the solution, some of the disulphonate must be decomposed, yielding sulphate. The numbers for the trisulphonate are much more satisfactory, being less than 1.7 per cent. too high, apparently because they represent the difference between two sulphate determinations, the error in the one counterbalancing the corresponding error in the other. When, however, we come to the numbers for the disulphonate, which are calculated from those for the other substances, it is seen how large the error may become, being in one case as much as 11.4 per cent. too low. Similarly, the quantity of nitrite, calculated from those of the other substances, may come out as much as 4.5 per cent. too high. The expression of the errors as percentages only holds good, of course, where the salts in an actual experiment are nearly in the same proportions as here taken, as they were generally found to be.

The quantities of nitrite and of gases yielded by the peroxyamine-sulphonate may also be each determined directly. The nitrite may be estimated by the urea method, as stated on p. 94, most of the sulphonate salts having first been crystallised out and washed with alcohol. The method for collecting and measuring the gases produced during the decomposition consists in letting this proceed in a closed vessel from which the air is withdrawn. A stout-walled, cylindrical bolt-head, of about 250 c.c. capacity, with a stopcock sealed on to it, was exhausted

and then opened with its mouth in the solution of peroxyamine-sulphonate and potassium hydroxide. About 200 c.c. were allowed to enter, holding between 6 and 7 grams of the salt in solution. The tube was again exhausted and the stopcock being then closed, the salt was decomposed by heating the solution. When cold, the apparatus was connected with a Sprengel pump and the gases drawn off and measured. They proved to be free from nitric oxide, but, on treatment with strong alcohol, a small proportion of nitrogen remained undissolved. The experiments on this method of determining the gases have been very few, and not such as have admitted of their utilisation in this paper, beyond giving proof that nitrogen in small quantity is generated along with the nitrous oxide, which is the main constituent of the gaseous mixture, and that the quantity of the gases may vary greatly in different experiments.

Where the decomposition of the peroxyaminesulphonate proceeds in the presence of lead peroxide, as it is made to do in the preparation of hydroxylaminetrisulphonate, no hydroxylaminedisulphonate can remain in the solution, and in place of it is found principally an increase in the quantities of trisulphonate and nitrite. The absence of the disulphonate simplifies the analysis, as is seen on p. 94.

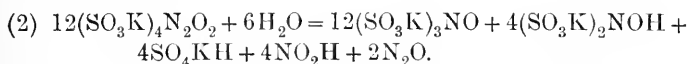

Eight analyses of the products of the spontaneous decomposition of the peroxyaminesulphonate were made. In Expt. 1, a solution holding 2.3184 grams of potassium peroxyaminesulphonate and 60 c.c. of *N*/10 solution of potassium hydroxide was made up to 150 c.c. and then found to weigh 150.79 grams. It was slowly heated to the boiling point, and kept boiling till decolorised. Expt. 2.—The solution, weighing 234.3 grams and containing 2.547 grams of the salt and 72.3 c.c. of *N*/10 potassium hydroxide, was left in the cold for two days, and then boiled until colourless. During the boiling, a reflux condenser was used to retain the water in the solution. Expt. 3.—A solution, weighing 120.42 grams and measuring 120 c.c. of 1.22 grams of salt and 11.4 c.c. of *N*/10 potassium hydroxide, was decomposed by boiling. Expt. 4.—The solution weighed 134.9 grams, and contained 1.8576 grams of salt and 30 c.c. of *N*/10 potassium hydroxide; it was decomposed by boiling. Expt. 5.—A solution of 0.6601 gram of salt and 20 c.c. of *N*/10 potassium hydroxide, weighing 34.25 grams, was left in the cold for a week, when it had become colourless. Expt. 6.—Like the last, but the solution weighed 266.7 grams and the salt 5.27 grams, whilst the potassium hydroxide was taken in about the same proportion as before. Expt. 7.—The solution was a portion of the same as had been used for Expt. 2. When kept in a closely-stoppered flask, it had only lost all its colour after about five months. Expt. 8.—This experiment differed from the others in the use of baryta-water in place of potassium hydroxide, and to this must be

attributed the production of so much sulphate and hydroxylamine-disulphonate. The solution took a month to lose all its colour.

In the table, the numbers of molecules of the several products yielded by  $100(\text{SO}_3\text{K})_4\text{N}_2\text{O}_2$  are given according to calculation from the analyses made in the way above described, and without any corrections for the probable, but variable, errors inherent in the method.

Mol. weight.	1.	2.	3.	4.	5.	6.	7.	8.
$(\text{SO}_3\text{K})_3\text{NO}$ .....	85	102.3	101.7	77.7	91.4	85.3	86	12.9
$(\text{SO}_3\text{K})_2\text{NOH}$ .....	61	30	23.6	65.4	42.3	42	40.4	133.2
$\text{SO}_4\text{KH}$ .....	23	33	47.6	36	41.2	60	61.2	94.7
$\text{HNO}_2$ .....	49	26	32.5	50.2	35	37	26.4	—

Without further experiments, it does not seem possible to account for the wide variations in these numbers, except where baryta was used. From Expts. 2 and 7, started on portions of the same solution, it seems clear that, with the slow decomposition of the peroxyaminesulphonate which goes on in the cold, instead of the rapid change which occurs at a boiling heat, molecular quantities of hydroxylaminedisulphonate and sulphate take the place of some of the hydroxylaminetrisulphonate, and that a little of the hydroxylamine-disulphonate is replaced by its equivalent of sulphate and nitrous oxide. This becomes more obvious when equations in these two cases are given with only 12 molecules instead of 100 molecules of decomposing peroxyaminesulphonate. This is possible without deviating from the numbers found more than the imperfections of the analytical method allow.

The production of small quantities of nitrogen and aminemonosulphonate is of necessity ignored in the above calculations.

The author gratefully acknowledges his indebtedness to Dr. Divers, F.R.S., for a thorough revision of his manuscript.

XI.—*Peroxyaminesulphonic Acid.*

By EDWARD DIVERS.

ALTHOUGH unrecorded in works on chemistry or chemical technology, it has long been known to inspectors and workers of the lead-chamber process for manufacturing sulphuric acid, that when, through improper working of the chambers, sulphur dioxide is allowed to pass into the Gay-Lussac tower, it produces with the nitrososulphuric acid, also present in the tower, what is called "purple acid," together with an effervescence due to the escape of nitric oxide (Carpenter and Linder, *J. Soc. Chem. Ind.*, 1902, 21, 1492). Sabatier has shown (*Compt. rend.*, 1896, 122, 1417, 1479, and 1537; 123, 255) how to give an intensely bluish-violet colour, evidently the same as that of "purple acid," to the monohydrate of sulphuric acid holding nitroso-sulphuric acid in solution, either by passing sulphur dioxide into it, or by mixing it with sulphuric acid of similar strength containing dissolved sulphur dioxide. Such a sulphuric acid solution of sulphur dioxide may also be treated for some time with a current of nitric oxide and air; or, excluding air, the nitric oxide alone will produce the colour, when a very small quantity of either copper sulphate or ferric or ferrous sulphate has been previously dissolved in the acid. Lastly, certain metals and other substances serve to produce this colour, or a modification of it, by acting on nitrososulphuric acid in monohydrated sulphuric acid, among them being finely divided copper, silver, or mercury. Sabatier has not isolated the substance which gives this violet colour to sulphuric acid treated by the foregoing processes, but has suggested that it may be the unknown acid of Fremy's *sulphazilate*, which he renames *nitrosodisulphonic acid*.

Now, in the preceding paper on peroxyaminesulphonates, Haga has adduced reasons for doubting the correctness of Sabatier's suggestion that the bluish-violet acid is sulphazilic acid, that is, peroxyamine-sulphonic acid. There is also one consideration which, although not mentioned by Haga, may, nevertheless, have affected his judgment. This is the fact that a substance which, according to Haga's most conclusive evidence, must be a peroxide, should be produced in the ways described by Sabatier. But this difficulty and those raised by Haga all seem to disappear when the changes which give rise to the acid and the very different conditions for the production of the salt and of the acid are all more closely examined, and leave nothing in the way of accepting the view that this acid is peroxyaminesulphonic acid.

The fact that the violet acid is dissolved in sulphuric acid, whereas the violet salt is in aqueous solution, has to be taken into account

when the differences in the behaviour of the two are under consideration. It will then be seen that these differences are really not greater than those between a sulphuric acid solution of nitrous acid (as nitroso-sulphuric acid) and an aqueous solution of potassium nitrite. The latter when acidified and the former when diluted both quickly lose most of the nitrous acid, there being no stable existence of this acid in the intermediate conditions. Potassium nitrite solution is unaffected by hydrogen peroxide or potassium permanganate, being, in fact, producible from nitric oxide by alkaline hydrogen peroxide (Carpenter and Linder, *loc. cit.*), and from hyponitrite by permanganate (Thum, *Monatsh.*, 1893, 14, 294), whereas nitrous acid is converted by these reagents into nitric acid. Lead peroxide may therefore very well be active towards a sulphuric acid solution of peroxyamine-sulphonic acid, although it does not interact with an aqueous solution of its salts. Again, that sulphur dioxide should not interact with peroxyaminesulphonic acid in presence of much sulphuric acid, and yet be very active towards a salt of the acid in water, may well be an instance of what indeed happens in the case of mercuric oxy-salts, on which, in presence of much sulphuric acid, sulphur dioxide is no longer active (Trans., 1886, 49, 576), or in that of ferric salts, which are very much more easily reduced by sulphur dioxide in the absence of sulphuric acid than in the presence of excess of it. Similarly, it may further be properly maintained that it does not follow that hydroxylaminetrisulphonic acid should be produced from peroxyamine-sulphonic acid in sulphuric acid solution because its salt is produced in a neutral or an alkaline aqueous solution of a peroxyamine-sulphonate. This contention being admitted, the non-formation of this acid, observed by Haga, is not significant.

Since the well-known compound, nitrososulphuric acid, is not a sulphonic derivative, as Sabatier takes it to be, but the mixed anhydride of nitrous and sulphuric acids, the nature of its conversion into the violet acid is easy to understand. Regarding the mixed anhydride as being simply nitrous anhydride (the sulphuric acid being undecomposed), the production from it of nitric oxide and peroxyaminesulphonic acid is seen to be only its usual decomposition into nitric oxide and nitric peroxide, except that the latter product is now sulphonated :

When metallic copper is used in place of sulphur dioxide, the generation of the necessary sulphur dioxide by the action of the metal on the pyrosulphuric acid of the nitrososulphuric acid only introduces an interesting complication. Pyrosulphuric acid at once interacts with copper in the cold (Trans., 1885, 47, 638).

There remains to be considered the production of the purple acid along with nitrososulphuric acid from nitric oxide and sulphuric acid in the presence of cupric or ferric sulphate as a catalytic agent. The sulphuric acid being represented as existing in its pyro-state (the form in which it acts in presence of an oxide of nitrogen), the change is expressed by the equation:

As to the peroxidising action of pyrosulphuric acid here shown, it may be well to recall the action of the acid on metallic tin in presence of hydrochloric acid (Heumann and Koechlin, *Ber.*, 1882, 15, 420):

In this equation the stannic chloride and the sulphur dioxide together take the place of the peroxyaminesulphonic acid in the previous one, for  $[\text{ON}(\text{SO}_3\text{H})_2]_2$  can evidently be expanded into  $\text{N}_2\text{O}_4 + 4\text{SO}_2 + 2\text{OH}_2$ .

It is difficult to conceive of any other rational interpretations of Sabatier's remarkable results than those given above, and these are all consistent with the assumption that the purple acid is not merely isomeric, but actually identical with peroxyaminesulphonic acid, and is therefore a peroximide and an exclusively trivalent nitrogen compound.

## XII.—*Constitution of Nitric Peroxide.*

By EDWARD DIVERS.

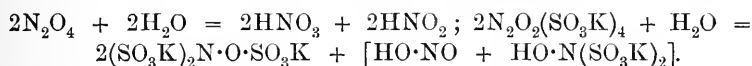

IN a paper now appearing (this vol., p. 78), Haga has demonstrated that Fremy's *sulphazilate* is an oxime-peroxide and a trivalent nitrogen compound. If Hantzsch and Semple's suggestion is accepted (*Ber.*, 1895, 28, 2744; compare Piloty and Schwerin, *Ber.*, 1901, 34, 1884 and 2354), that Fremy's salt is also a sulphonated nitric peroxide, it follows that the constitution of nitric peroxide is at last determined, being that of *nitrosyl peroxide*. Hantzsch and Semple must be right, for, after Haga's researches, a sulphazilate as a peroxyaminesulphonate cannot be supposed to be other than a sulphonated nitric peroxide. It only remains, therefore, to show that nitric peroxide is a true peroxide in its chemical relations.

It is formed from nitric oxide and oxygen, just as sodium peroxide is formed from sodium and oxygen. Nitrous acid cannot, indeed, be shown to pass simply into it and back again, as a hydroxylamine-

disulphonate (sulphonated nitrous acid) changes into a peroxyamine-sulphonate, but that is only on account of its own instability and that of nitrous acid.

Its interaction with organic oximes, in which it converts these substances into peroxides and becomes hydrogenised into nitrous acid (Scholl), is in accordance with its nature as a true peroxide. Similarly, it converts a hydroxylaminedisulphonate into a peroxyaminesulphonate (Haga).

Nitrosyl peroxide and a peroxyaminesulphonate both interact with water in essentially the same way, the apparent difference being due to the limits imposed by the sulphonation in the case of the latter substance. The former yields half its nitrogen as nitric acid and half as nitrous acid, whilst the latter yields half its nitrogen as a mixed anhydrosulphate (hydroxylaminetrisulphonate) and the other half as nitrous acid and sulphonated nitrous acid (hydroxylaminedisulphonate):

It would seem, therefore, that, wholly on the evidence afforded by Haga's work, it can now be confidently asserted that dinitric peroxide is nitrosyl peroxide and a compound of exclusively trivalent nitrogen. The constitution of mono-nitric peroxide, in regard to these two points, remains to be considered, but can hardly be very different.

Hantzsch and Semple have suggested (*loc. cit.*) that the bluish-violet dissolved form of a peroxyaminesulphonate corresponds with mono-nitric peroxide, and its crystalline form with di-nitric peroxide. Since then, Piloty and Schwerin (*loc. cit.*) have expressed the belief that *porphyrexide*, which has the colour of mono-nitric peroxide, may also be a derivative of this peroxide, because it contains the group :NO singly, as shown by the formula  $(\text{C}_5\text{H}_9\text{N}_3):\text{NO}$ . Its molecular weight, however, has been only indirectly ascertained, that is, by cryoscopic determinations of those of its nitrate and its chloro-derivatives. That its molecular weight is not double as great is a remarkable fact, for, in its chemical behaviour, and especially in its reversible relation with *porphyrexine*,  $(\text{C}_5\text{H}_9\text{N}_3):\text{NOH}$ , porphyrexide seems to belong to the class of oxime-peroxides. Piloty and Schwerin do not indeed recognise this, and have instead come to the conclusion that the nitrogen of the group :NO in porphyrexide and in mono-nitric peroxide must be quadrivalent. In the light of Haga's experimental results, this view of the matter has become untenable, since porphyrexide and the peroxyaminesulphonates appear to belong to the same class of nitroxy-compounds, as Piloty and Schwerin themselves have pointed out.

In the few cases in which it has been possible to determine

cryoscopically the molecular weight of a glyoxime-peroxide, this has been found to include :NO twice. This result may be owing to the glyoxime constitution of these peroxides, but, even so, there is still no peroxide, except mono-nitric peroxide, and possibly porphyrexide, the molecular weight of which is such that it contains the group :NO only once. The occurrence of many nitroso-compounds in a colourless, solid form, and in a bluish-violet liquid form, does not lend much assistance in deciding the molecular weights of the two forms of a peroxyaminesulphonate, since they contain not :NO but ·NO. But it must not be left out of sight that Piloty (who thinks otherwise, and has been followed by Schmidt, Bamberger, and others) has succeeded in showing that the white form of these compounds contains the group ·NO twice, and that the deeply-coloured modification contains it only once. But here the latter is the form which must be treated as the chemically active one, whilst the double weight found for the white form has to be left uninterpreted chemically, as, for example, in the case of the formula  $(C_8H_{17}NO)_2$  for nitroso-octane.

In the paper by Hantzsch and Semple (*loc. cit.*), there occurs, but in a foot-note only and without comment or explanation, the punctuated formula  $O:N:(SO_3K)_2$ ; whether this is to be regarded as a printer's error for  $O:N:(SO_3K)_2$  is uncertain, but if it is not, it indicates some recognition by these chemists of the presence of univalent oxygen. However this may be, the possibility of the nitrogen being quadri-valent being inadmissible, the only solution of the matter seems to be to consider that both mono-nitric peroxide and porphyrexide are compounds of univalent oxygen, although still peroxides. The fact that a molecular quantity, such as that formulated by  $HO, NO_2, (SO_3K)_2NO$ , or  $(C_5H_9N_2)NO$ , is never met with singly in chemical interactions militates against the acceptance of this explanation. Piloty and Schwerin, in discussing the quadrivalency of nitrogen, conceal this fact by stating that porphyrexide is produced from porphyrexine by the action of *half an atom* of oxygen. It is much more correct to hold with Haga that the molecule of peroxyaminesulphonate, and therefore also of mono-nitric peroxide and of porphyrexide, is not less than that represented by  $[NO(SO_3K)_2]_2, (NO_2)_2$ , or  $(C_5H_9ON_4)_2$ , as the case may be, if by molecule is meant the smallest chemically active weight of a substance. But still the fact remains that, when measured by comparison of their physical properties, the molecular weights of porphyrexide and red nitric peroxide are expressed by half the above formulæ, and that probably the bluish-violet form of a peroxyaminesulphonate has also a molecular weight, which, when physically considered, should be expressed by the formula  $NO(SO_3K)_2$ . These weights, only physically determined, have no chemical significance, and should be distinguished from their doubles, the truly chemical molecular weights. But, as

pseudo-chemical molecules, they must be represented as containing a univalent atom of oxygen.

It is, after all, not so difficult to admit that oxygen may be univalent in a peroxide. In fact, a true peroxide may be defined and differentiated from other oxides, as being a compound in which some or all of the oxygen is exerting on the rest of the compound only half its usual valency. Or, conversely, a peroxide may be defined as a compound containing oxygen which is either actually univalent or exterior and quasi-univalent. Apart from the unfamiliar nature of the conception of actually univalent oxygen, it seems natural enough to find a normal molecule of nitric peroxide dissociate at a gentle heat into two identical but simpler ones, in consequence of the linked oxygen atoms becoming parted and losing valency. On the other hand, the assumption that nitrogen is quadrivalent does not accord with the result actually obtained, when by cooling nitric peroxide it is found that the valency of the nitrogen decreases instead of increasing,  $2\text{O}:\text{N}:\text{O}$  becoming  $\text{O}:\text{N}\cdot\text{O}\cdot\text{O}:\text{N}:\text{O}$ .

---

### XIII.—*The Solubility Curves of the Hydrates of Nickel Sulphate.*

By BERTRAM DILLON STEELE, D.Sc., and F. M. G. JOHNSON.

THE experiments recorded in this paper were undertaken with the object of determining the conditions of equilibrium and the composition of the phases in the two component system, nickel sulphate—water.

Hydrates of nickel sulphate have been described containing 1, 2, 6, and 7 molecules of water. The heptahydrate, which is found in nature as the mineral moresonite, may be obtained by crystallisation at the ordinary temperature from neutral solutions of the salt. It occurs in the form of pale green, rhombic crystals isomorphous with heptahydrated magnesium sulphate, and on prolonged exposure to the atmosphere becomes changed into aggregates of blue crystals having the composition  $\text{NiSO}_4\cdot 6\text{H}_2\text{O}$ . This change has, for a long time, been regarded as being brought about by the action of sunlight (Phillips and Cooper, *Poggendorff's Annalen*, 1879, 6, 194), but Dobrosserdoff (*J. Russ. Phys. Chem. Soc.*, 1900, 32, 300) has recently shown that this is not the case, since sunlight has no effect on the heptahydrate, provided that the crystals are contained in a space saturated with water vapour and maintained at a low temperature; accordingly the

reaction in question is a simple case of efflorescence. The same hexahydrate was obtained by Brooke and Phillips (*loc. cit.*) and by Pierre (*Ann. Chim. Phys.*, 1846, [iii], 16, 252) in the form of blue, tetragonal crystals by crystallisation at the ordinary temperature from a solution containing sulphuric acid, and by Marignac and Mitscherlich from neutral solutions at about 40°.

Isothermal crystallisation of neutral solutions at temperatures between 60° and 70° yields a bright green, monoclinic salt which also contains 6 molecules of water.

The dihydrate is described by Étard (*Compt. rend.*, 1878, 87, 602) as being formed by the action of strong sulphuric acid on the hexa- or hepta-hydrates, and Lescœur (*Chem. Centr.*, 1895, i, 525) states that by adding concentrated sulphuric acid to a solution of nickel sulphate, a precipitate of the monohydrate is obtained.

The study of the solubility curves of nickel sulphate between -5° and 100° has not indicated the existence of any hydrate containing less than 6 molecules of water of crystallisation. Solubility determinations have not been made at temperatures above 100°, but from the curves of Étard and Engel (*Compt. rend.*, 1888, 106, 206) there appears to be a transition point at about 118°, and on analysing the solid phase separating at 131°, we found it to be the dihydrate,  $\text{NiSO}_4 \cdot 2\text{H}_2\text{O}$ .

The solubility of nickel sulphate has been determined at various temperatures by Tübler (*Annalen*, 1855, 95, 193). His results, however, differ considerably from ours, and are not sufficiently numerous to indicate the position of the various transition points.

#### *Preparation of the Hydrates.*

The heptahydrate was prepared by twice recrystallising the ordinary salt and shown to be pure by analysis. The salt used in estimating the solubilities at a few temperatures was prepared by precipitating a saturated aqueous solution with alcohol, and was thus obtained in the form of very small, green, granular crystals containing 21.12 per cent. of nickel, the calculated value being 20.91.

The foregoing salt, when left in contact with its saturated solution for some hours at any temperature between 32° and 53°, is converted into the blue hexahydrate, which was analysed with the following result: Found Ni = (1) 22.54; (2) 22.41.

$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  requires Ni = 22.23 per cent.

The blue hexahydrate, employed in the experiments made between 32° and 53°, was prepared by the slow evaporation at the ordinary temperature of solutions containing 30 per cent. of sulphuric acid.

The large crystals thus obtained were powdered and thoroughly washed with a saturated solution of nickel sulphate in order to remove sulphuric acid.

If the heptahydrate or the blue hexahydrate is left in contact with the saturated solution at temperature above  $54^{\circ}$ , it very rapidly becomes converted into the bright green, monoclinic salt which, on analysis, was found to have the same composition as the blue tetragonal hydrate.

Found, Ni = (1) 22.55 ; (2) 22.50.

$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  requires Ni = 22.23 per cent.

In order to determine the composition of the solid phase, which is present at temperatures above  $118^{\circ}$ , a quantity of the dry hexahydrate was sealed up in a thick walled glass tube and heated for some hours at  $131^{\circ}$ . A little below this temperature, the substance partially melted with the formation of a clear green solution and a dull yellowish-green, amorphous solid, for the separation of which the following method was adopted. The tube containing the mixture was carefully inverted, so that the greater part of the liquid drained away from the powder. After cooling in this position, it was cut into two parts, and the solid, placed on pieces of porous tile, was sealed up in another tube and again heated at  $131^{\circ}$ . The adherent liquid portion, which had solidified on cooling, again liquefied and was absorbed by the porous tile, leaving the new salt practically dry and pure, as indicated by the following analysis :

Found, Ni = (1) 30.8 ; (2) 30.87.

$\text{NiSO}_4 \cdot 2\text{H}_2\text{O}$  requires Ni = 30.87 per cent.

#### *Solubility Determinations.*

The solubilities were determined by enclosing the salt, with the requisite amount of distilled water, in tubes provided with well-fitting india-rubber stoppers. The tubes were attached to a shaking apparatus driven by a Henrici hot-air motor, and immersed in a thermostat provided with a toluene gas regulator, by means of which the temperature could be kept constant to a tenth of a degree. Preliminary experiments having shown that equilibrium was reached in about 12 hours, the tubes were shaken for twice that time to ensure saturation.

The solutions were filtered within the thermostat in the following manner. The india-rubber stopper in the solubility tube contained a hole, which was closed with a glass rod during the shaking. When it was desired to filter the solution, the rod was withdrawn, and in its place was inserted a piece of glass tubing with a small bulb blown in

the centre, this bulb being packed with asbestos to serve as a filter. The other end of the tube passed through an india-rubber stopper, which fitted into a weighing bottle, and through which passed a glass tube long enough to reach out of the thermostat. The solubility tube was thus attached to a weighing bottle by a filtering tube, and by inverting the two and applying suction to the projecting tube, the solution was filtered without having been for an instant removed from the bath. The filtrate in the weighing bottle was weighed and diluted to 500 c.c., a convenient portion of this solution being taken for analysis.

The nickel was estimated electrolytically, using a current density of 0.5 ampere, 8 to 10 hours being required for the electrolysis, which was carried out in a solution containing ammonium sulphate and excess of ammonia.

All the solubility results (with the exception of those at  $0^{\circ}$  and  $-5^{\circ}$ ) are the mean values of at least two closely concordant determinations carried out in different vessels.

Of the experiments recorded in Table I, the first was carried out in

TABLE I.\*

(1) The solubility curve of  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ .

Salt used.	Temperature.	Concentration.	Salt remaining.

\* In this and the other tables in the paper, concentrations are expressed as parts by weight dissolved in 100 grams of water.

a bath of brine surrounded by a mixture of powdered ice and salt, and maintained at a constant temperature by allowing a very slow current of warm brine to circulate through the bath. The second experiment was carried out in a bath of melting ice. For temperatures

below  $30^{\circ}$ , the heptahydrate only was used in determining the solubilities. For temperatures between  $30^{\circ}$  and  $34^{\circ}$ , a number of experiments were made, using both the heptahydrate and the blue hexahydrate in the hope that a portion of each curve extending beyond the transition point might be realised. This has been done for the heptahydrate, the metastable portion of the curve being represented by experiments 9, 11, and 14, in Table I, which give solubilities of the heptahydrate at temperatures close to the point of transition of this hydrate into the hexahydrate.

In experiment 8, in which the solid phase was originally the blue hexahydrate, transformation rapidly took place into the green heptahydrate, and although many attempts were made, it was not found possible to obtain the metastable portion of the curve for the hexahydrate.

In the accompanying diagram (p. 118), the experiments from this table are represented by the curve ABC.

TABLE II.

Solubility curve of  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (blue tetragonal).

Salt used.	Temperature.	Concentration.	Salt remaining.
$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)	$32.3^{\circ}$	43.57	$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)
"	$33.0$	43.35	—
$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$	$34.0$	43.84	—
"	$35.6$	43.79	—
$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$	$44.7$	48.05	—
$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$	$44.7$	47.97	—
$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)	$50.0$	50.15	—
—	$51.0$	50.66	—
—	$52.0$	52.34	—
—	$53.0$	52.34	—
—	$54.5$	52.5	$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (green)

On plotting the results collected in Tables I and II, the two curves are found to intersect between  $31^{\circ}$  and  $32^{\circ}$ . The transition point corresponding with the change  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O} \rightleftharpoons \text{NiSO}_4 \cdot 6\text{H}_2\text{O} + \text{saturated solution}$  therefore lies very near to  $31.5^{\circ}$ . In order to confirm this point and in the hope of determining it with greater accuracy, experiments were carried out with a dilatometer, which assumed the usual form of a large thermometer with a graduated stem partially filled with a mixture of the heptahydrate, the blue tetragonal hexahydrate, and a certain amount of *m*-xylene. The vessel, being exhausted to remove air bubbles from the salt, was then filled to the

required position with more of the hydrocarbon and placed in a bath at  $30^{\circ}$ . The temperature was now allowed to rise very slowly; a steady increase of volume occurred up to  $31.4^{\circ}$ , when there was a sudden break followed by a much smaller increase as the temperature was raised still further. The transition point may therefore be taken as lying between  $31.4^{\circ}$  and  $31.6^{\circ}$ .

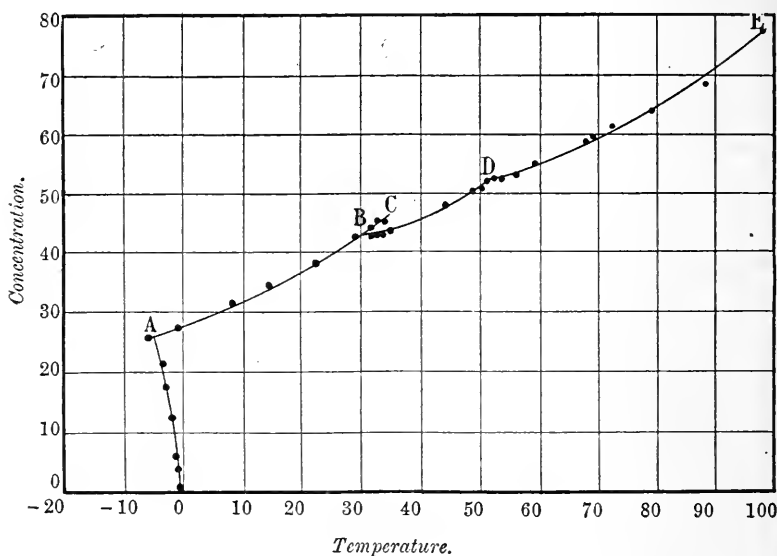

TABLE III.

Solubility curve of  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (green monoclinic).

Salt used.	Temperature.	Concentration.	Salt used.	Temperature.	Concentration.
$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)	$54.5^{\circ}$	52.50	$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$	$70.0^{\circ}$	59.44
$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ }	$57.0$	53.40	$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)	$73.0$	60.72
$\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (blue)	$60.0$	54.84	$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ }	$80.0$	63.17
$\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$	$69.0$	58.38	"	$89.0$	67.90
"			"	$99.0$	76.71

Throughout the series of determinations indicated in Table III, the remaining salt is the green, monoclinic hexahydrate.

The solubility data obtained in the neighbourhood of  $52^{\circ}$  indicate a

break in the curve, due to a second transition point. This inflexion, which is very slight and might be easily overlooked, is confirmed by the appearance of the residual solid phase after equilibrium is established. If we start with the blue, tetragonal hexahydrate, at temperatures above  $53^{\circ}$  a very rapid change takes place, the blue substance giving place to a bright green solid having the same composition. On the other hand, this green salt is rapidly converted at temperatures slightly below  $53^{\circ}$  into the blue modification, and on plotting, on a large scale, the results given in Tables II and III, the two curves are found to cut each other very close to  $53^{\circ}$ . In order to confirm this conclusion, experiments were made with a dilatometer containing initially the blue hexahydrate mixed with a small quantity of the green salt. No indication of a break could be detected until the mixture was heated for some time at  $70^{\circ}$ , when the salt was seen to have changed into the green modification. The dilatometer was then placed in a bath at  $56^{\circ}$  and allowed to cool slowly, when there was a steady contraction down to  $54.0^{\circ}$ , then little or no contraction until  $53.3^{\circ}$ , and then a steady contraction, but less than the original diminution. A duplicate experiment confirmed this result and also failed to detect any break on slowly raising the temperature from a point below  $53^{\circ}$ . According to this result, the temperature corresponding with the change  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (blue tetragonal)  $\rightleftharpoons$   $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (green monoclinic) lies between  $53.3^{\circ}$  and  $54^{\circ}$ . The solubilities give this temperature as lying near  $53^{\circ}$ , and  $53.3^{\circ}$  is probably not far from the true transition point.

Since the solubility curves of the three salts,  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ ,  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (blue), and  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  (green), lie so nearly in a straight line, it was thought that possibly a break in the curve between  $55^{\circ}$  and  $100^{\circ}$  might have been overlooked.

In order to test this, analyses of the undissolved salt were made at  $60^{\circ}$ ,  $70^{\circ}$ , and  $89^{\circ}$ , and in all cases the salt was found to be the hexahydrate. Moreover, the solid phase at all temperatures between the above limits has the bright green colour characteristic of the monoclinic hexahydrate. In the analysis of the solutions at  $89^{\circ}$  and  $99^{\circ}$ , the saturated solution was separated from the undissolved salt by the method of decantation in a bent tube employed by Étard and Engel (*loc. cit.*).

#### *Ice Curve and Cryohydrate Point.*

The ice curve was determined by measuring the temperature at which ice began to separate from solutions of nickel sulphate of known concentration, the measurements being carried out in a Beckmann freezing point apparatus.

The temperatures and concentrations from which the curve has been plotted are as follows:

Temperature.....	-0.47°	-0.72°	-1.46°	-2.15°	-2.85°
Concentration .....	3.35	5.53	11.97	17.23	21.18

The cryohydrate point was fixed in the following manner. A solution containing about 30 parts of the anhydrous sulphate,  $\text{NiSO}_4$ , to 100 parts of water was placed in the inner tube of the Beckmann apparatus, which was surrounded with a freezing mixture maintained at about  $-5^\circ$ , and the steady temperature at which ice and nickel sulphate separated was found to be  $-4.15^\circ$ .

### *Summary.*

The following is a summary of the results obtained with the system, nickel sulphate—water.

#### *(1) Quadruple Points.*

A. Cryohydrate point of the heptahydrate [ $-4.15^\circ$ ].

B. Transition point: heptahydrate  $\rightleftharpoons$  hexahydrate (blue) + saturated solution [ $31.5^\circ$ ].

D. Transition point: hexahydrate (blue)  $\rightleftharpoons$  hexahydrate (green) [ $53.3^\circ$ ].

Transition point: hexahydrate (green)  $\rightleftharpoons$  dihydrate + saturated solution (not accurately determined).

#### *(2) The Equilibrium Curves.*

The curves OA, ABC, BD, and DE in the diagram correspond with the solid phases: ice; the heptahydrate,  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ ; the blue hexahydrate,  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ ; and the green monoclinic hexahydrate,  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ , respectively.

#### XIV.—*The Relative Strengths of the Alkaline Hydroxides and of Ammonia as Measured by their Action on Cotarnine.*

By JAMES JOHNSTON DOEBBIE, M.A., D.Sc., ALEXANDER LAUDER, B.Sc., and CHARLES KENNETH TINKLER, Research Student of the University of Edinburgh.

IN a paper recently communicated to the Society (Trans., 1903, 83, 598), it was shown that the spectra of cotarnine in ethereal or chloroform solution, of cyanohydrocotarnine and of ethoxyhydrocotarnine are identical or nearly so with those of hydrocotarnine and its salts, whilst the spectra of dilute aqueous or alcoholic solutions are identical with those of the cotarnine salts. From this, it was argued that the substances in the first group are all constituted like hydrocotarnine, those in the second being like the cotarnine salts. This conclusion is supported by the fact that, whilst the substances in the first group are colourless, those in the second are yellow. It was further shown that an ethereal or chloroform solution of cotarnine becomes yellow when treated with alcohol and gives absorption spectra which approach more and more nearly to those of the cotarnine salts as the quantity of alcohol is increased. On the other hand, when an aqueous solution is treated with sodium hydroxide or other soluble base, the reverse change takes place and the yellow colour gradually disappears; the proportion of cotarnine which undergoes this change depending on the amount of basic hydroxide present. It was suggested that a fuller study of these reactions might throw light on the conditions of isomeric and tautomeric changes generally, and that it might be possible to use the action of the bases on cotarnine as a means of comparing their strengths. In the present paper, we propose to give the results of some preliminary experiments on the latter subject.

In our former paper, an account was given of the absorption curves of the two forms of cotarnine (Figs. I and II):

and photographs of the spectra were reproduced in Plates I and II (carbinol and ammonium forms respectively), which accompany the paper. Reference to these photographs will show that the spectra of the two forms are highly characteristic.

The change which cotarnine in aqueous solution undergoes when

acted on by sodium hydroxide depends, as already stated, on the quantity of this reagent present. After the addition of any given quantity of the hydroxide, a state of equilibrium between the two forms of cotarnine is established almost instantaneously and, provided that the temperature is kept constant, no further change takes place, at any rate in moderately dilute solutions, even after a lapse of several hours. Each additional quantity of sodium hydroxide causes a further change until the ammonium form is all converted into the carbinol form. This is practically the case when a milligram-molecule of cotarnine is dissolved in one litre of a normal solution of sodium hydroxide. By photographing the spectra of the solution after each addition of the alkali hydroxide, the change from the one form to the other can be followed through all its phases. Figs. 17—24 of Plate III, accompanying the paper already quoted, show generally how the spectra of the ammonium form change into those of the carbinol form as the quantity of sodium hydroxide is increased. The spectra thus obtained are in fact the spectra of mixtures of the two forms and can all be reproduced exactly by mixing together hydrocotarnine hydrochloride and cotarnine hydrochloride in the proper proportions. By preparing a series of such mixtures containing the two substances in known proportions, it is possible, from a comparison of their spectra with the spectra of an aqueous solution of cotarnine, which has been acted on by sodium hydroxide, to determine the amount of the ammonium form which has been changed into the carbinol form. By using other soluble bases in place of sodium hydroxide, the data are obtained which are required for a comparison of their strengths. As already stated, the action of bases on cotarnine is so rapid that no comparison of their strengths, founded on the amount of change produced by equimolecular quantities in a given time, is possible. Temperature has a considerable influence on the action, and consistent results can only be obtained when the experiments are carried out at the same temperature.\*

It will be seen from the tabulated comparison of the results obtained at 12° and 18° respectively (Table I) that the effect of heating is to diminish the action of the alkalis, a given quantity at the higher temperature producing a smaller effect than the same quantity at the lower temperature. The results are represented graphically in the accompanying curve (p. 123).

\* The results given in our previous paper were obtained at the ordinary temperature, without precautions being taken to ensure that the temperature was always the same. They therefore differ somewhat from those given in the present paper.

CURVE I.

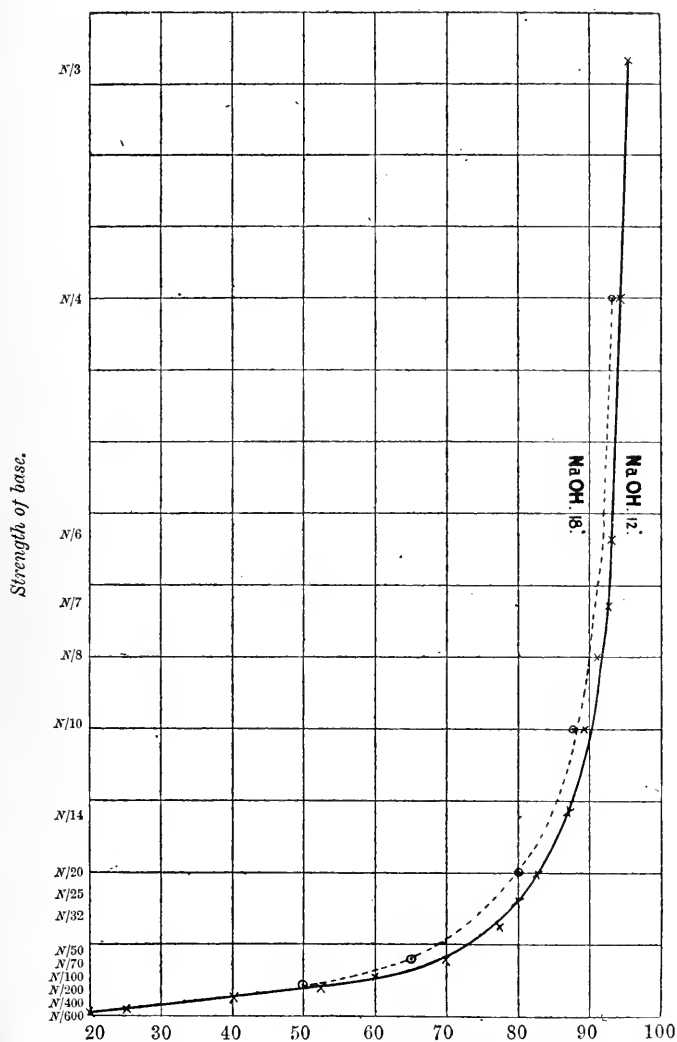

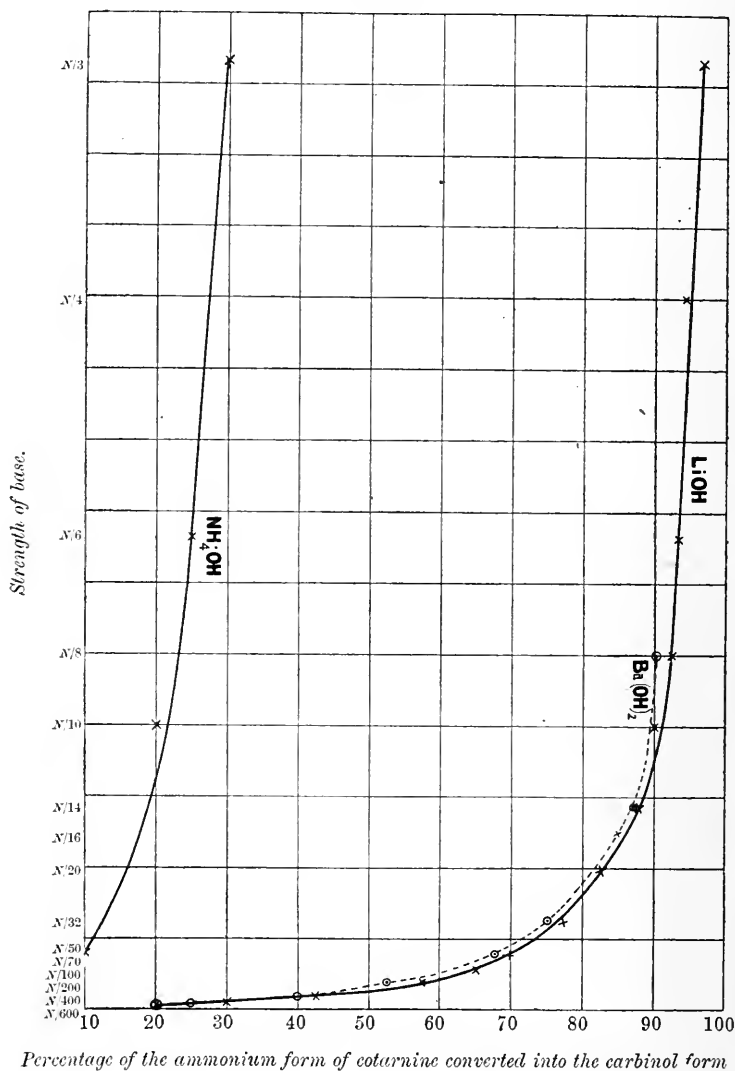

TABLE I.

Strength of sodium hydroxide.	Percentage of carbinol form produced.	
	At 12°.	At 18°.
N/4	94	93
N/10	89	87.5
N/20	82.5	80
N/50	70	65
N/100	52.5	50

In Table II, the results obtained at  $12^\circ$  by the action of equimolecular solutions of the hydroxides of the alkali and alkaline earth metals and ammonia are given, and the results are represented graphically in the accompanying curve. The percentages give the amount of ammonium form which is converted into the carbinol form.

CURVE II.

Percentage of the ammonium form of cotarnine converted into the carbinol form

The hydroxides of lithium, sodium, and potassium give nearly identical curves, showing that, so far as this reaction is concerned, they all have nearly the same strength. It is not possible to get a sufficient quantity of calcium or barium hydroxide into solution in one litre of water to convert a milligram-molecule of cotarnine entirely into the carbinol form, but that portion of the curve which can be drawn for these bases approximates closely to the corresponding portion of the curve for the hydroxides of the alkali metals, the slight difference between the curves indicating that the hydroxides of the alkali metals are the stronger. Some experiments were made with thallium hydroxide, but, as solutions of this substance themselves possess considerable absorptive power, trustworthy results could only be obtained with dilute solutions. These data indicate that thallium hydroxide is a weaker base than the alkali hydroxides, but very much stronger than ammonia. A very concentrated solution of ammonia (more than nine times the strength of a normal solution) is required to convert the ammonium form of cotarnine entirely into the carbinol form. We propose to discuss the case of ammonia more fully in connection with investigations on the alkylated ammonias.

The general result of our experiments is to show that in their action on cotarnine, the bases have the same relative strengths as in other reactions. The curves representing the relation between the amount

of change and the quantity of base producing it are apparently hyperbolic, but we have so far been unable to find an equation for them.

The action of sodium hydroxide on an aqueous solution of cotarnine is capable of explanation in terms of the dissociation theory of electrolytes. Cotarnine in dilute aqueous solution is a strong electrolyte (Hantzsch and Kalb, *Ber.*, 1899, 23, 3109). It may, therefore, be assumed that the solution contains a mixture in equilibrium of the undissociated ammonium form together with the hydroxyl and other ion resulting from its dissociation, with practically none of the carbinol form. By the addition of sodium hydroxide the active mass of the hydroxyl ions is increased and the dissociation of the ammonium form is diminished. The ammonium form then passes into the carbinol form, in which dissociation is at a minimum, until the equilibrium is restored. The further addition of sodium hydroxide leads to a repetition of these changes until, when the solution is normal, the ammonium form is practically all converted into the carbinol form. A very small quantity of sodium hydroxide produces no appreciable effect on an aqueous solution of cotarnine, but we have not found it possible to determine with accuracy the exact point at which the solutions are isohydric.

#### *Experimental Details.*

The determinations of the percentages of the ammonium form of cotarnine converted into the carbinol form, which are given in this paper, were made by comparing photographs of the absorption spectra\* of cotarnine in solution in sodium hydroxide, or other soluble base, with standard photographs of mixtures containing hydrocotarnine hydrochloride and cotarnine hydrochloride in known proportions. In the preparation of the standard series of mixtures used for this purpose, a solution containing 1 milligram-molecule of hydrocotarnine hydrochloride dissolved in one litre of water was taken as the starting point. This was mixed with a solution of cotarnine hydrochloride of the same equivalent strength in the proportions required to give a solution containing 97.5 per cent. of hydrocotarnine hydrochloride and

\* The method of photographing absorption spectra which we employ has already been sufficiently explained in former papers, see especially *Trans.*, 1889, 55, 649, and the papers by Hartley therein cited. The reference lines employed were those given by an alloy of cadmium, tin, and lead. The photographs of the spectra, from which the data discussed in this paper have been derived, have not been reproduced as illustrations on account of the difficulty of obtaining reproductions sufficiently delicate to show the details of the spectra on which their accurate comparison is based. So far as photographs are necessary for the elucidation of the paper, this purpose is served by those already published (Dobbie, Lauder, and Tinkler, *loc. cit.*).

2.5 per cent. of cotarnine hydrochloride. The proportion of cotarnine hydrochloride to hydrocotarnine hydrochloride was increased by 2.5 per cent. at a time until a solution containing 97.5 per cent. of the former and 2.5 per cent. of the latter was reached. The absorption spectra of these mixtures form a graduated series between the spectra characteristic of the two forms of cotarnine. The series of standard photographs having been prepared, it is easy to estimate the amount of change produced in an aqueous solution of cotarnine by any given quantity of a soluble base, by photographing the spectra of the solution and comparing the photographs with those of the reference series. If the photograph to be determined does not coincide exactly with any in the reference series, its position between two successive mixtures can always be found. A number of intermediate mixtures are then photographed until a photograph is obtained which exactly corresponds with the one under examination, the exact composition of the mixture in question being thus determined. In preparing the series of reference photographs, hydrocotarnine hydrochloride was preferred to the cyanohydrocotarnine formerly employed, on account of its greater stability and because of its solubility in water. These two substances have the same spectra.

The spectra of mixtures of hydrocotarnine hydrochloride with cotarnine hydrochloride are identical with those obtained by passing the light through an equal thickness of the two solutions contained in separate cells. Thus the spectrum obtained by passing the light through a 20 mm. layer of a mixture of hydrocotarnine hydrochloride and cotarnine hydrochloride solutions, in equal proportions, is identical with that obtained by passing it in succession through two cells each containing a layer 10 mm. thick of one of the solutions. The same result is obtained by using a 10 mm. cell filled with an aqueous solution of cotarnine and another cell of equal thickness containing a concentrated sodium hydroxide solution of cotarnine. These results were confirmed by numerous experiments, in which layers of various thicknesses were employed. In these experiments, the thickness of quartz employed was the same; when this precaution was not observed, the accuracy of the comparison was interfered with by the slight absorption due to the quartz plates.

We hope to render the foregoing method more accurate by a modification of our apparatus, and by using hydrastinine in place of cotarnine. With cotarnine, it is quite easy, in some parts of the series of mixtures of the two forms, to detect differences of 0.5 per cent. with certainty, but in mixtures containing a large proportion of the ammonium form it is not possible to detect with accuracy, differences of less than 2.5—5.0 per cent. The spectra of the ammonium form hydrastinine are more complicated than those of the corresponding

form of cotarnine, and admit of much smaller differences being readily distinguished.

We have to express our thanks to Professor Crum Brown and to the authorities of the University of Edinburgh for kindly affording us facilities for conducting part of this work in the University laboratory; and to Professor W. N. Hartley for the use of the apparatus with which the experiments were carried out.

XV.—*aa-Dimethylbutane- $\alpha\beta\delta$ -tricarboxylic Acid,  $\gamma$ -Keto- $\beta\beta$ -dimethylpentamethylene- $\alpha$ -carboxylic Acid, and the Synthesis of Inactive  $\alpha$ -Campholactone of Inactive  $\alpha$ -Campholytic Acid and of  $\beta$ -Campholytic Acid (isoLauronic Acid).*

By WILLIAM HENRY PERKIN, jun., and JOCELYN FIELD THORPE.

DURING the course of a long series of researches on the constitution of camphor and its derivatives, attention has been repeatedly directed to the advisability of synthesising the more important substances obtained by the degradation of camphor, in order, thus, to definitely establish their constitution. It has frequently been found that analytical methods have, alone, not been sufficient to prove the constitutions of such degradation products, and in the more difficult cases, as, for example, in the determination of the constitutions of camphoronic and isocamphoronic acids, a definite proof was first obtained by synthetical means (Perkin and Thorpe, *Trans.*, 1897, 71, 1169; 1899, 75, 897; Perkin, *Trans.*, 1902, 81, 246).

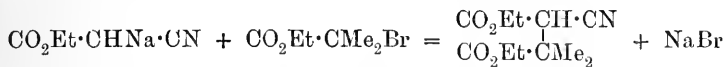

In continuing our experiments in this direction, we have endeavoured to find some means of synthesising, not only open chain acids, such as those mentioned above, but also closed chain compounds more closely allied to camphor and camphoric acid. We hope that it may eventually be found possible to prepare these substances themselves, in quantities sufficient for definite identification, by synthetical means, but the problem is an exceedingly difficult one.\*

In the present paper, we describe a series of reactions which has led

\* This investigation, an abstract of which appeared in the *Proceedings*, 1903, 19, 61, was completed and this paper written before the publication of G. Komppa's complete synthesis of camphoric and dehydrocamphoric acids (*Ber.*, 1903, 36, 4332).

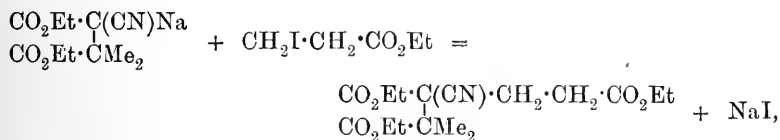

to the synthesis of inactive  $\alpha$ -campholytic acid, and indirectly to that of  $\beta$ -campholytic acid (*isolaunolic acid*).

When ethyl cyanoacetate is digested in alcoholic solution with sodium ethoxide and ethyl bromoisobutyrate, sodium bromide separates and ethyl cyanodimethylsuccinate is formed, thus :

(compare Bone and Sprankling, *Trans.*, 1899, **75**, 854).

The sodium compound of this cyano-ester interacts readily with ethyl  $\beta$ -iodopropionate, forming *ethyl  $\beta$ -cyano- $\alpha\alpha$ -dimethylbutane- $\alpha\beta\delta$ -tricarboxylate*,

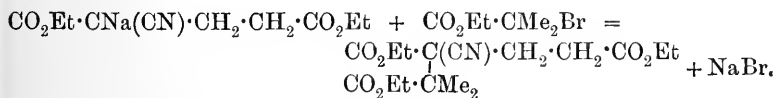

but, unfortunately, during this reaction, a large amount of the  $\beta$ -iodopropionic ester is decomposed with the elimination of hydrogen iodide and formation of ethyl acrylate,  $\text{CH}_2\text{:CH}\cdot\text{CO}_2\text{Et}$ , and by no variation in conditions could this be avoided. This loss of valuable material would have made further progress impossible had it not been discovered that the acrylate thus produced may be converted into ethyl cyanodimethylbutanetricarboxylate by the following series of reactions.

Ethyl acrylate condenses with the sodium compound of ethyl cyanoacetate, yielding the sodium compound of ethyl  $\alpha$ -cyanoglutarate, thus:  $\text{CO}_2\text{Et}\cdot\text{CHNa}\cdot\text{CN} + \text{CH}_2\text{:CH}\cdot\text{CO}_2\text{Et} =$

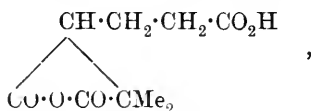

an ester which had already been prepared by L. Barthe (*Compt. rend.*, 1894, **118**, 1268) from the sodium compound of ethyl cyanoacetate and ethyl  $\beta$ -bromopropionate. The sodium compound of ethyl  $\alpha$ -cyanoglutarate, when digested in alcoholic solution with ethyl  $\alpha$ -bromoisobutyrate, gives a good yield of ethyl cyanodimethylbutanetricarboxylate,

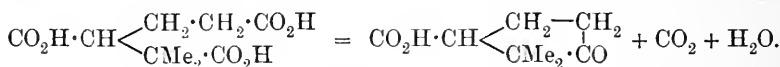

When boiled with hydrochloric acid, this cyano-ester is hydrolysed with the elimination of carbon dioxide and formation of  *$\alpha\alpha$ -dimethylbutane- $\alpha\beta\delta$ -tricarboxylic acid*,

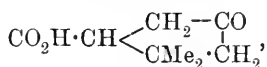

a crystalline, readily soluble acid which melts at 155—157°. When this acid is distilled under reduced pressure, it loses water and is converted into the *internal*  $\alpha\beta$ -anhydride of dimethylbutanetricarboxylic acid,

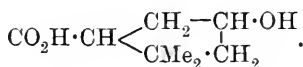

which melts at 98° and dissolves in water, regenerating the tribasic acid. If the dry sodium salt of the acid is heated with acetic anhydride at 140°, carbon dioxide is evolved and a new acid is produced,\* decomposition taking place according to the equation:

The  $\gamma$ -keto- $\beta\beta$ -dimethylpentamethylene- $\alpha$ -carboxylic acid thus obtained melts at 109—110° and yields an oxime and a sparingly soluble semicarbazone; it is isomeric with, and very closely allied to, the  $\delta$ -keto- $\beta\beta$ -dimethylpentamethylene- $\alpha$ -carboxylic acid,

which Perkin and Thorpe (Trans., 1901, 79, 782) obtained by the reduction of dimethylketodicyclopentanedicarboxylic acid, and which melts at 103°. The latter acid is not easily acted on by sodium amalgam, but if a large excess is employed, it is ultimately reduced to the corresponding hydroxydimethylpentamethylenecarboxylic acid (m. p. 115°):

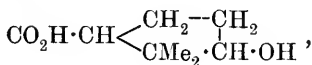

This acid must exist in *trans*- and *cis*-modifications, the latter of which should, like all *cis*- $\gamma$ -hydroxy-acids, readily yield a lactone, and since the acid (m. p. 115°) which was actually obtained showed no tendency to lose water with formation of a lactone, it is evidently the *trans*-modification.

On the other hand, it is interesting to note that the  $\gamma$ -keto-acid (m. p. 110°), unlike the  $\delta$ -keto-acid (m. p. 103°), is not reduced at all even when the aqueous solution of its sodium salt is boiled with a large excess of sodium amalgam, and this difference in behaviour is doubtless due to the proximity of the  $>\text{CMe}_2$  complex to the keto-

\* If this curious reaction should prove to be a general one, it will afford a convenient means of synthesising many important closed chain keto-acids and, for this reason, experiments are being carried out by one of us with the object of ascertaining the exact conditions under which the change takes place.

group in the latter case. Reduction of the  $\gamma$ -keto-acid may, however, be effected by adding sodium to the boiling alcoholic solution of the acid, when an almost quantitative yield of *trans*- $\gamma$ -hydroxy- $\beta\beta$ -dimethylpentamethylene- $\alpha$ -carboxylic acid (m. p.  $101^\circ$ ),

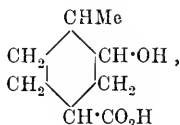

is obtained. The most remarkable property of this acid is its great stability\* since, although it is a  $\gamma$ -hydroxy-acid, it does not yield a lactone on boiling with dilute sulphuric acid and, even when distilled, it passes over for the most part unchanged.

This unusual stability, even of a *trans*-modification of a  $\gamma$ -hydroxy-acid, led us to suspect that some intramolecular change might have taken place during the energetic reduction with sodium and alcohol, but that this is not the case is proved by the behaviour of the hydroxy-acid on treatment with chromic acid, when it is very readily oxidised and converted into the  $\gamma$ -keto-acid from which it had been obtained by reduction.

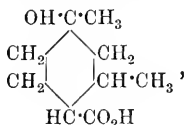

When *trans*- $\gamma$ -hydroxydimethylpentamethylenecarboxylic acid is heated with hydrobromic acid, it yields  $\gamma$ -bromodimethylpentamethylenecarboxylic acid, and this viscid, syrupy substance, when boiled with sodium carbonate, loses hydrogen bromide with the formation of dimethylcyclopentenecarboxylic acid (b. p.  $236^\circ$ ) :

\* The reason for the remarkable stability of this hydroxy-acid is difficult to understand, but it may be mentioned that other closed chain  $\gamma$ -hydroxy-acids are known—for example, the  $\gamma$ -hydroxyhexahydro-*p*-toluic acid :

prepared by Tiemann and Semmler (*Ber.*, 1895, **28**, 2143)—which also exhibit very little tendency to yield lactones (compare Perkin and Yates, *Trans.*, 1901, **79**, 1375).

On the other hand, *trans*-hydroxyhexahydro-xylic acid,

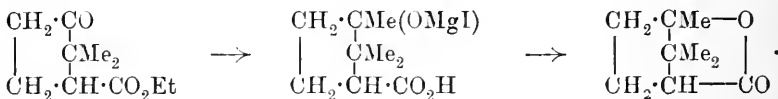

in which the hydroxy-group is in the  $\delta$ -position with respect to the carboxyl radicle, readily yields a lactone on distillation (Perkin and Lees, *Trans.*, 1901, **79**, 344), and this and other similar observations seem to point to the possibility of lactone formation taking place more readily in the  $\delta$ - than in the  $\gamma$ -position in ring compounds.

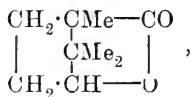

*Action of Magnesium Methyl Iodide on Ethyl Ketodimethylpentamethylenecarboxylate. Formation of  $\alpha$ -Campholactone and Synthesis of  $\alpha$ -Campholytic Acid and  $\beta$ -Campholytic Acid (isoLauronic Acid).*

As stated on p. 128, the primary object of this research was the synthesis of closed chain compounds closely allied to camphor and this was accomplished in the following way.

Ethyl ketodimethylpentamethylenecarboxylate is readily acted on by magnesium methyl iodide with the formation of several substances, among which is a new lactone produced according to the following scheme:

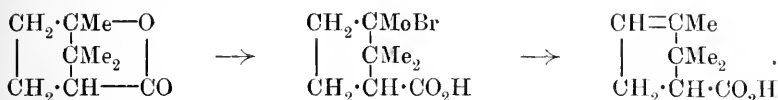

On account of its close relationship to campholactone,

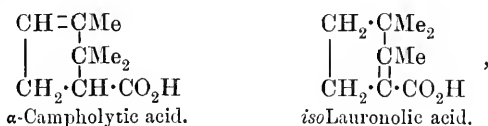

from which, indeed, it only differs in the reversal of the position of the lactone group, this new lactone has been named *inactive  $\alpha$ -campholactone*.\*

Inactive  $\alpha$ -campholactone is an oil which smells strongly of peppermint and distils at 155–157° under 50 mm. pressure; when treated with hydrobromic acid, it yields *inactive  $\gamma$ -bromotrimethylpentamethylenecarboxylic acid*, which melts at 108° and, when digested with sodium carbonate, loses hydrogen bromide with the formation of the corresponding unsaturated acid:

\* In the preliminary notice of this research in the *Proceedings* (*loc. cit.*), we named the new lactone "*isocampholactone*" in order to emphasise its great similarity to campholactone. We subsequently found, however, that this name had already been given to a lactone of unknown constitution which Noyes (*Ber.*, 1895, 28, 553) had prepared by the action of nitrous acid on aminolauronic acid. This latter lactone, which melts at 23° and has quite different properties to our synthetical lactone, was not obtained in sufficient quantity for analysis, but its method of formation makes it probable that it is isomeric (possibly stereoisomeric) with campholactone. Owing to the name "*isocampholactone*" having been previously used by Noyes, we have altered that of our lactone to " *$\alpha$ -campholactone*."

The formula of this unsaturated acid is that of *inactive α-campholytic acid*, an acid which was first obtained by one of us (Perkin, *Trans.*, 1903, 83, 853) by the reduction of *α*-camphylic acid,  $\text{C}_8\text{H}_{11} \cdot \text{CO}_2\text{H}$ , with sodium amalgam. In order to prove that the synthetical acid is *inactive α-campholytic acid*, it was digested with dilute sulphuric acid when crystals were formed which melted at  $132^\circ$  and were easily identified as *β-campholytic acid* (*isolauronic acid*), the well-known remarkable isomeric change indicated by the formulæ,

having taken place. That the *isolauronic acid* thus synthesised is identical with the acid obtained from camphoric acid was shown by mixing equal quantities of the two preparations when the mixture melted at  $132^\circ$ , the melting point of the constituents. Furthermore, the synthetical acid, on oxidation with permanganate, yielded *isolauronic acid*.

There can thus be no doubt that the above series of reactions constitutes a synthesis of both inactive *α*-campholytic acid and of *isolauronic acid* (*β*-campholytic acid) and therefore the constitution of these important acids may now be taken as definitely established.

If the formulæ of *α*-campholactone and the derivatives obtained from it are carefully examined, it will be at once seen how very closely these synthetical substances are related to camphoric acid. Thus if *γ*-bromotrimethylpentamethylenecarboxylic acid be taken as an example, it is only necessary to replace the bromine atom in that substance by the carboxyl group in order to accomplish a synthesis of camphoric acid :

Many experiments were made, under the most varied conditions, in the hope of being able to bring about this change, but with little success. Thus the bromo-acid and its ester were treated with silver cyanide, with solid potassium cyanide, alone and in the presence of anhydrous hydrogen cyanide, and with aqueous and alcoholic solutions of potassium cyanide, but although small quantities of a crystalline sub-

stance having properties identical with those of *i*-camphoric acid were obtained in two cases (see p. 146), the amount was too small for analysis and definite identification. The cause of the failure in these experiments is the great readiness with which the bromo-acid loses hydrogen bromide with the formation of  $\alpha$ -campholytic acid. Again  $\alpha$ -campholactone was heated with potassium cyanide and with anhydrous formic acid, but in both cases,  $\alpha$ -campholytic acid was the product of the reaction. Lastly, a synthesis, similar to that of benzoic acid from bromobenzene by the action of magnesium powder and carbon dioxide, was attempted with the ester of bromotrimethylpentamethylene-carboxylic acid, but again without success. It has not been thought worth while to describe all these various experiments in detail in this paper, the above short account being sufficient to indicate the reactions which were attempted with the object of synthesising camphoric acid from  $\alpha$ -campholactone.

*Condensation of Ethyl Cyanodimethylsuccinate with Ethyl  $\beta$ -Iodopropionate. Formation of Ethyl Cyanodimethylbutanetricarboxylate,*

In carrying out this condensation, it was found that even slight differences in temperature and other conditions had a very marked influence on the yield of the condensation product, and the best results were usually obtained by working in the following way. Sodium (23 grams) is dissolved in absolute alcohol (350 c.c.) and, after cooling thoroughly, mixed with ethyl cyanodimethylsuccinate (227 grams) and then ethyl  $\beta$ -iodopropionate (228 grams) added in small quantities, care being taken, by cooling with water, that the temperature never rises above 25°. After 12 hours, the product is heated on the water-bath for 2 hours, water is then added, and the oily ester, which smells strongly of ethyl acrylate, is twice extracted with ether. The ethereal solution is thoroughly washed with water, dried over calcium chloride, and the ether very slowly distilled off; the residual oil is then distilled at first under the ordinary pressure until the temperature rises to 130° in order that the ethyl acrylate which comes over below this may be collected for subsequent use (see p. 136).

The distillation flask is then attached to the vacuum apparatus and the distillation continued under 20 mm. pressure when, after several fractionations, *ethyl cyanodimethylbutanetricarboxylate* is readily obtained pure as a colourless oil boiling at about 210° (20 mm.).

0.2976 gave 11.3 c.c. of nitrogen at 23° and 760 mm.  $N = 4.3$ .

$\text{C}_{16}\text{H}_{25}\text{O}_6\text{N}$  requires  $N = 4.3$  per cent.

The yield of this ester varies in a remarkable way in different experiments carried out, apparently, under precisely the same conditions. In one instance, an almost theoretical yield was obtained, but in other cases hardly a trace was produced, the average yield being about 25 per cent. of the theoretical. The remainder consists of ethyl acrylate and unchanged ethyl cyanodimethylsuccinate and sometimes a considerable quantity of an oil having a high boiling point is produced.

The cyanogen group in ethyl cyanodimethylbutanetricarboxylate is hydrolysed only with great difficulty, even on long boiling with hydrochloric or dilute sulphuric acid the process is far from complete, and it was only by employing concentrated sulphuric acid in the first instance that a satisfactory result was ultimately obtained. The cyano-ester (in quantities of 50 grams) is dissolved in an equal volume of concentrated sulphuric acid, and, when the solution is cold, water is added until oily drops just commence to separate. The whole is then boiled on the sand-bath, the alcohol produced being allowed to escape through the air-condenser, and small quantities of water are added from time to time in order to prevent charring. After 8 hours, the solution is diluted with an equal volume of water, saturated with ammonium sulphate, and extracted several times with ether; the solvent is then evaporated and the residue dissolved in a small quantity of water and mixed with an equal volume of concentrated hydrochloric acid. After two days, the crystalline crust which has separated is collected and purified by recrystallisation from hydrochloric acid, from which it separates as a sandy powder.

0.1444 gave 0.2615  $\text{CO}_2$  and 0.0860  $\text{H}_2\text{O}$ . C = 49.4; H = 6.6.

0.1298 „ 0.2359  $\text{CO}_2$  „ 0.0750  $\text{H}_2\text{O}$ . C = 49.5; H = 6.4.

$\text{C}_9\text{H}_{14}\text{O}_6$  requires C = 49.5; H = 6.4 per cent.

*Dimethylbutanetricarboxylic acid* melts at 155—157° and is readily soluble in water, but sparingly so in concentrated hydrochloric acid. It is rather sparingly soluble in dry ether, and crystallises from this solvent in small, glistening prisms or leaflets.

On titration with decinormal caustic soda, 0.2018 gram neutralised 0.1108 gram of NaOH, whereas this quantity of a tribasic acid,  $\text{C}_9\text{H}_{14}\text{O}_6$ , should neutralise 0.1110 gram of NaOH.

The hydrochloric acid mother liquors from the purification of the acid contain a large quantity of very impure material; this is extracted with ether, and, after evaporating off the solvent, the residue is esterified by boiling with alcohol and sulphuric acid. The ester is extracted

in the usual way and fractionated under reduced pressure, when pure *ethyl dimethylbutanetricarboxylate*,

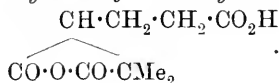

is obtained as a colourless oil boiling at about  $195^\circ$  (40 mm.).

0.1722 gave 0.3761  $\text{CO}_2$  and 0.1319  $\text{H}_2\text{O}$ .  $\text{C} = 59.5$  ;  $\text{H} = 8.5$ .

$\text{C}_{15}\text{H}_{26}\text{O}_6$  requires  $\text{C} = 59.6$  ;  $\text{H} = 8.6$  per cent.

From this ester, the pure tribasic acid is readily obtained by hydrolysis with concentrated hydrochloric acid.

*The Internal Anhydride of Dimethylbutanetricarboxylic Acid,*

When dimethylbutanetricarboxylic acid is heated under reduced pressure (45 mm.), it melts and then, at once, gives off water, and the anhydro-acid distils at about  $255^\circ$  as a viscid, colourless syrup which soon begins to crystallise in stellate groups and gradually becomes solid. By dissolving in hot benzene and allowing to cool slowly, the substance is obtained in well-defined, four-sided plates, but if the solution is rapidly stirred, it separates as a sandy, crystalline precipitate.

0.1776 gave 0.3503  $\text{CO}_2$  and 0.0959  $\text{H}_2\text{O}$ .  $\text{C} = 53.8$  ;  $\text{H} = 6.0$ .

$\text{C}_9\text{H}_{12}\text{O}_5$  requires  $\text{C} = 54.0$  ;  $\text{H} = 6.0$  per cent.

The anhydride melts at  $98^\circ$  and is sparingly soluble in cold water ; it dissolves, however, readily on boiling with water, and if an equal volume of hydrochloric acid is added to the concentrated solution, crystals separate which melt at  $155$ — $157^\circ$  and consist of the pure tribasic acid.

*Formation of Ethyl Cyanodimethylbutanetricarboxylate from Ethyl Acrylate, Ethyl Cyanoacetate, and Ethyl Bromoisobutyrate.*

The reasons which led to this method being carefully worked out are given in the introduction. Sodium (23 grams) was dissolved in 300 grams of alcohol, mixed with ethyl cyanoacetate (113 grams), and, after well cooling, ethyl acrylate (100 grams) added in several portions. The condensation takes place very rapidly and with evolution of a considerable amount of heat, and in a short time the whole of the sodium compound of the ethyl cyanoacetate will have passed into solution. The mixture is heated on the water-bath for about two hours, and until a drop of the liquid, on dilution with water, no

longer deposits an oil ; it is then mixed with ethyl bromoisobutyrate (195 grams) and heated in soda-water bottles in a boiling salt-bath for eight hours. On diluting with water, extracting the oily product with ether, and fractionating under reduced pressure, pure ethyl cyanodimethylbutanetricarboxylate is obtained, the yield being 75—80 per cent. of the theoretical.

0.2646 gave 10.2 c.c. of nitrogen at 20° and 755 mm.  $N = 4.4$ .

$C_{16}H_{25}O_6N$  requires  $N = 4.3$  per cent.

That this cyano-ester has the same constitution as that obtained by the process described on p. 134 was proved by hydrolysis with sulphuric acid, when a good yield of dimethylbutanetricarboxylic acid was obtained which melted at 155—157°.

0.1516 gave 0.2759  $CO_2$  and 0.0886  $H_2O$ .  $C = 49.6$  ;  $H = 6.5$ .

$C_9H_{14}O_6$  requires  $C = 49.5$  ;  $H = 6.4$  per cent.

Much of the acid required for this investigation was prepared by the foregoing process.

#### *Partial Hydrolysis of Ethyl Cyanodimethylbutanetricarboxylate.*

During the course of this investigation, a number of experiments were instituted with the object of eliminating the carboxyl radicle adjacent to the cyanogen group in ethyl cyanodimethylbutanetricarboxylate, and the results obtained may be briefly described as follows.

When an alcoholic solution of 12 grams of pure caustic potash is mixed with 35 grams of the cyano-ester and the whole allowed to remain overnight, a crystalline potassium salt separates in quantity. This was collected at the pump, washed with alcohol, in which it is sparingly soluble, and dried at 100° ; it then weighed 10 grams.

0.3484 gave 0.1781  $K_2SO_4$ .  $K = 22.9$ .

$C_{12}H_{15}O_6NK_2$  requires  $K = 22.4$  per cent.

The constitution of this salt is probably represented by the formula

It was very soluble in water and gave no precipitate on acidifying with hydrochloric acid ; the whole was therefore repeatedly extracted with ether, the ethereal solution dried over calcium chloride and evaporated, when a colourless oil was obtained, which, over sulphuric acid in a vacuum desiccator, became very viscid but did not crystallise. The analysis shows that this substance is *ethyl dihydrogen cyanodimethylbutanetricarboxylate*, corresponding with the above potassium salt.

0.1974 gave 8.3 c.c. of nitrogen at 17° and 759 mm.  $N = 4.9$ .

$C_{12}H_{17}O_6N$  requires  $N = 5.2$  per cent.

When this dibasic acid is heated at 150°, it decomposes with evolution of carbon dioxide, and, when the evolution of gas has ceased, the residue distils almost completely at 245—250° (50 mm.) as a viscid oil which consists of *ethyl hydrogen cyanodimethylbutanedicarboxylate*,

0.2138 gave 11.5 c.c. of nitrogen at 20° and 759 mm.  $N = 6.2$ .

$C_{11}H_{17}O_4N$  requires  $N = 6.2$  per cent.

*Ketodimethylpentamethylenecarboxylic Acid*,  $CO_2H \cdot CH < \begin{matrix} CH_2 - CH_2 \\ CMe_2 \cdot CO \end{matrix}$ .

This acid is formed when the sodium salt of dimethylbutanetricarboxylic acid is heated with acetic anhydride. The sodium salt is prepared by dissolving the pure acid (109 grams) in water, adding 80 grams of anhydrous sodium carbonate, and evaporating the alkaline liquid to dryness. In order to obtain the salt as finely divided as possible, it is powdered and passed through a fine wire sieve, being then again dried at 100° and transferred to a flask, into the neck of which is fitted a tube bent twice at right angles. After adding 150 grams of freshly distilled acetic anhydride, the whole is slowly heated in an oil-bath when it will be noticed that carbon dioxide begins to come off below 100°, as can be readily seen by causing the tube attached to the flask to dip under baryta water. The temperature is kept at 135—140° for about 6 hours, then 50 grams of acetic anhydride are added and the heating continued until the evolution of carbon dioxide has practically ceased, which is the case after about three hours. As soon as the product is cold, it is esterified by adding an excess of a solution of one volume of sulphuric acid in three volumes of alcohol and heating for 6 hours on the water-bath in an open flask in order that as much ethyl acetate as possible may be removed by evaporation. The product, which smells strongly of ethyl acetate, is diluted with water and extracted several times with ether; the ethereal solution is then thoroughly washed with water and dilute sodium carbonate solution\* and evaporated.

On fractionating this oil under 100 mm. pressure, about 50 grams distil at 160—180° leaving a viscid, nearly black residue† in the retort

\* The dark sodium carbonate extract, on acidifying and extracting with ether, yields a brown oil from which considerable quantities of ketodimethylpentamethylenecarboxylic acid may be obtained by treatment with semicarbazide or by esterification and distillation under reduced pressure and subsequent hydrolysis.

† The residues from several preparations were mixed and fractionated under

and, on repeatedly fractionating the distillate, an oil (35 grams) is obtained which boils at  $170\text{--}172^\circ$  (100 mm.) and consists of pure *ethyl ketodimethylpentamethylenecarboxylate*.

0.1765 gave 0.4196  $\text{CO}_2$  and 0.1397  $\text{H}_2\text{O}$ . C = 64.8; H = 8.8.

0.1584 „ 0.3771  $\text{CO}_2$  „ 0.1242  $\text{H}_2\text{O}$ . C = 64.9; H = 8.7.

$\text{C}_{10}\text{H}_{16}\text{O}_3$  requires C = 65.2; H = 8.7 per cent.

This ester is hydrolysed by boiling with an excess of methyl-alcoholic potash; the solution is diluted with water, neutralised, and evaporated until free from alcohol. After acidifying with hydrochloric acid and extracting six times with pure ether, the ethereal solution is dried over calcium chloride and evaporated, when a pale yellow oil is obtained which, on cooling, rapidly solidifies. The mass is left in contact with porous porcelain to remove a trace of oily impurity, and then dissolved in a small amount of water, from which the pure acid separates slowly in groups of colourless needles.

0.1485 gave 0.3360  $\text{CO}_2$  and 0.1043  $\text{H}_2\text{O}$ . C = 61.6; H = 7.8.

0.1634 „ 0.3686  $\text{CO}_2$  „ 0.1144  $\text{H}_2\text{O}$ . C = 61.5; H = 7.8.

$\text{C}_8\text{H}_{12}\text{O}_3$  requires C = 61.5; H = 7.7 per cent.

*Ketodimethylpentamethylenecarboxylic acid* melts at  $109\text{--}110^\circ$ ; it dissolves readily in benzene, acetone, ether, alcohol, and chloroform, but is sparingly soluble in light petroleum. It is exceedingly soluble in hot water but much less so in the cold, and it may be obtained in long, colourless needles if the hot solution is allowed to cool very slowly. The pure acid also crystallises readily from ether in the form of hard, glistening prisms.

A slightly alkaline solution of the ammonium salt of the acid gives no precipitate with barium or calcium chloride, even on boiling; with copper sulphate, no precipitate is formed in the cold, but, on boiling, a pale blue, apparently crystalline, copper salt separates.

The *oxime*,  $\text{C}_6\text{H}_{11}(\text{C:N}\cdot\text{OH})\cdot\text{CO}_2\text{H}$ , was prepared by dissolving the acid in a considerable excess of caustic potash solution, adding twice the calculated quantity of hydroxylamine hydrochloride, and allowing the whole to remain for two days. On acidifying with hydrochloric acid, a crystalline precipitate separated, which was extracted with ether, the ethereal solution was carefully dried with calcium chloride and evaporated to a small bulk, when the oxime soon began to separate in crystalline crusts.

30 mm. pressure, when about one-third distilled at  $180\text{--}190^\circ$ . This portion, on hydrolysis with hydrochloric acid, yielded a considerable quantity of crude dimethylbutanetricarboxylic acid, which was purified by recrystallisation, first from hydrochloric acid and then from ether.

0.203 gave 15.3 c.c. nitrogen at 19° and 737 mm.  $N = 8.3$ .

$C_8H_{13}O_3N$  requires  $N = 8.2$  per cent.

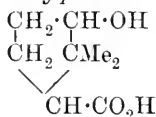

*Ketoximedimethylpentamethylenecarboxylic acid* melts at about 195°, but it turns brown and commences to decompose below this temperature. It is somewhat sparingly soluble even in boiling water, and separates, on cooling, as a sandy powder. It dissolves readily in sodium carbonate, and, when heated in a test-tube, it decomposes with a slight explosion, and yields an oily distillate which crystallises on cooling.

The *semicarbazone*,  $C_6H_{11}(C:N \cdot NH \cdot CO \cdot NH_2) \cdot CO_2H$ , separates at once as a sandy powder when a concentrated aqueous solution of the acid is mixed with semicarbazide hydrochloride and sodium acetate. It melts at about 217° and is very sparingly soluble in water.

0.1544 gave 26.6 c.c. nitrogen at 19° and 751 mm.  $N = 19.5$ .

$C_9H_{15}O_3N_3$  requires  $N = 19.7$  per cent.

*Reduction of Ketodimethylpentamethylenecarboxylic Acid. Formation of trans-γ-Hydroxydimethylpentamethylenecarboxylic Acid,*

It is stated in the introduction that ketodimethylpentamethylenecarboxylic acid is not reduced by sodium amalgam, and this was shown by the fact that when 30 grams of the acid, dissolved in dilute aqueous caustic soda, was boiled with 2500 grams of 4 per cent. sodium amalgam, and the solution subsequently acidified and extracted with ether, almost the whole of the keto-acid was recovered unchanged. When, however, the boiling alcoholic solution of the acid is treated with sodium, reduction is readily effected. The pure acid (30 grams) was dissolved in about 500 c.c. of absolute alcohol, heated to boiling in a reflux apparatus, and treated, as rapidly as possible, with 70 grams of sodium, boiling alcohol being added from time to time as the reaction slackened. The product was dissolved in much water, evaporated on the water-bath until free from alcohol, acidified with an excess of hydrochloric acid, and heated on the water-bath for half an hour in the expectation that the hydroxy-acid, if present, would thus be converted into its lactone. As, however, no neutral oil separated, the whole was saturated with ammonium sulphate, and extracted 10 times with ether. The ethereal solution was dried over calcium chloride and evaporated, when 28 grams of a viscid oil remained and solidified on cooling. That no unchanged keto-acid was present in this product was shown by treating a small portion with semicarbazide and sodium

acetate, when no trace of the very sparingly soluble semicarbazone (p. 140) was formed. Considerable difficulty was experienced in recrystallising the crude reduced acid, but this was ultimately accomplished by dissolving it in dry ether, adding an equal volume of benzene, and allowing the solution to evaporate slowly at the ordinary temperature. The crystalline crusts thus obtained were drained on porous porcelain, and dissolved in a small quantity of hot water, when, on slowly cooling, the pure acid separated in well-defined, glistening prisms.

0.1690 gave 0.3762  $\text{CO}_2$  and 0.1326  $\text{H}_2\text{O}$ .  $\text{C} = 60.7$ ;  $\text{H} = 8.7$ .

0.1353 „ 0.3012  $\text{CO}_2$  „ 0.1075  $\text{H}_2\text{O}$ .  $\text{C} = 60.7$ ;  $\text{H} = 8.8$ .

$\text{C}_8\text{H}_{14}\text{O}_3$  requires  $\text{C} = 60.8$ ;  $\text{H} = 8.8$  per cent.

*trans*- $\gamma$ -Hydroxydimethylpentamethylenecarboxylic acid melts at  $100$ – $101^\circ$  and is readily soluble in water, alcohol, and ether. That it is a monobasic acid was shown by its behaviour with decinormal caustic soda, when 0.1977 gram of the acid required for neutralisation 0.0507 gram of  $\text{NaOH}$ , whereas this amount of a monobasic acid,  $\text{C}_8\text{H}_{14}\text{O}_3$ , should neutralise 0.0506 gram of  $\text{NaOH}$ .

This  $\gamma$ -hydroxy-acid is remarkably stable, and shows no tendency to become converted into a lactone when boiled with dilute hydrochloric or sulphuric acid, and, even on distillation, it does not yield a lactone, as is proved by the following experiment.

Three grams of the pure acid were distilled under 40 mm. pressure, when the whole passed over at  $205$ – $210^\circ$  as a viscid, colourless oil resembling glycerol, and this, on cooling, solidified to a brittle, transparent, glassy mass. This product was completely soluble in cold dilute sodium carbonate solution, showing that it was not a lactone, and, without further purification, it yielded numbers which differ little from those required by the hydroxy-acid.

0.1649 gave 0.3718  $\text{CO}_2$  and 0.1348  $\text{H}_2\text{O}$ .  $\text{C} = 61.4$ ;  $\text{H} = 9.0$ .

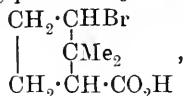

$\text{C}_8\text{H}_{14}\text{O}_3$  requires  $\text{C} = 60.8$ ;  $\text{H} = 8.8$  per cent.

*Oxidation by Means of Chromic Acid.*—Owing to the curious properties of this hydroxy-acid, it was thought necessary to investigate its behaviour on oxidation in order to prove that its constitution is that represented by the formula indicated on p. 140. The pure acid (2 grams) was dissolved in water, mixed with potassium dichromate (1.4 grams) and a small amount of sulphuric acid, and gradually heated to boiling when oxidation readily took place. The product was extracted with ether, the ethereal solution dried over calcium chloride and evaporated to a small bulk, when crystalline crusts (1.5 grams) slowly separated, which melted at  $109^\circ$ , and consisted of pure ketodimethylpentamethylenecarboxylic acid.

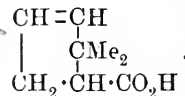

0.1558 gave 0.3513  $\text{CO}_2$  and 0.1096  $\text{H}_2\text{O}$ .  $\text{C} = 61.5$ ;  $\text{H} = 7.8$ .

$\text{C}_8\text{H}_{12}\text{O}_3$  requires  $\text{C} = 61.5$ ;  $\text{H} = 7.7$  per cent.

*$\gamma$ -Bromodimethylpentamethylenecarboxylic Acid,*

*and Dimethylcyclopentenecarboxylic Acid,*

Finely powdered  $\gamma$ -hydroxydimethylpentamethylenecarboxylic acid dissolves readily in fuming hydrobromic acid (saturated at  $0^\circ$ ), but the bromo-acid does not separate after a time as is the case with the corresponding trimethyl acid (see p. 145). The solution was therefore heated in a sealed tube at  $100^\circ$  for about fifteen minutes, when, on cooling, an oily layer had separated on the surface of the hydrobromic acid. The whole was diluted with water, extracted with ether, the ethereal solution thoroughly washed with water, dried over calcium chloride, and evaporated, when an almost colourless oil remained which, after leaving for some hours over sulphuric acid in a vacuum desiccator, was analysed with the following result :

0.3373 gave 0.2346  $\text{AgBr}$ .  $\text{Br} = 35.9$ .

$\text{C}_8\text{H}_{13}\text{O}_3\text{Br}$  requires  $\text{Br} = 36.2$  per cent.

*$\gamma$ -Bromodimethylpentamethylenecarboxylic acid*, when prepared in this way, shows no signs of crystallising, even when left for a long time in a freezing mixture, and, on exposure to the air, it becomes darker and finally almost black. A quantity of the freshly prepared bromo-acid was dissolved in excess of sodium carbonate and boiled for several minutes; the solution was then acidified and extracted with ether. After drying over calcium chloride and evaporating, an oil was obtained which distilled for the most part at  $160$ — $170^\circ$  (50 mm.), but there was a considerable quantity of a viscid oil left in the flask, which probably consisted of regenerated  $\gamma$ -hydroxy-acid. The distillate was fractionated under the ordinary pressure, when almost the whole passed over at  $236^\circ$  (760 mm.) as an oil which was colourless when hot but became deep sage-green on cooling, a behaviour often observed in connection with substances belonging to the camphor and terpene series.

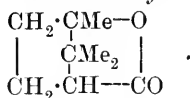

Owing to its method of formation, there can be no doubt that the oily acid thus obtained is *dimethylcyclopentenecarboxylic acid*. That it is an unsaturated acid is shown by the fact that its solution in sodium carbonate instantly decolorises permanganate.

0.2128 gave 0.5315  $\text{CO}_2$  and 0.1638  $\text{H}_2\text{O}$ . C = 68.2 ; H = 8.5.

0.1730 „ 0.4336  $\text{CO}_2$  „ 0.1335  $\text{H}_2\text{O}$ . C = 68.3 ; H = 8.6.

$\text{C}_8\text{H}_{12}\text{O}_2$  requires C = 68.6 ; H = 8.6 per cent.

*The Action of Magnesium Methyl Iodide on Ethyl Ketodimethylpentamethylenecarboxylate. Formation of Inactive  $\alpha$ -Campholactone.*

After a long series of comparative experiments, the following process was ultimately adopted for the preparation of  $\alpha$ -campholactone. Finely-divided magnesium filings (7.2 grams) are placed in a 2 litre flask connected with a long water condenser and covered with ether (300 c.c.) which had been very carefully freed from water, and finally distilled over phosphoric oxide. Methyl iodide (45 grams) is then added in two portions, the vigorous reaction being kept under control by immersing the flask in ice water occasionally.

Ethyl ketodimethylpentamethylenecarboxylate (37 grams) is dissolved in pure ether (300 c.c.) in a large flask, connected with a reflux condenser, and immersed in powdered ice and water ; the ethereal solution of magnesium methyl iodide is then cautiously poured down the condenser tube in several small quantities, the flask being well agitated and allowed to cool thoroughly after each addition. As each quantity of the magnesium methyl iodide comes into contact with the ethereal solution of the keto-ester, a yellowish-white turbidity is produced, and ultimately the magnesium compound separates on the sides of the flask as a sticky mass. After half an hour, the product is decomposed by the careful addition of dilute hydrochloric acid, the yellow ethereal solution is separated, washed with dilute hydrochloric acid and evaporated, and the residue, which is a mixture of the lactone, unchanged keto-ester, and a neutral substance (which has not yet been investigated), is treated as follows. The deep yellow oil is dissolved in methyl alcohol, and digested for 10 minutes with a solution of caustic potash (20 grams) in methyl alcohol, by which means the lactone and keto-ester are hydrolysed ; water is then added, and the neutral substance removed by extraction with ether. The aqueous solution is evaporated on the water-bath until free from ether and methyl alcohol ; it is then diluted with water and acidified, when a viscid oil separates, which, on heating on the water-bath for 15 minutes, becomes limpid, owing to the conversion of the hydroxy-acid into the corresponding lactone. The whole is extracted with ether, the ethereal solution repeatedly washed with dilute aqueous sodium carbonate, dried over calcium chloride, and evaporated, when an oil

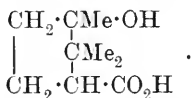

(6—8 grams) is obtained which, after repeated fractionation, distils constantly at 155—157° (50 mm.), and consists of pure *inactive*  $\alpha$ -campholactone.

0.1649 gave 0.4227 CO<sub>2</sub> and 0.1392 H<sub>2</sub>O. C = 69.9; H = 9.3.

0.1485 „ 0.3819 CO<sub>2</sub> „ 0.1238 H<sub>2</sub>O. C = 70.0; H = 9.2.

C<sub>9</sub>H<sub>14</sub>O<sub>2</sub> requires C = 70.1; H = 9.1 per cent.

Inactive  $\alpha$ -campholactone is a pale yellow oil which has a most pungent odour of peppermint; it is readily volatile in steam, and distils under the ordinary pressure almost without decomposition. It is insoluble in sodium carbonate solution, but dissolves readily and completely in warm dilute aqueous caustic soda, and the well-cooled solution, on acidifying, remains clear for a considerable time, indicating that the hydroxy-acid corresponding with the lactone is present; this acid is slowly decomposed at the ordinary temperature, and more rapidly on warming, with a separation of the lactone. A special experiment was made in the hope of being able to obtain the hydroxy-acid in a crystalline condition, in order that a direct comparison might be made with the hydroxydihydrocampholytic acid described by Noyes\* (*Amer. Chem. J.*, 1894, 16, 307, 502; 1896, 18, 685), and which he considers has the same constitution, namely,

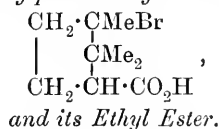

The pure lactone (2 grams) was dissolved in hot baryta water, the solution cooled with ice, acidified, and extracted with ether. On removing the ether by a current of dry air, a viscid oil remained, which was obviously the hydroxy-acid, since it dissolved readily and completely in dilute sodium carbonate solution.

0.1496 gave 0.3454 CO<sub>2</sub> and 0.1252 H<sub>2</sub>O. C = 64.0; H = 9.3.

C<sub>9</sub>H<sub>16</sub>O<sub>3</sub> requires C = 62.8; H = 9.3 per cent.

*Inactive*  $\gamma$ -cis-hydroxytrimethylpentamethylenecarboxylic acid, when left over sulphuric acid in a vacuum desiccator, rapidly loses water with the formation of  $\alpha$ -campholactone and, when boiled with hydrochloric acid, the change is complete in a few minutes. Hydroxydihydrocampholytic acid, on the contrary, is perfectly stable and, indeed, does not shew any tendency to yield a lactone even when boiled with acids; if then it has the constitution represented above, it must obviously be the *trans*-modification.

\* Compare Meyer and Jackson (*Lehrbuch der Org. Chem.*, Vol. II, 1021).

*Inactive  $\gamma$ -Bromotrimethylpentamethylenecarboxylic Acid,*

When  $\alpha$ -campholactone is mixed with three times its volume of fuming hydrobromic acid (saturated at  $0^\circ$ ) it dissolves, but almost immediately the liquid clouds and a viscid oil separates on the surface of the acid. This oily layer soon darkens in colour and crystallises, and in preparing the pure bromo-acid it is best to stir vigorously with a glass rod, so that solidification may be complete before decomposition sets in. The solid is thoroughly washed with water to remove hydrobromic acid and spread on porous porcelain to separate the oily impurity. The residue, which should be almost colourless, is made into a paste with a small quantity of formic acid (sp. gr. 1.22) and again transferred to porous porcelain, and after the operation has been repeated, a colourless, crystalline mass is obtained which softens at  $105^\circ$  and melts at about  $108^\circ$  with decomposition.

0.2202 gave 0.1735 AgBr. Br = 33.5.

$\text{C}_9\text{H}_{15}\text{O}_2\text{Br}$  requires Br = 34.0 per cent.

Inactive  $\gamma$ -bromotrimethylpentamethylenecarboxylic acid readily decomposes with loss of hydrogen bromide and formation of *inactive*  $\alpha$ -campholytic acid (see p. 147) and therefore no attempts were made to purify it by recrystallisation. As explained in the introduction, it is exactly similar in its chemical properties to the hydrobromide of  $\alpha$ -campholytic acid (*cistrans*-campholytic acid), which, according to Noyes (*Ber.*, 1898, 28, 551), melts at  $98$ — $100^\circ$  and decomposes in moist air, evolving hydrogen bromide.

The *ethyl* ester,  $\text{C}_9\text{H}_{14}\text{Br} \cdot \text{CO}_2\text{Et}$ .—In preparing this ester, the pure lactone (4 grams) was mixed with phosphorous pentabromide (15 grams), when a vigorous action took place and much hydrogen bromide was evolved. After 10 minutes, the whole was heated on the water-bath for 5 minutes and then poured, in a thin stream, into a large excess of absolute alcohol. As soon as the reaction had subsided, the solution was allowed to cool, diluted with water, and the heavy oil extracted with ether, the ethereal solution was washed with water and dilute sodium carbonate solution, dried over calcium chloride, evaporated, and the residual oil rapidly fractionated under 70 mm. pressure.

A small quantity of oil passed over below  $165^\circ$  and then almost

the whole of the remainder distilled at 165—170° leaving only a small, black residue in the flask.

0.1854 gave 0.1377 AgBr. Br = 31.6.

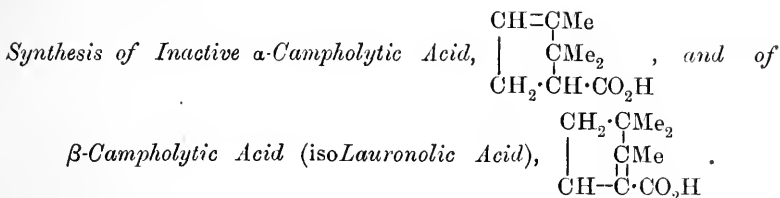

$C_{11}H_{19}O_2Br$  requires Br = 30.5 per cent.

This oil was made the starting-point in a long series of experiments instituted in the hope of synthesising camphoric acid (see p. 133) but without success. The above analysis and general properties of the oil leave, however, scarcely any doubt that it is *inactive ethyl  $\gamma$ -bromotrimethylpentamethylenecarboxylate*.

*Action of Potassium Cyanide on Bromotrimethylpentamethylenecarboxylic Acid.*—It was stated in the introduction that, in experimenting on the action of cyanides on this bromo-acid, an acid identical in properties with *i*-camphoric acid was obtained in very small quantities in two cases. In one instance, the experiment was carried out as follows: freshly prepared bromotrimethylpentamethylenecarboxylic acid (10 grams) was dissolved in alcohol, mixed with a concentrated aqueous solution of pure potassium cyanide (5 grams) and 5 c.c. of anhydrous hydrogen cyanide, the mixture being allowed to remain for 14 days. The dark brown product was heated on the water-bath for one hour, evaporated, and the residue mixed with concentrated hydrochloric acid and, after remaining overnight, heated for three hours on the water-bath. Water was then added and the whole distilled in steam until the distillate was free from  $\beta$ -campholytic acid (see p. 147). The residue was digested with animal charcoal, filtered, evaporated to a small bulk, and repeatedly extracted with ether, when a yellow oil was obtained which became semi-solid when left for some weeks over sulphuric acid.

This substance was drained on porous porcelain until all the oil had been absorbed and the residue recrystallised from a little water. As the crystalline product, which could not have weighed more than a few milligrams, melted indefinitely between 180° and 190°, it was heated in a test-tube with a small quantity of acetic anhydride when, on cooling, crystals separated which were drained on porous porcelain and washed with a little acetic anhydride. These crystals closely resembled the anhydride of *i*-camphoric acid, since they melted at 215—217° and gave on hydrolysis an acid, melting at 204°, whereas *i*-camphoric acid melts at 200—203° and yields an anhydride melting at 221°. Unfortunately, the amount at our disposal was quite insufficient to enable us to establish the identity of the substance by analysis.\*

\* The method of formation of this small quantity of acid and its properties leave scarcely room for doubt that it was *i*-camphoric acid, and experiments were in progress which it was hoped would have yielded enough material for definite

When  $\gamma$ -bromotrimethylpentamethylenecarboxylic acid is mixed with excess of sodium carbonate solution, it rapidly dissolves, and if the liquid is heated just to boiling, cooled, and acidified with hydrochloric acid, a viscid, oily layer of *inactive  $\alpha$ -campholytic acid* separates. This was extracted with ether, the ethereal solution washed until quite free from hydrochloric acid, dried over calcium chloride, evaporated, and the residual oil distilled under reduced pressure, when the whole passed over at  $162\text{--}164^\circ$  (45 mm.) as a colourless, viscid oil.

0.1441 gave 0.3696  $\text{CO}_2$  and 0.1185  $\text{H}_2\text{O}$ .  $\text{C} = 69.9$ ;  $\text{H} = 9.1$ .

$\text{C}_9\text{H}_{14}\text{O}_2$  requires  $\text{C} = 70.1$ ;  $\text{H} = 9.1$  per cent.

*Methyl  $\alpha$ -Campholytate*.—This ester was prepared by leaving the acid in contact with methyl alcohol and sulphuric acid for a short time and then precipitating with water. After extracting with ether, washing with sodium carbonate, drying over calcium chloride, and evaporating, an oil was obtained which distilled constantly at  $200^\circ$ .

0.1475 gave 0.3882  $\text{CO}_2$  and 0.1287  $\text{H}_2\text{O}$ .  $\text{C} = 71.7$ ;  $\text{H} = 9.7$ .

$\text{C}_8\text{H}_{13}\cdot\text{CO}_2\text{Me}$  requires  $\text{C} = 71.4$ ;  $\text{H} = 9.5$  per cent.

On hydrolysis with caustic potash and acidifying, this ester yielded liquid  $\alpha$ -campholytic acid, showing that no isomeric change had taken place during esterification (see below).

That the acid obtained in the way described above was inactive  $\alpha$ -campholytic acid and identical with the acid first obtained by the reduction of  $\alpha$ -camphylic acid with sodium amalgam (Trans., 1903, 83, 853) was proved by digesting a small quantity with 25 per cent. sulphuric acid for a few minutes, when, on cooling, a mass of crystals of  $\beta$ -campholytic acid (isolauronolic acid) separated.

These were collected, washed with water, and recrystallised from dilute acetic acid, when leaflets were obtained which melted at  $130^\circ$ .

0.1681 gave 0.4318  $\text{CO}_2$  and 0.1394  $\text{H}_2\text{O}$ .  $\text{C} = 70.0$ ;  $\text{H} = 9.1$ .

$\text{C}_9\text{H}_{14}\text{O}_2$  requires  $\text{C} = 70.1$ ;  $\text{H} = 9.1$  per cent.

identification. In the meantime, Komppa (*loc. cit.*) has published his brilliant synthesis of camphoric acid, which, once for all, establishes the correctness of Bredt's formula, and it is therefore quite unnecessary to investigate our much less satisfactory process any further.

The identity of this acid with the  $\beta$ -campholytic acid, obtained by the action of aluminium chloride on camphoric anhydride, was proved, firstly, by mixing equal quantities of the two acids, when no alteration in the melting point could be detected, and, secondly, by converting the synthetical acid into *isolauronic* acid by oxidation.

Two grams of the synthetical acid were dissolved in aqueous sodium carbonate, cooled with powdered ice, and then 2 per cent. potassium permanganate solution run in, drop by drop, until the pink colour just remained. The slight excess was destroyed by the addition of sodium sulphite, the whole was then heated to boiling and filtered, and the filtrate evaporated to a small bulk. The yellow liquid gave, on acidifying, a mass of pale yellow crystals which, after crystallising from water, melted at  $133^{\circ}$  and consisted of pure *isolauronic* acid.

0.1149 gave 0.2720  $\text{CO}_2$  and 0.0753  $\text{H}_2\text{O}$ .  $\text{C} = 64.5$ ;  $\text{H} = 7.3$ .

$\text{C}_9\text{H}_{12}\text{O}_3$  requires  $\text{C} = 64.3$ ;  $\text{H} = 7.1$  per cent.

Inactive  $\alpha$ -campholytic acid has been repeatedly obtained during the course of the experiments which have been carried out with  $\gamma$ -bromotrimethylpentamethylenecarboxylic acid and with  $\alpha$ -campholactone. Thus, for example, it is formed almost quantitatively when the bromo-acid is digested with potassium cyanide in alcoholic solution and when  $\alpha$ -campholactone is heated with dry potassium cyanide at  $110^{\circ}$ .

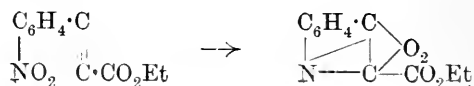

The authors wish to express their thanks to Mr. D. T. Jones for his valuable assistance in carrying out these experiments, and to state that much of the expense incurred during this investigation has been met by repeated grants from the Government Grant Fund of the Royal Society.

OWENS COLLEGE,  
MANCHESTER.

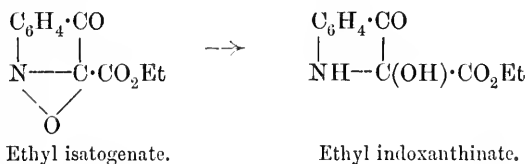

## XVI.—o-Nitrobenzoylacetic Acid.

By EDWARD RUSHTON NEEDHAM and WILLIAM HENRY PERKIN, jun.

IN the year 1881 (*Ber.*, 14, 1742), Baeyer showed that, when ethyl o-nitrophenylpropiolate is treated with sulphuric acid and the product poured into water, ethyl isatogenate is formed, and in explaining this remarkable process, he assumed that intramolecular change took place according to the scheme

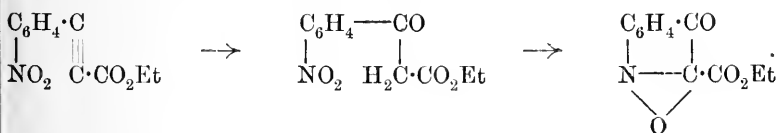

At a later date (*Ber.*, 1882, 15, 780) the same author, having discovered the reduction of ethyl isatogenate to ethyl indoxanthinate, explained this reaction by modifying the formula of the former ester and represented its relationship to the latter thus :

Subsequently he published a preliminary notice on benzoylactic acid (*Ber.*, 1882, 15, 2705) showing that its ethyl ester is produced when ethyl phenylpropiolate is dissolved in sulphuric acid and the product poured on to ice.

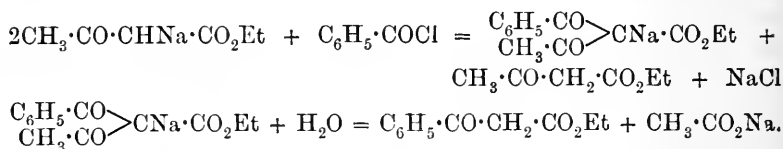

As far as we know, no explanation of the remarkable intramolecular change from ethyl *o*-nitrophenylpropiolate to ethyl isatogenate has ever been published, but the following series of changes has always appeared to one of us to be a possible explanation.

Just as ethyl phenylpropiolate when acted on by sulphuric acid takes up the elements of water yielding ethyl benzoylacetate, so in the case of ethyl *o*-nitrophenylpropiolate the first product of the reaction is probably ethyl *o*-nitrobenzoylacetate, which is then converted into ethyl isatogenate by an internal condensation brought about by the excess of sulphuric acid present :

During the course of a long series of researches on ethyl benzoylacetate, carried out some years ago, many attempts were made to prepare ethyl *o*-nitrobenzoylacetate, not only with the object of testing the above view of the mechanism of the formation of ethyl isatogenate, but also on account of the close relationship which exists between ethyl *o*-nitrobenzoylacetate and many members of the indigo group. The attempts were, however, all unsuccessful at the time.

In 1896 (*Annalen*, 291, 67) Claisen described a very convenient method for preparing ethyl benzoylacetate, which consists in acting on two molecules of ethyl sodioacetoacetate with benzoyl chloride and then decomposing the sodium compound of ethyl benzoylacetate thus produced by boiling with ammonia and ammonium chloride :

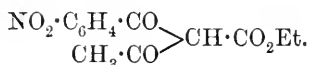

This process gives an excellent yield, and is not only much simpler than the preparation from ethyl phenylpropiolate and sulphuric acid, but is also to be preferred to the earlier method of Claisen and Lowman (*Ber.*, 1887, 20, 653) which consists in acting on a mixture of ethyl benzoate and ethyl acetate with sodium.

After experimenting with Claisen's process with very satisfactory results, we endeavoured to prepare ethyl *o*-nitrobenzoylacetate by a similar series of reactions, and were ultimately successful. When the ethyl sodioacetoacetate is treated with *o*-nitrobenzoyl chloride under the conditions described in the experimental part of this paper, the sodium compound of ethyl *o*-nitrobenzoylacetate,

is produced, and, when this is decomposed with hydrochloric acid, a red oil is obtained, which consists of nearly pure ethyl *o*-nitrobenzoylacetate,

This substance is not new, but has already been prepared by Gevekoht (*Annalen*, 1883, 221, 323), who proved its constitution by showing that, when boiled with dilute sulphuric acid, it yields *o*-nitroacetophenone,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CH}_3$ . When the sodium compound of ethyl *o*-nitrobenzoylacetate is digested with ammonia and ammonium chloride, it is decomposed with the elimination of the acetyl group, and a red oil is produced which is crude *ethyl o*-nitrobenzoylacetate,

This is readily purified by conversion into the green, crystalline, copper compound,  $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CHCu}\cdot\text{CO}_2\text{Et}$ , and is thus obtained as a pale reddish-brown oil, which in its properties closely resembles ethyl benzoylacetate.

Experiments were next made on the action of concentrated sulphuric acid on ethyl *o*-nitrobenzoylacetate in the expectation that ethyl isatogenate would result, but we found, to our surprise, that the sulphuric acid had simply acted as a hydrolysing agent, and that the product of the action was *o*-nitrobenzoylactic acid,

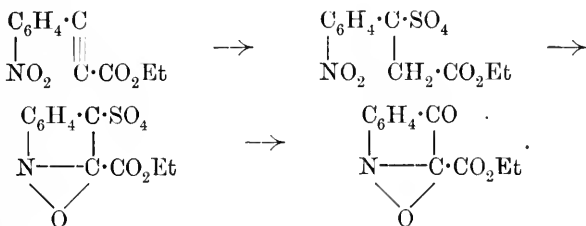

Even when the ester was heated with sulphuric acid at 90°, large

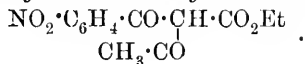

quantities of *o*-nitrobenzoylactic acid were formed, showing clearly that under these conditions there is no tendency for internal condensation to take place between the nitro-group and the methylene radicle.

The experiments described in this paper clearly prove that ethyl *o*-nitrobenzoylacetate is not an intermediate step in the conversion of ethyl *o*-nitrophenylpropiolate into ethyl isatogenate, and the problem of the mechanism of this remarkable reaction therefore remains unsolved.

In this conversion of ethyl *o*-nitrophenylpropiolate into ethyl isatogenate, it is possible that an additive compound with sulphuric acid may first be formed, this substance then undergoing internal condensation to yield a product, which, when decomposed with water, gives rise to ethyl isatogenate:

*Preparation of Ethyl o-Nitrobenzoylacetate,*

In preparing considerable quantities of this ester, we used a process based on the conditions recommended by Claisen (*Annalen*, 1896, 291, 67) for the preparation of ethyl benzoylacetate, and which differs in many respects from that described by Gevekoht (*Annalen*, 1883, 221, 323). *o*-Nitrobenzoic acid (100 grams) contained in a fractionating flask is gradually mixed with phosphorus pentachloride (135 grams), and as soon as the reaction, which commences in the cold, has slackened, the whole is heated on the water-bath until the crystals of the acid have entirely dissolved. The flask is then connected with the vacuum apparatus, and the phosphorus oxychloride distilled off at the lowest possible temperature. Sodium (31 grams) is now dissolved in 400 grams of absolute alcohol, and the solution made up to 500 c.c. by the addition of more alcohol. Pure ethyl acetoacetate (90 grams) is mixed with 250 c.c. of the sodium ethoxide solution, the whole cooled to 0°, and 56 grams of the *o*-nitrobenzoyl chloride added in small quantities at a time and with frequent shaking, care being taken that the temperature does not rise above 5°. After half an hour, 125 c.c. of the sodium ethoxide solution are added, and, after

thoroughly mixing, 28 grams of the acid chloride run in under the same conditions as before, then the whole is again left for half an hour and treated with the rest of the sodium ethoxide and *o*-nitrobenzoyl chloride. After remaining overnight at the ordinary temperature, the thick, yellow precipitate, which consists of the sodium compound of ethyl *o*-nitrobenzoylacetoacetate mixed with sodium chloride, is collected at the pump, and washed first with alcohol, and then with ether. It is then added to excess of dilute hydrochloric acid, cooled by the addition of powdered ice, and the whole shaken thoroughly with ether. The ethereal solution is washed with dilute aqueous sodium hydrogen carbonate, dried over calcium chloride, and evaporated, when a brownish-red oil is obtained which consists of nearly pure ethyl *o*-nitrobenzoylacetoacetate.

0.1696 gave 8.0 c.c. of nitrogen at 20° and 750 mm.  $N = 5.3$ .

$C_{13}H_{13}O_6N$  requires  $N = 5.0$  per cent.

Ethyl *o*-nitrobenzoylacetoacetate is a reddish-brown oil which gives a reddish-violet coloration when its solution in alcohol is mixed with ferric chloride. It dissolves in dilute aqueous caustic potash, and on adding a concentrated solution of this reagent a crystalline potassium compound,  $C_{13}H_{12}O_6NK$ , separates (compare Gevekoht, *loc. cit.*).

*Ethyl o-Nitrobenzoylacacetate*,  $NO_2 \cdot C_6H_4 \cdot CO \cdot CH_2 \cdot CO_2Et$ .

In the preparation of ethyl *o*-nitrobenzoylacacetate from ethyl *o*-nitrobenzoylacetoacetate, a method similar to that employed by Claisen (*loc. cit.*) in analogous cases, was adopted.

The crude sodium compound of ethyl *o*-nitrobenzoylacetoacetate, in quantities of 100 grams, was mixed with a solution of ammonium chloride (25 grams) in water (500 c.c.); 10 c.c. of concentrated aqueous ammonia, diluted with 90 c.c. of water, were then added, and the mass vigorously stirred with a turbine. As soon as the sodium compound had completely dissolved, the whole was mixed with powdered ice, acidified with hydrochloric acid, and at once extracted with ether. After washing with water, drying over anhydrous sodium sulphate and evaporating, crude ethyl *o*-nitrobenzoylacacetate remains as a brown oil, the yield being about 50 grams. This ester was purified in the following way. A solution of the blue cuprammonium compound, prepared by adding ammonia in slight excess to copper sulphate, was placed in a strong bottle, mixed with the crude ethyl *o*-nitrobenzoylacacetate dissolved in ten times its volume of ether, and vigorously shaken on the machine for 6 hours; the deep green copper compound, which had separated, was collected and washed, first with water and then with ether. After drying in a vacuum desiccator, the copper compound was

rapidly dissolved in excess of boiling toluene, from which it separates usually as a green powder, but if the crystallisation takes place very slowly and from dilute solutions, the substance is sometimes obtained in the form of definite violet crystals. When heated, this compound explodes with the formation of a thick, brown smoke, a behaviour which rendered its analysis very difficult. Ultimately the substance was first decomposed by gently warming with concentrated sulphuric acid, and, after driving off the excess of sulphuric acid, the residue was heated over the blowpipe, but, even in this way, a slight loss was unavoidable.

0.3050 gave 0.0406 CuO. Cu = 10.7.

0.4172 „ 0.0568 CuO. Cu = 11.0.

$\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{CHCu} \frac{1}{2} \cdot \text{CO}_2\text{Et}$  requires Cu = 11.8 per cent.

In order to obtain pure ethyl *o*-nitrobenzoylacetate, the copper compound was ground to a fine paste with water, mixed with powdered ice, and decomposed by shaking with dilute hydrochloric acid and ether. The ethereal solution was washed thoroughly with water and dilute aqueous sodium hydrogen carbonate, dried over anhydrous sodium sulphate, evaporated, and the residual light brown oil left in a vacuum desiccator over sulphuric acid for two days.

0.1481 gave 0.3034  $\text{CO}_2$  and 0.0641  $\text{H}_2\text{O}$ . C = 55.8 ; H = 4.8.

0.2459 „ 12.2 c.c. of nitrogen at  $17^\circ$  and 754 mm. N = 5.9.

$\text{C}_{11}\text{H}_{11}\text{O}_5\text{N}$  requires C = 55.7 ; H = 4.6 ; N = 5.9 per cent.

*Ethyl o*-nitrobenzoylacetate has, so far, not been obtained in a crystalline condition ; when cooled to  $-10^\circ$ , it solidifies to a transparent resin which does not crystallise on rubbing. The alcoholic solution gives, with ferric chloride, an intense orange-red coloration which has a much yellower tint than that shown by either ethyl *p*- or *m*-nitrobenzoylacetate. It dissolves readily and completely in dilute caustic potash solution, forming an intense yellow solution, and is reprecipitated on the addition of acids, but if the yellow solution is mixed with concentrated aqueous caustic potash, a deep yellow, viscid oil separates, which when stirred vigorously, solidifies to a yellow cake of crystals, consisting of the *potassium* derivative of *ethyl o*-nitrobenzoylacetate,  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{CHK} \cdot \text{CO}_2\text{Et}$ . This product was drained on porous porcelain, rubbed up with a little water, and again transferred to porous porcelain, and after repeating this process, it was dried at  $100^\circ$  and analysed with the following result :

0.1450 gave 0.0466  $\text{K}_2\text{SO}_4$ . K = 14.4.

$\text{C}_{11}\text{H}_{10}\text{O}_5\text{NK}$  requires K = 14.2 per cent.

This potassium compound dissolves readily in water and when

acidified and extracted with ether, pure ethyl *o*-nitrobenzoylacetate is obtained as an almost colourless oil. When ethyl *o*-nitrobenzoylacetate is dissolved in dilute aqueous caustic soda and a strong solution of caustic soda added, the sodium compound is precipitated, but it is much more soluble than the potassium compound, and was not further investigated. Attempts were made to prepare the pure sodium compound by adding ether to the solution of the ester in the calculated quantity of sodium ethoxide, but no separation took place. If the same experiment is carried out with either ethyl *p*- or *m*-nitrobenzoylacetate, the sodium compound separates at once as a deep yellow, crystalline precipitate.

*o*-Nitrobenzoylactic acid,  $\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}$ .

When ethyl *o*-nitrobenzoylacetate dissolves in concentrated sulphuric acid heat is generated, and the dark brown solution, when left for two or three days and then diluted with powdered ice, yields a brown solid which becomes almost colourless when drained on porous porcelain. The solid residue, which consists of almost pure *o*-nitrobenzoylactic acid, may be crystallised from water if the operation is rapidly carried out, but otherwise there is a great loss owing to decomposition into *o*-nitroacetophenone and carbon dioxide. The colourless needles thus obtained were dried over sulphuric acid and analysed with the following results:

0.1756 gave 0.3351  $\text{CO}_2$  and 0.0575  $\text{H}_2\text{O}$ .  $\text{C} = 52.0$ ;  $\text{H} = 3.4$ .

0.2274 „ 13.2 c.c. of nitrogen at  $16^\circ$  and 760 mm.  $\text{N} = 6.7$ .

$\text{C}_9\text{H}_7\text{O}_5\text{N}$  requires  $\text{C} = 51.7$ .  $\text{H} = 3.3$ ;  $\text{N} = 6.7$  per cent.

*o*-Nitrobenzoylactic acid melts at about  $117\text{--}120^\circ$  with vigorous decomposition, evidently yielding carbon dioxide and *o*-nitroacetophenone. It is readily soluble in alcohol and almost insoluble in cold, light petroleum; it dissolves moderately readily in warm benzene, and crystallises on cooling in colourless needles. The alcoholic solution of the pure acid gives a deep red coloration with ferric chloride. The composition of the acid was further controlled by titration, when it was found that 0.177 gram required for neutralisation 0.0335 gram of caustic soda, whereas this amount of a monobasic acid,  $\text{C}_9\text{H}_7\text{O}_5\text{N}$ , should neutralise 0.0339 gram of the alkali.

In order to study the decomposition products of *o*-nitrobenzoylactic acid, 3 grams of the pure acid were boiled with water, when a brisk effervescence took place, due to the evolution of carbon dioxide, and a heavy oil separated. This was extracted with ether, the ethereal solution washed with dilute aqueous sodium carbonate, dried over calcium chloride and evaporated, when an oil remained which was identified as *o*-nitroacetophenone.

0.1601 gave 11.9 c.c. of nitrogen at 15° and 745 mm.  $N = 8.4$ .

$C_8H_7O_3N$  requires  $N = 8.5$  per cent.

Five grams of pure ethyl *o*-nitrobenzoylacetate were dissolved in 20 c.c. of concentrated sulphuric acid and heated in a water-bath at 90° for 10 minutes. On cooling and diluting with ice, a solid soon separated which consisted of nearly pure *o*-nitrobenzoylacetic acid, and was finally purified in the manner already described.

0.2251 gave 13.1 c.c. of nitrogen at 15° and 750 mm.  $N = 6.8$ .

$C_9H_7O_5N$  requires  $N = 6.7$  per cent.

This experiment shows that the ethyl ester when heated with concentrated sulphuric acid is simply hydrolysed without undergoing any internal condensation.

## XVII.—*The cis- and trans-Modifications of ααγ-Tri-methylglutaconic Acid.*

By WILLIAM HENRY PERKIN, jun., and ALICE EMILY SMITH, B.Sc.,  
1851 Exhibition Scholar of University College, Bangor.

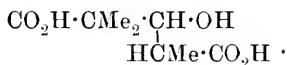

IN a recently published paper (Trans., 1903, 83, 772), it was shown that when ethyl *ααγ*-trimethylacetonedicarboxylate,

is reduced with sodium amalgam, it is converted into a mixture of the stereoisomeric modifications of *β*-hydroxy-*ααγ*-trimethylglutaric acid,

*Cis*, m. p. 115°.

*Trans*, m. p. 155°.

Both the *cis*- and *trans*-acids, when treated successively with phosphorus pentachloride and diethylaniline, yield *trans-ααγ*-trimethylglutaconic acid, which melts at 150°:

The *trans*-hydroxy-acid, when rapidly heated in small quantities, distils without decomposition, whereas the *cis*-hydroxy-acid is readily decomposed on distillation, forming an oily acid (see below) and a neutral crystalline substance,  $C_8H_{10}O_3$  (m. p. 88°), and it was suggested

that this latter is probably the anhydride of the *cis*-modification of  $\alpha\gamma$ -trimethylglutaconic acid:

We have continued the investigation, and find that this view of the constitution of the substance  $\text{C}_8\text{H}_{10}\text{O}_3$  is correct. It is insoluble in aqueous sodium carbonate, but dissolves in warm dilute alkalis, and the solution, on acidifying and extracting with ether, yields *cis*- $\alpha\gamma$ -trimethylglutaconic acid,  $\begin{array}{c} \text{CO}_2\text{H}\cdot\text{CMe}_2\cdot\text{CH} \\ \text{CO}_2\text{H}\cdot\text{CMe}_2\cdot\text{H} \end{array}$ , as a colourless, crystalline substance which melts at  $125^\circ$ .

When this acid is treated with bromine, it is readily converted into *cis*- $\beta\gamma$ -dibromo- $\alpha\gamma$ -trimethylglutaric acid,

which melts at  $168^\circ$  and is isomeric with the corresponding *trans*-acid described in the previous paper (*loc. cit.*, p. 779). It was stated above that the *trans*-hydroxy-acid, when heated in small quantities, distils with little decomposition, and we now find that, when considerable quantities of the acid are slowly heated, decomposition sets in, and a semi-solid distillate is obtained which consists of the above-mentioned anhydride of *cis*-trimethylglutaconic acid and an oily acid boiling at about  $213^\circ$ .

The latter is *crotonyldimethylacetic acid*, produced from  $\alpha\gamma$ -trimethylglutaconic acid by the elimination of carbon dioxide according to the equation:

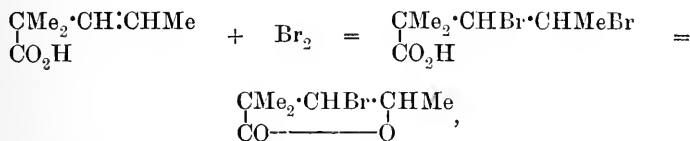

Crotonyldimethylacetic acid is also formed in considerable quantities during the preparation of the anhydride of *cis*-trimethylglutaconic acid by the distillation of *cis*-hydroxytrimethylglutaric acid (see above). It is an unsaturated acid which, when digested with dilute sulphuric acid, is converted into the lactone of  $\gamma$ -hydroxy- $\alpha\gamma$ -trimethylbutyric acid,

a substance which has already been described by Anschütz and Gillet (*Annalen*, 1888, 247, 107), who obtained it from *aa*-dimethylævulic acid,  $\text{CO}_2\text{H}\cdot\text{CMe}_2\cdot\text{CH}_2\cdot\text{COMe}$ , by reduction with sodium amalgam and named it  $\alpha$ -dimethylvalerolactone.

When crotonyldimethylacetic acid is treated with bromine, the colour rapidly disappears, but, even at low temperatures and in the dark, hydrogen bromide is eliminated. The product of this reaction—

a neutral, crystalline substance melting at  $83^\circ$ —is evidently the *lactone* of  $\beta$ -bromo- $\gamma$ -hydroxy- $\alpha\alpha\gamma$ -trimethylbutyric acid, produced in the following way :

but the ease with which the dibromo-acid loses hydrogen bromide is very unusual.

*cis- $\alpha\alpha\gamma$ -Trimethylglutaconic Acid*,  $\text{CO}_2\text{H} \cdot \text{CMe}_2 \cdot \text{CH} : \text{CMe} \cdot \text{CO}_2\text{H}$ .

In preparing this acid, pure *cis*-hydroxytrimethylglutaric acid was rapidly distilled in small quantities and under the ordinary pressure, when carbon dioxide and water vapour were given off and an oily distillate was obtained, which, on cooling, became semi-solid; this mass was cooled in a freezing mixture and collected at the pump on a funnel surrounded with ice and salt, the residue being then left in contact with porous porcelain until the oily impurity had been completely absorbed. By recrystallisation from light petroleum, colourless needles were obtained which melted at  $88^\circ$ .

0.1239 gave 0.2829  $\text{CO}_2$  and 0.0748  $\text{H}_2\text{O}$ .  $\text{C} = 62.7$ ;  $\text{H} = 6.7$ .

$\text{C}_8\text{H}_{10}\text{O}_3$  requires  $\text{C} = 62.3$ ;  $\text{H} = 6.5$  per cent.

The *anhydride* of *cis-trimethylglutaconic acid* is very readily soluble in chloroform and in ether, less so in cold benzene, and sparingly so in cold light petroleum. The solution in chloroform does not decolorise bromine, and when the benzene solution is mixed with aniline, no crystalline anilic acid separates. The anhydride is almost insoluble in cold water, but it dissolves on warming and is not at once hydrolysed, since, if the solution is rapidly cooled and shaken, a considerable amount of the anhydride crystallises out unchanged. It is insoluble in cold sodium carbonate solution, but dissolves readily in warm dilute aqueous caustic potash, and on acidifying a clear solution is obtained. In order to isolate the very readily soluble *cis*-acid, the liquid was saturated with ammonium sulphate, when the acid separated in needles; the whole was then extracted three times with ether, the ethereal solution dried over calcium chloride and evaporated, and the solid residue purified by recrystallisation from a very small quantity of water.

0.1507 gave 0.3103  $\text{CO}_2$  and 0.0945  $\text{H}_2\text{O}$ .  $\text{C} = 56.2$ ;  $\text{H} = 7.0$ .

$\text{C}_8\text{H}_{12}\text{O}_4$  requires  $\text{C} = 55.8$ ;  $\text{H} = 7.0$  per cent.

*cis*- $\alpha\alpha\gamma$ -Trimethylglutaconic acid melts at about  $125^\circ$  with evolution of gas and is readily soluble in water, chloroform, benzene, alcohol, or ether; its solution in aqueous sodium carbonate decolorises permanganate, but not instantaneously. When the acid is exposed to dry bromine vapour for about three hours and the excess of bromine removed over caustic potash in a vacuum desiccator, a solid residue is obtained which crystallises from formic acid (sp. gr. 1.22), in which it is very sparingly soluble, in hard, crystalline crusts. The analysis shows that this acid, which melts at about  $168^\circ$  with decomposition, is *cis*- $\beta\gamma$ -dibromo- $\alpha\alpha\gamma$ -trimethylglutaric acid,  $\text{CO}_2\text{H}\cdot\text{CMe}_2\cdot\text{CHBr}\cdot\text{CMeBr}\cdot\text{CO}_2\text{H}$ .

0.1929 gave 0.2180 AgBr. Br = 48.1.

$\text{C}_8\text{H}_{12}\text{O}_4\text{Br}_2$  requires Br = 48.2 per cent.

*Crotonyldimethylacetic Acid*,  $\text{CO}_2\text{H}\cdot\text{CMe}_2\cdot\text{CH}\cdot\text{CHMe}$ .

The oily filtrate, which had been separated from the crystals of the anhydride of *cis*-trimethylglutaconic acid, was dissolved in ether and the ethereal solution extracted with sodium carbonate, by which means the crotonyldimethylacetic acid is dissolved, whereas the above anhydride, which is still present in considerable quantities, remains in the ether.

After acidifying and extracting with ether, an oily acid was obtained which distilled at  $210$ — $220^\circ$ , and as this still contained traces of anhydride, the treatment with sodium carbonate was repeated and the acid again distilled, when almost the whole quantity passed over at  $213^\circ$  as a colourless oil having a penetrating and most disagreeable odour.

0.1291 gave 0.3088  $\text{CO}_2$  and 0.1101  $\text{H}_2\text{O}$ . C = 65.2; H = 9.4.

$\text{C}_7\text{H}_{12}\text{O}_2$  requires C = 65.6; H = 9.4 per cent.

When boiled with 25 per cent. sulphuric acid for a few minutes, crotonyldimethylacetic acid is readily and almost completely converted into the lactone of  $\gamma$ -hydroxy- $\alpha\alpha\gamma$ -trimethylbutyric acid,

The product was extracted with ether, the ethereal solution washed with dilute aqueous sodium carbonate, dried over calcium chloride, and evaporated, when a colourless oil remained, which smelt strongly of camphor and crystallised on cooling. The crystals, when left in contact with porous porcelain until quite dry, melted at  $48$ — $52^\circ$ .

0.1760 gave 0.4232  $\text{CO}_2$  and 0.1494  $\text{H}_2\text{O}$ . C = 65.5; H = 9.4.

$\text{C}_7\text{H}_{12}\text{O}_2$  requires C = 65.5; H = 9.4 per cent.

This lactone has already been prepared by Anschütz and Gillet

(*Annalen*, 1888, 247, 107,) who give  $52^\circ$  as the melting point. Crotonyldimethylacetic acid dissolves in chloroform, and if the solution is treated with bromine at the ordinary temperature the colour disappears, heat is generated, and a considerable quantity of hydrogen bromide is produced. This formation of hydrogen bromide cannot be avoided by keeping the chloroform solution in a blackened test tube at  $0^\circ$  and adding the bromine slowly. On allowing the product of bromination to evaporate spontaneously, a colourless residue is obtained, which crystallises from light petroleum (b. p.  $50-60^\circ$ ) in long prisms and melts at  $82-83^\circ$ .

0.3020 gave 0.2748 AgBr. Br = 38.8.

$C_7H_{11}O_2Br$  requires Br = 38.7 per cent.

As stated in the introduction, this substance is evidently the *lactone* of  $\beta$ -bromo- $\gamma$ -hydroxy- $\alpha\gamma$ -trimethylbutyric acid.

THE OWENS COLLEGE,  
MANCHESTER.

### XVIII.—*Derivatives of $\beta$ -Resorcylic Acid and of Protocatechuic Acid.*

By WILLIAM HENRY PERKIN, jun., and EMANUEL SCHIESS.

DURING the course of a long series of researches on the constitution of brazilin and hæmatoxylin, it was found necessary, for the purposes of comparison, to prepare and investigate several new derivatives of resorcinol and catechol, and in this paper we give a brief account of some of the compounds which were thus prepared.

*Dimethylresorcylic Acid*,  $(MeO)_2C_6H_3 \cdot CO_2H$ , and its *Methyl and Ethyl Esters*.

*Methyl dimethyl- $\beta$ -resorcylicate*,  $(MeO)_2C_6H_3 \cdot CO_2Me$ , is readily obtained when  $\beta$ -resorcylic acid is treated with caustic potash and methyl sulphate in aqueous solution. It is thus seen that the hydroxyl group in  $\beta$ -resorcylic acid, which is in the *o*-position with respect to the carbonyl group, may be methylated by means of aqueous caustic potash and methyl sulphate, whereas, as is well known, the hydroxyl group in the above position in this and other similar compounds is hardly attacked by the usual treatment with alcoholic potash and methyl iodide.

$\beta$ -Resorecylic acid (30 grams) is dissolved in 240 grams of 10 per

cent. aqueous caustic soda, and then methyl sulphate (65 grams) added in small quantities at a time. After each addition, the bottle containing the mixture is vigorously shaken on the machine and cooled, if necessary, no further quantity being added until the last portion has been completely decomposed. Care is also taken, by adding small quantities of strong caustic soda solution from time to time, that the liquid is always strongly alkaline. The oil which separates is extracted with ether, the ethereal solution washed with dilute aqueous caustic soda, dried over calcium chloride, and evaporated, and the residual oil fractionated under reduced pressure, when almost the whole distils at 160—162° (13 mm.). The boiling point of this oil under the ordinary pressure was observed to be 294—296°.

0.2261 gave 0.4978 CO<sub>2</sub> and 0.1126 H<sub>2</sub>O. C = 60.9 ; H = 6.1.

C<sub>10</sub>H<sub>12</sub>O<sub>4</sub> requires C = 61.2 ; H = 6.1 per cent.

The yield of methyl dimethyl-β-resorcyate (which does not appear to have been previously prepared) varies considerably, but is usually 30—40 per cent. of the theoretical. As, however, by acidifying the alkaline liquids, quantities of methyl- and dimethyl-β-resorcylic acids may be precipitated and used in a subsequent operation, the total yield from a given quantity of β-resorcylic acid is actually much greater than this. When the above methyl ester is boiled with alcoholic potash for a few minutes and the solution, after evaporating with water, acidified with hydrochloric acid, dimethyl-β-resorcylic acid separates at once, and after recrystallising melts at 108°.

*Ethyl Dimethyl-β-resorcyate*, (MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>·CO<sub>2</sub>Et.

This ester was prepared by boiling dimethyl-β-resorcylic acid with alcohol and sulphuric acid for about 6 hours, and then adding water and extracting with ether. After washing with sodium carbonate, drying over calcium chloride, and distilling off the ether, an oil was obtained which distilled constantly at 170° under 13 mm. pressure.

0.1337 gave 0.3080 CO<sub>2</sub> and 0.0826 H<sub>2</sub>O. C = 62.8 ; H = 6.9.

C<sub>11</sub>H<sub>14</sub>O<sub>4</sub> requires C = 62.9 ; H = 6.7 per cent.

*2:4-Dimethoxybenzoylacetophenone*, (MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>·CO·CH<sub>2</sub>·CO·C<sub>6</sub>H<sub>5</sub>.

This substance is produced by the condensation of ethyl β-resorcyate and acetophenone in the presence of sodium, and in our first experiments, which were carried out under ordinary conditions (see, for example, Kostanecki, Różycki, and Tambor, *Ber.*, 1900, **33**, 3413), great difficulty was experienced in isolating more than traces of the crystalline product of the reaction. On using, however, conditions

similar to those recommended by the Farbwerke vorm. Meister, Lucius, and Brüning (*Ber.*, 1890, 23, *Ref.* 40; see also Bülow and Riess, *ibid.*, 1902, 35, 3902), we were able to obtain an excellent yield of 2:4-dimethoxybenzoylacetophenone. Ethyl dimethyl- $\beta$ -resorcyate (21 grams) is dissolved in dry ether, mixed with acetophenone (12 grams) and treated with finely divided sodium (2.5 grams).<sup>\*</sup> Any rise of temperature is prevented by placing the flask in ice-water, the reaction is promoted by repeated shaking, and after two hours the flask is allowed to remain overnight at the ordinary temperature. The sodium gradually passes into solution and the sodium compound separates as a crystalline powder, the whole ultimately becoming a semi-solid mass. In order to isolate the dimethoxybenzoylacetophenone, the product is made slightly acid by the addition of dilute acetic acid, extracted with ether, the ethereal solution washed with dilute sodium carbonate solution and well agitated on the machine with aqueous copper acetate until no further separation of the green copper derivative takes place. This is collected at the pump, washed with water and alcohol, and purified by recrystallisation from benzene, from which the copper derivative of 2:4-dimethoxybenzoylacetophenone separates in slender, green needles containing one molecule of benzene of crystallisation.<sup>†</sup>

0.2335 gave 0.0259 CuO. Cu = 8.6.

$C_{34}H_{30}O_8Cu, C_6H_6$  requires Cu = 8.4 per cent.

After drying at 110° until constant, the following complete analysis was made:

0.1803 gave 0.4277 CO<sub>2</sub>, 0.0778 H<sub>2</sub>O, and 0.0226 CuO.

C = 64.7; H = 4.8; Cu = 10.0.

$C_{34}H_{30}O_8Cu$  requires C = 64.9; H = 4.8; Cu = 10.0 per cent.

The pure copper compound was then mixed with excess of dilute hydrochloric acid and the diketone extracted with ether, the ethereal solution was washed with water until free from copper, dried over calcium chloride, and evaporated, when an oil was obtained which rapidly solidified. The substance was further purified by recrystallisation from alcohol, from which it separates in plates.

0.1501 gave 0.3948 CO<sub>2</sub> and 0.0779 H<sub>2</sub>O. C = 71.7; H = 5.8.

$C_{17}H_{16}O_4$  requires C = 71.8; H = 5.7 per cent.

2:4-Dimethoxybenzoylacetophenone melts at 55° and is readily soluble

<sup>\*</sup> This condition is best obtained by melting the sodium under boiling toluene and then shaking vigorously.

<sup>†</sup> It is noteworthy that the copper derivative of 3:5-dimethoxybenzoylacetophenone also crystallises with one molecule of benzene (Bülow and Riess, *loc. cit.*).

in benzene, ether, and chloroform, more sparingly in alcohol and light petroleum. Its solution in alcohol gives with ferric chloride an intense reddish-brown coloration.

2 : 4-Dimethoxycinnamic Acid,  $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{CH}:\text{CH}\cdot\text{CO}_2\text{H}$ .

This acid was first obtained from umbelliferone by Will and Tiemann (*Ber.*, 1882, 15, 2080 ; 1883, 16, 2116) in two forms— $\alpha$ - and  $\beta$ -—which melt at  $138^\circ$  and  $184^\circ$  respectively, and obviously represent the *cis*- and *trans*-modifications of the acid. Since it was probable that we should require considerable quantities of this acid, a number of experiments were made with the object of preparing the substance synthetically, with the result that two methods were devised by which it may be readily obtained in quantity from dimethyl- $\beta$ -resorcyraldehyde.

*Method I. Preparation of 2 : 4-Dimethoxycinnamic Acid from Dimethyl- $\beta$ -resorcyraldehyde by the Action of Sodium Acetate and Acetic Anhydride.*

Dimethyl- $\beta$ -resorcyraldehyde (10 grams) is intimately mixed with anhydrous sodium acetate (10 grams) and heated with acetic anhydride (30 grams) in a reflux apparatus for 20 hours in an oil-bath at  $170^\circ$ . The brown mass is diluted with water and the excess of acetic acid removed by distillation in steam, the residue is then made alkaline by adding sodium carbonate, and allowed to remain until quite cold. The unchanged aldehyde which separates is filtered off, the filtrate acidified with hydrochloric acid, and the very sparingly soluble dimethoxycinnamic acid, which separates at once, collected and purified by recrystallisation from acetic acid. The acid thus obtained is the  $\beta$ -modification and melts at  $186^\circ$ .

0.1420 gave 0.3317  $\text{CO}_2$  and 0.0780  $\text{H}_2\text{O}$ .  $\text{C} = 63.7$  ;  $\text{H} = 6.1$ .

$\text{C}_{11}\text{H}_{12}\text{O}_4$  requires  $\text{C} = 63.5$  ;  $\text{H} = 5.8$  per cent.

*Method II. Preparation of Ethyl 2 : 4-Dimethoxycinnamate,  $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{CH}:\text{CH}\cdot\text{CO}_2\text{Et}$ , by the Condensation of Dimethyl- $\beta$ -resorcyraldehyde with Ethyl Acetate in the presence of Sodium.*

This ethyl ester was first prepared by the esterification of the acid with alcohol and sulphuric acid, and was thus obtained as a crystalline solid which melted at  $61^\circ$  and distilled at  $210\text{--}212^\circ$  under 13 mm. pressure. Subsequently it was discovered that it can be obtained directly, and in a yield of at least 80 per cent. of the theoretical amount, by

the general method devised by Claisen (*Ber.*, 1890, 23, 977), and which appears to be not nearly so well known as it deserves to be. Dimethyl- $\beta$ -resorcyraldehyde (16.6 grams) is dissolved in 30 grams of ethyl acetate (which has been carefully freed from water and alcohol) and then finely divided sodium (2.5 grams, see foot-note, p. 161) added all at once. The sodium begins to act immediately, and, after two hours in ice-water, the mixture is left overnight at the ordinary temperature, when all the sodium will have disappeared. The dark brown liquid is acidified with dilute acetic acid, extracted with ether, the ethereal solution well washed, dried over calcium chloride, and evaporated, when an oil is obtained which rapidly solidifies. In purifying this substance, it is best to distil the product first under reduced pressure, when almost the whole passes over at  $208\text{--}212^\circ$  (13 mm.), leaving only a small quantity of resinous matter in the retort. The distillate, which solidifies at once, is pure enough for most experiments, but for analysis the substance was recrystallised from light petroleum, from which it separated in slender needles melting at  $61^\circ$ .

0.1518 gave 0.3668  $\text{CO}_2$  and 0.0941  $\text{H}_2\text{O}$ . C = 65.9; H = 6.9.

$\text{C}_{13}\text{H}_{16}\text{O}_4$  requires C = 66.1; H = 6.8 per cent.

*Ethyl 2:4-dimethoxycinnamate* is readily soluble in alcohol, ether, or benzene, but sparingly so in cold light petroleum. Attempts were made to convert this ester into ethyl dimethoxyphenyl- $\alpha\beta$ -dibromopropionate by the action of bromine, but, so far, these have not been successful. When bromine is added to the chloroform solution of the ester, dark decomposition products are formed, and hydrogen bromide is evolved even at  $0^\circ$ . Possibly under different conditions, a method of avoiding this decomposition and substitution may be found, and further experiments with this end in view are in progress.

### 3:4-Dimethoxycinnamic Acid, $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{CH}:\text{CH}\cdot\text{CO}_2\text{H}$ .

The methyl ester of this acid is formed when 3:4-dihydroxycinnamic acid (caffeic acid) or either of its two isomeric 3- and 4-monomethyl derivatives,  $(\text{MeO})(\text{OH})\text{C}_6\text{H}_3\cdot\text{CH}:\text{CH}\cdot\text{CO}_2\text{H}$ , called respectively ferulic and isoferulic acids, is heated with methyl iodide and caustic potash in methyl alcoholic solution (Tiemann and Nagai, *Ber.*, 1878, 11, 652; Tiemann and Will, *ibid.*, 1881, 14, 959).

The melting point of the methyl ester is given as  $64^\circ$ , and that of the free acid as  $180\text{--}181^\circ$ . Although 2:4-dimethoxycinnamic acid (see p. 162) exists in two well-defined stereoisomeric forms, the 3:4-dimethoxy-acid has, so far, only been obtained in the one modification. In our experiments on the synthesis of 3:4-dimethoxycinnamic acid, we employed in the first instance an exactly similar

process to that described in the case of the 2:4-dimethoxy-acid, that is, we heated a mixture of 3:4-dimethoxybenzaldehyde (dimethylcatecholaldehyde) and sodium acetate with acetic anhydride. The yield of acid obtained was upwards of 50 per cent. of the aldehyde employed, and a good deal of the latter was recovered unchanged. 3:4-Dimethoxycinnamic acid melts at  $180^\circ$  and crystallises from acetic acid in needles; it is very sparingly soluble in water.

0.1439 gave 0.3358  $\text{CO}_2$  and 0.0739  $\text{H}_2\text{O}$ .  $\text{C} = 63.6$ ;  $\text{H} = 5.7$ .

$\text{C}_{11}\text{H}_{12}\text{O}_4$  requires  $\text{C} = 63.5$ ;  $\text{H} = 5.8$  per cent.

*Ethyl 3:4-Dimethoxycinnamate*,  $(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{CH}:\text{CH}\cdot\text{CO}_2\text{Et}$ .

When 3:4-dimethoxybenzaldehyde is condensed with ethyl acetate under the conditions described in the case of the preparation of the ethyl salt of the 2:4-dimethoxy-acid (p. 162) and the product purified by fractionation, ethyl 3:4-dimethoxycinnamate is readily obtained pure and in a yield of 85 per cent. of that theoretically possible. It crystallises from light petroleum in plates, melts at  $59^\circ$ , and distils at  $196\text{--}197^\circ$  under 13 mm. pressure.

0.1507 gave 0.3642  $\text{CO}_2$  and 0.0936  $\text{H}_2\text{O}$ .  $\text{C} = 65.9$ ;  $\text{H} = 6.9$ .

$\text{C}_{13}\text{H}_{16}\text{O}_4$  requires  $\text{C} = 66.1$ ;  $\text{H} = 6.8$  per cent.

It dissolves readily in alcohol, benzene, or chloroform, but is sparingly soluble in light petroleum.

*Ethyl 3:4-Dimethoxyphenyl- $\alpha\beta$ -dibromopropionate*,

$(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{CHBr}\cdot\text{CHBr}\cdot\text{CO}_2\text{Et}$ ,

and *3:4-Dimethoxyphenylpropionic Acid*,

$(\text{MeO})_2\text{C}_6\text{H}_3\cdot\text{C}:\text{C}\cdot\text{CO}_2\text{H}$ .

In its behaviour towards bromine, ethyl 3:4-dimethoxycinnamate shows much greater stability than the corresponding 2:4-dimethoxy-compound (p. 163), and this enabled us to prepare, without much difficulty, considerable quantities of the dibromo-additive product in a pure condition. Ethyl 3:4-dimethoxycinnamate (23.6 grams) is dissolved in chloroform (40 grams), the solution cooled with ice-water, and then 16 grams of bromine, dissolved in 30 grams of chloroform, gradually added. When the colour of the bromine has disappeared, the chloroform is removed at as low a temperature as possible, by distillation under reduced pressure, and the oily residue then solidifies to a hard, yellow, crystalline cake. After triturating with cold light petroleum and filtering at the pump, the substance is then crystallised from the same solvent.

0.2218 gave 0.2092 AgBr. Br = 40.2.

$C_{13}H_{16}O_4Br_2$  requires Br = 40.4 per cent.

*Ethyl 3:4-dimethoxyphenyl- $\alpha\beta$ -dibromopropionate* crystallises from light petroleum in colourless needles and melts at 110—111°; it is readily soluble in alcohol, ether, benzene, chloroform, or hot light petroleum, but sparingly so in the latter solvent in the cold.

*3:4-Dimethoxyphenylpropionic acid* is readily obtained when ethyl 3:4-dimethoxyphenyl- $\alpha\beta$ -dibromopropionate (1 mol.) is digested for 8 hours with a large excess of alcoholic potash (6 mols.). The product is evaporated on the water-bath to remove the bulk of the alcohol, the residue dissolved in water, and neutralised with hydrochloric acid. After filtering from a small quantity of dark resinous matter which usually separates, the clear solution is acidified, when the new acid is precipitated in white flocks. It is collected at the pump, washed thoroughly with water, dried on porous porcelain, and purified by recrystallisation from benzene.

0.1426 gave 0.3338  $CO_2$  and 0.0694  $H_2O$ . C = 63.9; H = 5.0.

$C_{11}H_{10}O_4$  requires C = 64.1; H = 4.8 per cent.

*3:4-Dimethoxyphenylpropionic acid* melts at 149° with decomposition and is readily soluble in alcohol, but sparingly so in cold benzene or chloroform; it dissolves very sparingly in hot water and is almost insoluble in the cold; it crystallises best from benzene, from which it separates in colourless, microscopic needles.

MANCHESTER.

## XIX.—*The Formation of Phloroglucinol by the Interaction of Ethyl Malonate with its Sodium Derivative.*

By CHARLES WATSON MOORE.

IN the year 1885, Baeyer made the important discovery that when ethyl malonate is heated with its sodium derivative at 145°, condensation takes place and a derivative of phloroglucinol is formed which melts at 104°, and which Baeyer considered was ethyl phloroglucinoltricarboxylate,  $C_6(OH)_3(CO_2Et)_3$  (*Ber.*, 1885, 18, 3457).

During the course of an investigation involving the use of ethyl malonate, the author was led to reinvestigate this matter, and has been able to prove that the substance formed under the conditions employed

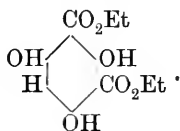

by Baeyer is ethyl phloroglucinoldicarboxylate,  $C_6H(OH)_3(CO_2Et)_2$ , and not the above-mentioned tricarboxylate.

Since the difference in percentage composition between these two esters is small (a fact which accounts for the mistakes which have arisen as to its composition), the molecular weight was determined in benzene solution by the cryoscopic method, and two determinations gave 270 and 273, whereas the molecular weights of the dicarboxylic and tricarboxylic esters are 270 and 342 respectively.

The determination of the ethoxyl groups, which was kindly carried out by Dr. W. H. Perkin, sen., in his new modification of Zeisel's apparatus (Trans., 1903, 83, 1367), also gave numbers which clearly show that the substance is a dicarboxylic ester.

When treated with bromine, it yields a bromo-compound having the composition  $C_6Br(OH)_3(CO_2Et)_2$ , which was first prepared by Oscar Bally (*Ber.*, 1888, 21, 1770), the process being a simple case of substitution of hydrogen by bromine, whereas Bally, who supposed that the original ester was the tricarboxylic ester, was forced to assume that, during bromination, elimination of ethyl bromide and carbon dioxide had taken place, in order to account for the composition of the bromo-compound. If then the product of the condensation of ethyl malonate with its sodium compound is the dicarboxylic ester, it follows that during the condensation, elimination of ethyl alcohol and carbon dioxide must have taken place, and, in proof of this, the author finds that the mixture invariably contains considerable quantities of sodium carbonate.

Since ethyl phloroglucinoldicarboxylate readily yields a triacetyl compound when heated with acetic anhydride, there can scarcely be a doubt that its constitution is represented by the formula :

*Ethyl Phloroglucinoldicarboxylate*,  $C_6H(OH)_3(CO_2Et)_2$ .

During this investigation, the above ester was repeatedly prepared according to the directions given by Baeyer (*loc. cit.*), but the purification was found to be tedious, for the compound, as Baeyer states, is yellow, and the alcoholic solution must be boiled for a long time with animal charcoal before the yellow colour can be removed. The pure ester, after repeated crystallisation, melted at  $107^\circ$  (Baeyer gives  $104^\circ$ ), and was analysed with the following result :

0.2014 gave 0.3944 CO<sub>2</sub> and 0.0948 H<sub>2</sub>O. C = 53.4; H = 5.2.

C<sub>6</sub>H(OH)<sub>3</sub>(CO<sub>2</sub>Et)<sub>2</sub> requires C = 53.3; H = 5.2 per cent.

C<sub>6</sub>(OH)<sub>3</sub>(CO<sub>2</sub>Et)<sub>3</sub> „ C = 52.6; H = 5.2 „

The analytical numbers given by Baeyer are C = 52.4; H = 5.2 per cent. As the difference in the percentage composition of the di- and tri-carboxylic esters is so small, the molecular weight was determined by the cryoscopic method, using benzene as the solvent. Two experiments gave the values 270 and 273, whereas the molecular weight of the dibasic ester, C<sub>12</sub>H<sub>14</sub>O<sub>7</sub>, is 270, and that of the tribasic ester, C<sub>15</sub>H<sub>18</sub>O<sub>9</sub>, is 342.

The view that the ester is ethyl phloroglucinoldicarboxylate received further confirmation from the determination of the ethoxyl groups by Dr. W. H. Perkin.\*

0.3436 gave 0.5641 AgI, corresponding with OEt = 31.5.

0.3504 „ 0.5807 AgI, „ „ „ = 31.8.

The dibasic ester, C<sub>12</sub>H<sub>14</sub>O<sub>7</sub>, contains OEt = 33.3 per cent.

The tribasic ester, C<sub>15</sub>H<sub>18</sub>O<sub>9</sub>, „ OEt = 39.4 „

*Ethyl Triacetylphloroglucinoldicarboxylate*, C<sub>6</sub>H(C<sub>2</sub>H<sub>3</sub>O<sub>2</sub>)<sub>3</sub>(CO<sub>2</sub>Et)<sub>2</sub>.

This substance, which has already been described by Oscar Bally (*Ber.*, 1888, 21, 1768), was prepared by his method. After repeated recrystallisation from alcohol, it was obtained as a colourless, crystalline mass which melted at 96° (the m. p. 75—76° given by Bally is evidently a clerical error).

0.1488 gave 0.2970 CO<sub>2</sub> and 0.0690 H<sub>2</sub>O. C = 54.4; H = 5.1.

C<sub>18</sub>H<sub>20</sub>O<sub>10</sub> requires C = 54.5; H = 5.0 per cent.

Bally found C = 53.9 and H = 5.0, a result which agrees fairly well with the above, but he assumed that his substance was the triacetyl compound of ethyl phloroglucinoltricarboxylate.

*Ethyl Bromophloroglucinoldicarboxylate*, C<sub>6</sub>Br(OH)<sub>3</sub>(CO<sub>2</sub>Et)<sub>2</sub>.

This substance was first obtained by Bally (*loc. cit.*) by treating the ester prepared by Baeyer's process with bromine in chloroform solution. In this preparation also, Bally's directions were carefully followed and the bromo-compound was obtained, exactly as he describes, in colourless needles melting at 128°. The results obtained on analysis were: C = 40.9; H = 3.7; Br = 22.8.

C<sub>12</sub>H<sub>13</sub>O<sub>7</sub>Br requires C = 41.2; H = 3.7; Br = 22.8 per cent.

\* The determination of ethoxyl groups always gives figures rather lower than the theoretical, the loss being apparently due to the conversion of a small amount of the ethyl iodide into ethylene during the process

The analytical results obtained by Bally agree fairly well with those just given, and it is curious that he should assume, in order to explain the composition of this bromo-compound, that, during the bromination, carbon dioxide and ethyl bromide are eliminated, thus converting ethyl phloroglucinoltricarboxylate into ethyl bromophloroglucinoldicarboxylate, whereas there is no indication of any such elimination of carbon dioxide.

That carbon dioxide is formed during the condensation of ethyl malonate with its sodium compound by the process recommended by Baeyer was proved by carrying out the operation in a flask fitted with a dropping funnel, and through which hydrogen was passing during the whole operation. On adding hydrochloric acid through the dropping funnel to the product and leading the gases through baryta water, it was at once seen that quantities of carbon dioxide were being evolved.

*Preparation of Ethyl Phloroglucinoldicarboxylate by Heating Ethyl Sodiomalonate with Ethyl Malonate in Alcoholic Solution.*

This method, which gives a pure product much more readily than that described by Baeyer, was carried out as follows.

Sodium (14.4 grams) is dissolved in alcohol (200 grams) and, when nearly cold, mixed with 200 grams of ethyl malonate. The mixture, while still warm, is transferred to soda-water bottles and heated in a boiling brine bath at 105—108° for 15 hours. The white precipitate, which separates during this operation, consists of the sodium compound of ethyl phloroglucinoldicarboxylate mixed with sodium carbonate; it is collected at the pump, washed with alcohol, and then dissolved in water acidified with hydrochloric acid, when carbon dioxide is evolved and the ester precipitated as an almost colourless crystalline mass. After one crystallisation from alcohol, the ester was perfectly colourless and melted at 106—107°.

0.1736 gave 0.3393  $\text{CO}_2$  and 0.0815  $\text{H}_2\text{O}$ .  $\text{C} = 53.3$ ;  $\text{H} = 5.2$ .

$\text{C}_6\text{H}(\text{OH})_3(\text{CO}_2\text{Et})_2$  requires  $\text{C} = 53.3$ ;  $\text{H} = 5.2$  per cent.

This ester yields phloroglucinol on hydrolysis, and its identity with the ester prepared by Baeyer's process was proved by mixing equal quantities of the two specimens when there was no alteration in the melting point.

The yield obtained in alcoholic solution is practically the same as that obtained by Baeyer's process, but a large amount of ethyl malonate may be recovered and used in a subsequent operation.

XX.—*The Resolution of dl-Methylhydrindamine. Isomeric Salts of d- and l-Methylhydrindamines with d-Chlorocamphorsulphonic Acid.*

By GEORGE TATTERSALL, B.Sc.

IN a recent communication (Tattersall and Kipping, Trans., 1903, 83, 918), a method was described by which *dl*-methylhydrindamine could be resolved into its enantiomorphously related components by the use of *d*-bromocamphorsulphonic acid. As the yield of these salts of the *d*- and *l*-bases was always small compared with the quantity of original material taken, and also varied considerably with the conditions of the experiment, the author, at Dr. Kipping's suggestion, attempted to find a more satisfactory process for the resolution of the *dl*-base.

Experiments then showed that *d*-tartaric acid is a more suitable agent with which to effect the resolution. When a solution of this acid is added to *dl*-methylhydrindamine in sufficient quantity to form the hydrogen tartrate and the product fractionated from water at the ordinary temperature, an excellent separation of the *d*- and *l*-bases is effected. The most sparingly soluble fractions, which contain the hydrogen tartrate of the *d*-base in a pure condition, amount to about one-third of the whole material.

The purification of the bases was carried out by converting the first fractions, containing chiefly the *d*-base, and the last fractions (the remaining two-thirds) into the *d*-bromocamphorsulphonates separately, and finally fractionating the products by crystallising from water.

The production of isomeric salts by the combination of *d*- and *l*-methylhydrindamines with *d*-bromocamphorsulphonic acid has been already described (Tattersall and Kipping, *loc. cit.*), and in this paper an account is given of similar experiments made with *d*-chlorocamphorsulphonic acid and the same bases.

The salt of each base, prepared from very carefully purified materials, was subjected to repeated fractional crystallisation and the final fractions examined. In both cases, the melting points of successive fractions were found to decrease from the first to the last, this behaviour corresponding with that observed in the case of the bromocamphorsulphonates. An important point of difference between the chlorocamphorsulphonates and the bromocamphorsulphonates, however, is that in the case of the former acid the specific rotations of the last fractions are higher than those of the first fractions, whereas with the latter acid the reverse is the case. These generalisations are true

both for aqueous and chloroform solutions. The following table summarises the results obtained :

*l*-Methylhydrindamine *d*-chlorocamphorsulphonate.

	M. p.	[ $\alpha$ ] <sub>D</sub> .	
		In chloroform.	In water.
First fraction	239°	+ 3.3°	+ 34.2°
Last     ,,	231—233°	8.0	35.8

*d*-Methylhydrindamine *d*-chlorocamphorsulphonate.

	M. p.	[ $\alpha$ ] <sub>D</sub> .	
		In chloroform.	In water.
First fraction	247°	+ 56°	+ 60°
Last     ,,	225—230°	63	63

These results are similar to those obtained with the hydrindamine *d*-chlorocamphorsulphonates (Kipping, Trans., 1903, 83, 902), but it was not found possible to isolate the isomerides of higher specific rotation.

#### EXPERIMENTAL.

About 30 grams of purified *dl*-methylhydrindamine *d*-bromocamphorsulphonate, obtained as previously described (Tattersall and Kipping, *loc. cit.*), was decomposed with barium hydroxide and the base distilled in steam. A solution of *d*-tartaric acid was added to the distillate until the latter was just acid, and then a further equal quantity of acid in order that the hydrogen tartrate might be produced. The solution was evaporated and the salt fractionally crystallised. The first deposit on recrystallisation was obtained in vitreous prisms, whilst the mother liquors slowly deposited clusters of small, opaque crystals. When the fractionation had proceeded so far that the first deposit had been twice crystallised, the first two fractions were examined. The first was found to be hydrated and when dried, melted at about 150°; the second was almost anhydrous and melted at 190° (approximately). The fractions were therefore different.

The first fraction, amounting to about one-fourth or one-third of the whole, was decomposed with caustic potash, the base distilled in steam, the distillate neutralised with *d*-bromocamphorsulphonic acid, and the solution evaporated and crystallised, when the salt of *d*-methylhydrindamine was obtained. The sparingly soluble fractions of the hydrogen tartrate therefore contain the *d*-base.

Owing to the difficulty usually experienced in obtaining a pure salt

from the mother liquors, and considering the great ease with which *dl*-methylhydrindamine *d*-bromocamphorsulphonate can be separated from the salt of the *d*- or *l*-base, the last fractions were decomposed with caustic potash, the base distilled in steam and combined with *d*-bromocamphorsulphonic acid. On crystallising, the salt of *l*-methylhydrindamine first separated and the salt of the *dl*-base was found in the mother liquors.

The *d*-base can, obviously, be obtained pure from the first deposits of the hydrogen tartrate, but the purification of the *l*-base was always carried out by converting the last fractions into the *d*-bromocamphorsulphonate.

By this process, about two-thirds of the original *dl*-base can be resolved into its enantiomorphously related components.

*d*-Methylhydrindamine Hydrogen Tartrate,  $C_{10}H_{13}N, C_4H_6O_6, 2H_2O$ .—This salt crystallises from water in long, vitreous, hydrated prisms which become opaque on warming in contact with a solution of the salt; it is moderately soluble in alcohol or water, but more sparingly so in the latter solvent than the corresponding salt of the *l*-base, and is practically insoluble in chloroform, ether, ethyl acetate, and light petroleum. The melting point of the dried salt is  $153-155^\circ$ , being somewhat indefinite owing to slight decomposition.

The water was estimated in air-dried samples by determining the loss of weight at  $100^\circ$ .

2.6761 lost 0.2868.  $H_2O = 10.7$ .

$C_{10}H_{13}N, C_4H_6O_6, 2H_2O$  requires  $H_2O = 10.8$  per cent.

The specific and molecular rotations were determined in aqueous solution with samples of the anhydrous salt, 20 c.c. of solution being used.\*

Weight of salt.	$\alpha_D$ .	$[\alpha]_D$ .	$[M]_D$ .
0.5376	+1.74°	+32.4°	+98.0°
0.5925	1.99	33.6	99.7

As the molecular rotation of *d*-tartaric acid in the metallic hydrogen tartrates is  $[M]_D + 42^\circ$ , that of the base would be  $[M]_D + 57^\circ$ , a value which agrees very closely with that ( $[M]_D + 60^\circ$ ) previously determined from an examination of the *d*-bromocamphorsulphonates (Tattersall and Kipping, *loc. cit.*).

*l*-Methylhydrindamine Hydrogen Tartrate,  $C_{10}H_{13}N, C_4H_6O_6$ .—This salt crystallises from water in aggregates of small, vitreous, anhydrous prisms, which are readily soluble in water, sparingly so in

\* A 200 mm. tube was used in all the polarimetric observations recorded in this paper.

alcohol, and practically insoluble in chloroform, ethyl acetate, ether, and light petroleum; it melts at  $197^{\circ}$  with slight decomposition. The specific and molecular rotations were determined in aqueous solution with samples dried at  $100^{\circ}$ , 20 c.c. of solution being used.

Weight of salt.	$\alpha_D$ .	$[\alpha]_D$ .	$[M]_D$ .
0.7076	- $0.36^{\circ}$	- $5.0^{\circ}$	- $14.8^{\circ}$
0.6649	0.32	4.8	14.3

In this case, also, the calculated value for the molecular rotation of the *l*-base, namely,  $[M]_D - 56.5^{\circ}$ , agrees closely with that previously deduced from the optical examination of the *d*-bromocamphorsulphonates.

*l*-Methylhydrindamine *d*-Chlorocamphorsulphonate,  
 $C_{10}H_{13}N, C_{10}H_{14}OCl \cdot SO_3H$ .

This salt was prepared in the usual way, the *l*-methylhydrindamine being carefully purified by the crystallisation of its *d*-bromocamphorsulphonate. The product was subjected to prolonged fractional crystallisation from water and separated into eight fractions. At the conclusion of the fractionation, the melting points of the several fractions were determined, those of the first and last fractions being  $239^{\circ}$  and  $231-233^{\circ}$  respectively. The other fractions each melted over a range of  $2-3^{\circ}$ , the values gradually decreasing from the melting point of the first fraction to that of the last. These fractions all crystallised in anhydrous needles resembling the corresponding salt with *d*-bromocamphorsulphonic acid.

The first and last fractions were dried at  $100^{\circ}$  and examined polarimetrically in chloroform and aqueous solutions.

*First Fraction.*

Weight of salt.	Solvent.	Vol. of solution.	$\alpha_D$	$[\alpha]_D^*$	$[M]_D$
I. 0.3496	Chloroform	20 c.c.	+ $0.12^{\circ}$	+ $3.4^{\circ}$	+ $14.0^{\circ}$
II. 0.3351	"	"	0.11	3.28	13.5
I. 0.3496	Water	"	1.19	34.1	140.8
II. 0.3351	"	"	1.15	34.3	141.6

*Last Fraction.*

I.	0.3294	Chloroform	20 c.c.	+ $0.27^{\circ}$	+ $8.2^{\circ}$	+ $33.8^{\circ}$
II.	0.3327	"	"	0.26	7.8	32.2
I.	0.3294	Water	"	1.18	35.8	147.8
II.	0.3327	"	"	1.19	35.8	147.8

It will be noticed that the specific rotations of the last fraction are higher than those of the first both in chloroform and in aqueous solutions. This conclusively proves that the observed difference in rotation cannot be due to any impurity, although the absence of the latter was independently proved, as in all previous experiments. The existence of isomeric salts is therefore established in this case.

*d*-Methylhydrindamine *d*-Chlorocamphorsulphonate,  
 $C_{10}H_{13}N, C_{10}H_{14}OCl \cdot SO_3H$ .

*d*-Methylhydrindamine, purified by the crystallisation of its bromocamphorsulphonate, was combined with *d*-chlorocamphorsulphonic acid, the product subjected to fractional crystallisation from water, and the melting points of the successive fractions determined. The first fraction melted at  $247^\circ$  and the last at  $225-230^\circ$ .

The intermediate fractions had melting points which, extending over a small range, gradually decreased from the melting point of the first fraction to that of the last. These fractions all separated in anhydrous needles resembling the corresponding bromocamphorsulphonate. The first and last fractions were dried at  $100^\circ$  and examined polarimetrically in chloroform and aqueous solutions.

*First Fraction.*

Weight of salt.	Solvent.	Vol. of solution	$\alpha_D$ .	$[\alpha]_D$ .	$[M]_D$ .
I. 0.3912	Chloroform	20 c.c.	+ $2.20^\circ$	+ $56.2^\circ$	+ $231.1^\circ$
II. 0.3953	"	"	2.20	55.7	230.0
I. 0.4049	Water	"	2.44	60.2	248.6
II. 0.4012	"	"	2.41	60.1	248.2

*Last Fraction.*

I. 0.3696	Chloroform	20 c.c.	+ $2.35^\circ$	+ $63.6^\circ$	+ $262.6^\circ$
II. 0.3917	"	"	2.43	62.2	256.8
I. 0.3696	Water	"	2.34	63.4	261.8
II. 0.3917	"	"	2.44	62.4	257.7

In the foregoing tables, numbers I and II indicate different portions of the same sample of material.

The data show that the specific rotations of the last fraction are higher than those of the first, and for the same reasons as in previous cases, these results establish the existence of isomeric salts.

The materials used in this investigation were part of those

previously employed in a former research, and were provided out of a grant made by the Government Grant Committee of the Royal Society.

The author desires to express his thanks to Professor Kipping for the interest he has taken in this research.

UNIVERSITY COLLEGE,  
NOTTINGHAM.

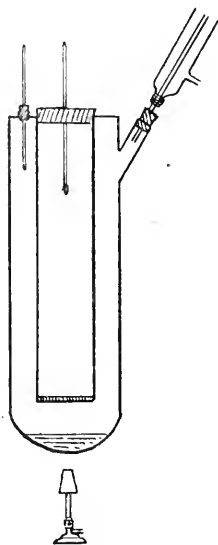

## XXI.—*The Influence of Substitution in the Nucleus on the Rate of Oxidation of the Side-chain. I. Oxidation of the Mono- and Di-chlorotoluenes.*

By JULIUS BEREND COHEN and JAMES MILLER.

ISOLATED observations on the effect of different oxidising agents, and on the influence of certain groups in accelerating or retarding oxidation of the side-chain, have been made by different observers, but the subject has never been systematically investigated. Wroblewsky (*Ber.*, 1882, 15, 1021), without giving experimental details, states that "if benzene with hydrocarbon side-chains in which hydrogen is replaced by a halogen or a nitro-group is submitted to oxidation by chromic acid mixture, those side-chains pass into carboxyl which are farthest from the halogen." Lellmann's *Organische Synthese*, p. 196, contains the following statement: "Negative atomic groups in the ortho-position protect the alkyl group from the action of oxidising agents, whereas alkaline oxidising agents attack this group." The exact reference is not given, but the statement is apparently based on that of Wroblewsky and also on certain observations of W. A. Noyes (*Amer. Chem. J.*, 1885, 7, 145; 1886, 8, 185; 1889, 11, 161). The latter investigator found that *o*-bromotoluene is oxidised with difficulty to *o*-bromobenzoic acid by means of potassium ferricyanide; also that *m*-nitrotoluene is less readily oxidised by this reagent than its isomerides. Schöpff (*Ber.*, 1891, 24, 3778) concludes from the results of his attempts to oxidise *o*-bromo-*m*-xylene that "the oxidation of a methyl group in the ortho-position (to bromine) with acid oxidising agents is effected slowly and with difficulty." Rupp (*Ber.*, 1892, 25, 347) experienced the same difficulty with tetrachloro- and tetrabromo-*p*-xylenes, and only succeeded with a mixture of nitric acid and permanganate. It is clear that no satisfactory generalisation can be drawn from these isolated facts. Certain points which were noticed in the course

of the researches in which one of us has been engaged in collaboration with H. D. Dakin (Trans., 1901, 79, 1111) and with S. H. C. Briggs (Trans., 1903, 83, 1213) on the oxidation of the halogen derivatives of toluene suggested the present inquiry.

The method which we have adopted is to heat about a gram of the substance with dilute nitric acid in a sealed tube for a length of time insufficient for complete oxidation, and to estimate the proportion of acidic product and unchanged substance. In our first experiments, the substance was weighed in small specimen tubes which were slipped into the tube containing the acid. The sealed tubes were heated in a cylindrical, jacketed, tin-plate air-bath which was fixed horizontally, the required temperature being attained by boiling turpentine contained in the outer jacket. The results of the experiments with this apparatus were not concordant. We attributed this partly to the specimen tubes, which to some extent protected the substance from the action of the acid. These tubes were therefore discarded and the substance introduced directly into the acid. We found, moreover, that the inner compartment of the air-bath was about  $5^{\circ}$  hotter at the bottom than at the top, so that the lower tubes were at a higher temperature than the upper ones. The horizontal air-bath was therefore replaced by a vertical one, jacketed as before, and covered with flannel as shown in the figure.

The liquid in the jacket was coal-tar naphtha boiling at  $140\text{--}150^{\circ}$ . Although there was still a difference of about  $3^{\circ}$  between the temperature of the top and bottom of the inner compartment, yet as the tubes, which were approximately of equal length, were placed vertically, they were consequently exposed to the same conditions of temperature.

Care was taken to prevent direct contact between the tubes and the metal of the bath by fixing a cork pad at the bottom and covering the tubes with flannel. Under these modified conditions, concordant results were obtained. The substances employed were the three monochlorotoluenes and the six dichlorotoluenes, all of which were carefully purified by fractional distillation, and in the case of 3:5-dichlorotoluene by crystallisation. The monochlorotoluenes were obtained quite colourless by distillation under diminished pressure, but this treatment was not found necessary in the case of the dichlorotoluenes.

The following are the boiling points of the substances employed:

Monochlorotoluenes.			Dichlorotoluenes.		
	b. p.	mm.		b. p.	b. p.
Ortho-	100°	129	2:3-	200—202°	2:6- 192—194°
Meta-	102	130	2:4-	194·5—195·5	3:4- 203—204
Para-	85	61	2:5-	195—197	3:5- m. p. 26—27

A weighed quantity of the substance (about 1 gram) was introduced into the tube, and about six times this amount of dilute acid (1 vol. nitric acid of sp. gr. 1·4 to 2 vols. water) was added and the tube sealed.

In order to ascertain the effect of the length of the tube on the rate of oxidation, equal quantities of 3:5-dichlorotoluene were heated in two tubes, one of which was about half the length of the other. It was found that the acid formed in the shorter tube was less pure and rather larger in amount, but the difference was insignificant and would be inappreciable in tubes so nearly of the same length as those which we employed.

The air-bath was closed loosely by a cork holding a thermometer and heated until the temperature was constant. The tubes were then introduced, and when the temperature of the inner compartment reached 138—140° the tubes were left for 1½ hours, during which the temperature of the interior did not exceed 145°. The bath was then allowed to cool and the tubes removed and opened. The method of analysis was as follows: the contents of each tube were in turn rinsed into a separating funnel with ether, the contents being then vigorously shaken, whereby the ether dissolved out the whole of the organic compounds. The acid layer was then drawn off and sodium carbonate solution added in excess to the ether and well shaken to extract the organic acid. The alkaline layer was removed and the ethereal extract washed with a small quantity of water, the washings being added to the alkaline liquid. The ethereal solution, which contained the unaltered substance (possibly also a little aldehyde), was dehydrated over calcium chloride, decanted into a tared flask, the ether removed, and the residue weighed. The alkaline liquid was acidified with hydrochloric acid, extracted with ether, the ethereal solution dehydrated over calcium chloride and treated as described above. The purity of the acid was in each case ascertained from the melting point. This and the total quantity of products obtained when compared with the substance taken was a satisfactory check on the result, although, of course, the method lacks the precision of an exact analytical process.

In the following experiments, all the tubes were heated together under precisely the same conditions.

*1st Series.*

Chloro- toluene.	Actual amount taken.	Calculated to 1 gram.			m. p. of acid.	Correct m. p. of acid.
		Chloro- benzoic acid.	Unchanged substance.	Total.		
Ortho-	1·005	1·011	0·040	1·051	135—136°	137°
Meta-	0·989	1·092	0·029	1·121	145—148	153
Para-	0·964	1·058	0·019	1·077	233—234	236
2:3-	1·032	0·942	0·135	1·077	159—162	163
2:4-	1·035	1·073	0·051	1·124	160—161	160
2:5-	1·065	0·864	0·157	1·021	139—142	153
2:6-	1·036	0·825	0·236	1·061	123—132	139—140
3:4-	1·024	1·060	0·047	1·107	200—201	200—201
3:5-	1·046	0·726	0·297	1·023	183—184	182—183
3:5- (short tube)	0·988	0·759	0·228	0·987	184—205	

It will be seen from the above table that the monohalogen compounds are more rapidly attacked than the majority of the dihalogen derivatives, for the former are almost completely converted into acid, whilst only two of the latter are completely oxidised. The dihalogen compounds show well-marked differences; the 3:5-compound is least attacked. The next in order being the 2:5- and 2:6-isomerides, which are oxidised to approximately the same extent, although the 2:6-compound yields a very impure acid. The 2:3-compound comes next, and finally the 2:4- and 3:4-derivatives, which may be bracketed together as being almost completely oxidised.

As the monohalogen compounds were too far oxidised for any conclusions to be drawn as to their relative rates of oxidation, a second experiment was made in which the tubes were heated for only half an hour at 140—145°.

# 178 OXIDATION OF THE MONO- AND DI-CHLOROTOLUENES.

It is therefore evident that the meta-compound is least affected, then follows the ortho-derivative, and finally the para-isomeride, which is almost entirely converted into the corresponding chlorobenzoic acid.

Two other series of experiments which were made with the dihalogen compounds confirm the results of the first series.

## 2nd Series.

3·5	1·000	0·357	0·581	0·938	182—183	182—183

So far as the special conditions of the above experiments are concerned, namely, the use of halogen compounds on the one hand and of nitric acid as oxidising agent on the other, the results are perfectly definite. The meta-compounds retard oxidation, and the para-compounds assist it, whilst the ortho-compounds occupy an intermediate position. Thus, *m*-chlorotoluene and 3 : 5-dichlorotoluene are least attacked. *p*-Chlorotoluene and the two dichlorotoluenes substituted in the para-position (2 : 4 and 3 : 4) are most readily oxidised. It is not clear why the 2 : 3-dichloro-compound should be more readily

oxidised than the 2:5-derivative, for they are both substituted in the meta- as well as in the ortho-position with respect to the methyl group, nor is it evident why the 2:6- and 2:5-compounds should be oxidised to the same extent. It is interesting to note that Noyes, when working with the nitrotoluenes and potassium ferricyanide, found that the meta-compound is less readily oxidised than the other two isomerides. On the other hand, Wroblewsky's observation (*vide ante*) seems to be only true in part, unless, indeed, chromic acid has a very different action from that of the other two oxidising agents. It is difficult to account for the behaviour of the different isomerides. It is clear that (contrary to the view which we were led to adopt as the result of our preliminary experiments) it is not a question of steric hindrance. The only process which seems to offer any analogy to the present one is that of substitution in the nucleus in which the formation of meta-compounds is sharply differentiated from that of the ortho- and para-compounds, yet it is difficult to see how any process of substitution in the nucleus can be applied to explain the conversion of a side-chain into a carboxyl group. We have accumulated a number of facts in regard to the oxidation of simple and mixed dihalogen derivatives and nitro-halogen compounds of toluene, which we hope shortly to publish.

## XXII.—*Derivatives of Highly Substituted Anilines.*

By FREDERICK DANIEL CHATTAWAY and JOHN MELLO WADMORE.

A NUMBER of acyl derivatives of the 2:4-dihalogen and the 2:4:6-trihalogen anilines have been prepared during the last few years in the course of an investigation on the phenomena of intramolecular rearrangement in aromatic amines, and their properties are here placed on record.

The anilides can be obtained by heating the substituted aniline with the equivalent amount of propionyl or benzoyl chloride. Vigorous action generally occurs at 160—180°, and the heating is preferably continued so long as hydrogen chloride is evolved. The product can be crystallised from either alcohol or a mixture of chloroform and petroleum. The nitrogen chlorides may all be prepared by adding an excess of a cooled solution of bleaching powder to the anilide dissolved in glacial acetic acid, complete conversion being ensured by extracting with chloroform and vigorously shaking the solution with fresh, slightly

acidified calcium hypochlorite for some hours. The chloroform solution, when dried over calcium chloride and evaporated in a current of dry air, yields the chloroamine derivative in the form of a viscid liquid which at once solidifies on cooling and stirring with light petroleum, and can then be crystallised from petroleum or from a mixture of this solvent with a little chloroform. A pure anilide invariably yields a product which solidifies at once and crystallises readily in lustrous, well-shaped crystals; whereas the presence of even a very small quantity of an admixed isomeride renders the product incapable of solidification. If such a mixture is dissolved in warm petroleum, no crystals form on cooling, but a viscid, semi-solid mass separates, which only occasionally becomes partly crystalline.

*4-Chloro-6-bromobenzanilide*,  $C_6H_3ClBr \cdot NH \cdot CO \cdot C_6H_5$ , separates from alcohol in slender, colourless prisms and melts at  $130.5^\circ$ .

0.2486 yielded 0.2662 mixed AgCl and AgBr. Halogen = 37.30.

$C_{13}H_9ONClBr$  requires halogen = 37.17 per cent.

The percentage of halogen throughout has been calculated on the assumption that silver chloride and silver bromide are present in the precipitate in the same proportion as the respective halogens in the anilide.

*1-Benzoylchloroamino-4-chloro-6-bromobenzene*,  $C_6H_3ClBr \cdot NCl \cdot C_6H_5$ , separated in colourless plates melting at  $62^\circ$ .

0.5084 required 29.2 c.c. *N*/10 I. Cl (as NCl) = 10.18.

$C_{13}H_8ONCl_2Br$  requires Cl (as NCl) = 10.28 per cent.

*4-Chloro-6-bromopropionanilide*,  $C_6H_3ClBr \cdot NH \cdot COEt$ , forms slender, colourless prisms and melts at  $128.5^\circ$ .

0.2332 yielded 0.2947 mixed AgCl and AgBr. Halogen = 44.03.

$C_9H_9ONClBr$  requires halogen = 43.96 per cent.

*2-Chloro-4-bromobenzanilide*,  $C_6H_3ClBr \cdot NH \cdot COPh$ , crystallises from alcohol in transparent, colourless, flattened prisms, and melts at  $145^\circ$ .

0.1868 yielded 0.2007 mixed AgCl and AgBr. Halogen = 37.43.

$C_{13}H_9ONClBr$  requires halogen = 37.17 per cent.

*1-Benzoylchloroamino-2-chloro-4-bromobenzene*,  $C_6H_3ClBr \cdot NCl \cdot COPh$ , forms colourless plates melting at  $74^\circ$ .

0.4224 required 24.7 c.c. *N*/10 I. Cl (as NCl) = 10.36.

$C_{13}H_8ONCl_2Br$  requires Cl (as NCl) = 10.28 per cent.

*2-Chloro-4-bromopropionanilide*,  $C_6H_3ClBr \cdot NH \cdot COEt$ , crystallises in colourless, hair-like needles and melts at  $129^\circ$ .

0.2036 yielded 0.2581 mixed AgCl and AgBr. Halogen = 44.16.

$C_9H_9ONClBr$  requires halogen = 43.96 per cent.

1-Benzoylchloroamino-2 : 4 : 6-tribromobenzene,  $C_6H_2Br_3 \cdot NCl \cdot CPh$ , which separates in glistening, colourless, rhombic plates with domed edges, melts at 115°.

0.2368 required 10 c.c. *N*/10 I. Cl (as NCl) = 7.48.

$C_{13}H_7ONClBr_3$  requires Cl (as NCl) = 7.57 per cent.

4-Chloro-2 : 6-dibromobenzanilide,  $C_6H_2ClBr_2 \cdot NH \cdot CPh$ , forms transparent, colourless plates and melts at 194°.

0.2114 yielded 0.2802 mixed AgCl and AgBr. Halogen = 49.88.

$C_{13}H_8ONClBr_2$  requires halogen = 50.16 per cent.

1-Benzoylchloroamino-4-chloro-2 : 6-dibromobenzene,

was obtained in short, colourless, transparent, four-sided prisms with domed ends melting at 111°.

0.2352 required 11.1 c.c. *N*/10 I. Cl (as NCl) = 8.37.

$C_{13}H_7ONCl_2Br_2$  requires Cl (as NCl) = 8.36 per cent.

4-Chloro-2 : 6-dibromopropionanilide,  $C_6H_2ClBr_2 \cdot NH \cdot COEt$ , separates in long, colourless, flattened prisms melting at 185°.

0.2388 yielded 0.3646 mixed AgCl and AgBr. Halogen = 57.45.

$C_9H_8ONClBr_2$  requires halogen = 57.21 per cent.

1-Propionylchloroamino-4-chloro-2 : 6-dibromobenzene,

forms slender, transparent, colourless prisms and melts at 74°.

0.2602 requires 13.7 c.c. *N*/10 I. Cl (as NCl) = 9.33.

$C_9H_7ONCl_2Br_2$  requires Cl (as NCl) = 9.43 per cent.

2 : 6-Dichloro-4-bromobenzanilide,  $C_6H_2Cl_2Br \cdot NH \cdot CPh$ , crystallises in short, colourless prisms and melts at 195°.

0.2448 yielded 0.3345 mixed AgCl and AgBr. Halogen = 43.43.

$C_{13}H_8ONCl_2Br$  requires halogen = 43.73 per cent.

1-Benzoylchloroamino-2 : 6-dichloro-4-bromobenzene,

forms transparent, colourless plates and melts at 95°.

0.2030 requires 10.7 c.c. *N*/10 I. Cl (as NCl) = 9.34.

$C_{13}H_7ONCl_3Br$  requires Cl (as NCl) = 9.34 per cent.

2 : 6-Dichloro-4-bromopropionanilide,  $C_6H_2Cl_2Br \cdot NH \cdot COEt$ , crystallises in colourless, flattened prisms melting at  $184^\circ$ .

0.2418 yielded 0.3843 mixed AgCl and AgBr. Halogen = 50.51.

$C_9H_5ONCl_2Br$  requires halogen = 50.80 per cent.

1-Benzoylchloroamino-2 : 4-dichloro-6-bromobenzene,

forms transparent, colourless, four-sided prisms with steeply domed ends and melts at  $92^\circ$ .

0.2204 required 11.7 c.c.  $N/10$  I. Cl (as NCl) = 9.41.

$C_{13}H_7ONCl_3Br$  requires Cl (as NCl) = 9.34 per cent.

2 : 4-Dichloro-6-bromopropionanilide,  $C_6H_2Cl_2Br \cdot NH \cdot COEt$ , crystallises in colourless needles and melts at  $165^\circ$ .

0.2089 yielded 0.3338 mixed AgCl and AgBr. Halogen = 50.78.

$C_9H_5ONCl_2Br$  requires halogen = 50.80 per cent.

2-Chloro-4 : 6-dibromobenzanilide,  $C_6H_2ClBr_2 \cdot NH \cdot CPh$ , which was obtained in colourless, short prisms terminated by pyramids, melts at  $192^\circ$ .

0.1704 yielded 0.2272 mixed AgCl and AgBr. Halogen = 50.17.

$C_{13}H_5ONClBr_2$  requires halogen = 50.16 per cent.

1-Benzoylchloroamino-2-chloro-4 : 6-dibromobenzene,

separates in colourless, short, four-sided prisms with domed ends and melts at  $97^\circ$ .

0.2240 requires 10.7 c.c.  $N/10$  I. Cl (as NCl) = 8.46.

$C_{13}H_7ONCl_2Br_2$  requires Cl (as NCl) = 8.36 per cent.

2-Chloro-4 : 6-dibromopropionanilide,  $C_6H_2ClBr_2 \cdot NH \cdot COEt$ , forms colourless needles melting at  $185.5^\circ$ .

0.1862 yielded 0.2828 mixed AgCl and AgBr. Halogen = 57.15.

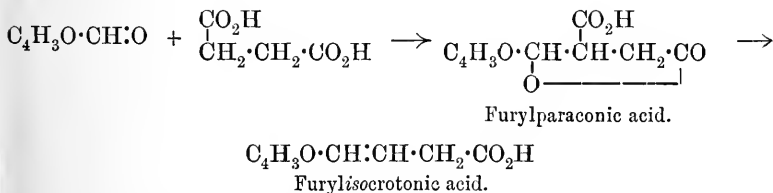

$C_9H_5ONClBr_2$  requires halogen = 57.21 per cent.

XXIII.—*The Condensation of Furfuraldehyde with Sodium Succinate.*

By ARTHUR WALSH TITHERLEY and JAMES FREDERICK SPENCER, B.Sc.

IN the course of an investigation on the higher acids of the succinic series, the authors, in seeking new methods of synthesis, selected furfuraldehyde as a starting point with the intention of converting it into acids of the type  $C_4H_3O \cdot CH:CH \cdot [CH_2]_n \cdot CO_2H$ , and these into suberic acid and its homologues, by processes similar to those by which Baeyer obtained *n*-pimelic acid,  $CO_2H \cdot [CH_2]_5 \cdot CO_2H$ , from furylacrylic acid,  $C_4H_3O \cdot CH:CH \cdot CO_2H$  (*Ber.*, 1877, 10, 695, 1358).

It was anticipated that  $\beta$ -furfurylidene-*propionic* acid (furyl*isocrotonic* acid),  $C_4H_3O \cdot CH:CH \cdot CH_2 \cdot CO_2H$ , the simplest compound of the above type, would be readily formed, according to Fittig's method, by the condensation of furfuraldehyde with sodium succinate in the presence of acetic anhydride (*Annalen*, 1883, 216, 97 ; 1889, 255, 1—142).

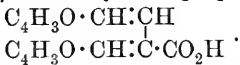

A considerable number of experiments, which have been carried out under a great variety of conditions, show beyond doubt, however, that furfuraldehyde behaves abnormally. Neither furylparaconic acid nor furyl*isocrotonic* acid could be isolated, but two unexpected derivatives,  $C_{13}H_{10}O_4$  and  $C_{14}H_8O_5$ , were obtained, but in such comparatively small yields that their investigation has been attended with considerable difficulty.

In dealing with the two compounds resulting from the condensation, it was at first suspected that the anomalous results might be due to the acetic anhydride having taken part in the reaction, but further investigation disproved this assumption, and it was ultimately shown that one of the products,  $C_{13}H_{10}O_4$ , could be obtained, in the absence of acetic anhydride, by the interaction of furfuraldehyde, sodium succinate, and succinic anhydride.

The compound  $C_{14}H_8O_5$ , which crystallises in long, dark orange-coloured needles melting at  $187^\circ$ , has the properties of a substituted succinic anhydride, and the other,  $C_{13}H_{10}O_4$ , which forms yellow, crystalline plates melting at  $213^\circ$ , was found to be a monobasic acid ; both substances, which are distinctly unsaturated, are produced by the

condensation of 2 molecules of furfuraldehyde with 1 molecule of sodium succinate; the orange-coloured compound being difurfurylidenesuccinic anhydride,

$\text{C}_4\text{H}_3\text{O} \cdot \text{CH} : \text{C} \cdot \text{CO} \begin{array}{c} \diagup \text{O} \\ | \\ \text{C}_4\text{H}_3\text{O} \cdot \text{CH} : \text{C} \cdot \text{CO} \end{array}$ , whilst the yellow compound is  $\alpha\gamma$ -difurfurylidenepropionic acid ( $\alpha$ -furfurylidenefuryliscrotonic acid),

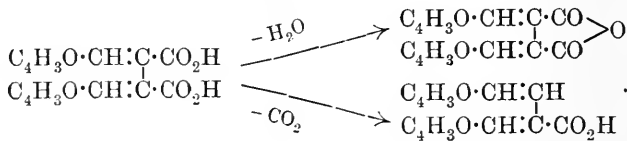

Since the orange-coloured compound is insoluble in cold aqueous alkali hydroxides, whilst the yellow compound dissolves in these solutions, the separation of the two products is readily effected. Unfortunately, their production is accompanied by large quantities of resinous substances having both acid and neutral properties, a fact which renders the purification very tedious.

In spite of a large number of experiments carried out under widely differing conditions, no evidence was obtained of the formation of the monofurfurylidene derivatives. The interaction of furfuraldehyde and sodium succinate in the presence of acetic anhydride may be represented as occurring in the following stages:

The dicarboxylic acid is liberated from the sodium salt by the acetic acid, resulting from the action of the eliminated water on a portion of the acetic anhydride, the excess of the latter reagent then converting the dicarboxylic acid into its anhydride. At the same time, carbon dioxide is removed from another portion of the dicarboxylic acid, giving rise to the monobasic acid:

The final product of the reaction contains, therefore, in addition to a certain amount of the unchanged reagents, the orange-coloured anhydride, the yellow acid and its sodium salt, sodium acetate, acetic and succinic acids, some succinic anhydride,\* and traces of furylacrylic

\* It has been shown beyond question, by separate experiments, that succinic anhydride and sodium acetate are formed when sodium succinate and acetic anhydride are heated together. A double decomposition of this nature was assumed by Fittig and Ott (*Annalen*, 1885, 227, 79) to take place between sodium *isobutyrate* and acetic anhydride, giving rise to *isobutyric* anhydride and sodium acetate, but although the results obtained by these authors could only be interpreted on this assumption, the change was not demonstrated experimentally.

acid. Carbon dioxide is steadily disengaged during the course of the reaction, especially if the temperature is allowed to rise, and whilst the production of yellow acid increases at higher temperatures, that of the orange-coloured anhydride decreases to a corresponding extent.

The succinic anhydride formed as a secondary product in the reaction does not appear to play any special part in the formation of the orange-coloured anhydride, such as might at first be suspected. There can be no doubt that it is the sodium salt alone which enters into action with the aldehyde, as with other condensations of this order (Fittig, *loc. cit.*), for furfuraldehyde could not be made to condense with succinic anhydride in the absence of sodium succinate, either by varying the temperature or by adding acetic anhydride or other dehydrating agents.

Difurfurylidenesuccinic anhydride has a bright scarlet colour resembling that of azobenzene; it is stable towards hydrolytic agents, and is attacked only slowly by boiling aqueous sodium hydroxide, yielding the sodium salt of the corresponding dicarboxylic acid. The acid itself is a pale yellow powder which melts at  $185^{\circ}$ , regenerating the original orange-coloured anhydride. The marked stability of the latter is comparable with that of pyrocinchonic anhydride and the tetra-alkylsuccinic anhydrides, and there can be little doubt that the cyclic structure,  $\begin{array}{c} \text{C} \cdot \text{C} \\ | \quad \diagup \\ \text{C} \cdot \text{C} \end{array} > \text{O}$ , in the orange-coloured compound is more closely allied to the furan nucleus than to the ring present in succinic anhydride. This configuration is, moreover, present in the two furyl groups, and the colour of the compound must in some way be associated with this peculiarity in constitution, and possibly with a special structure in the furan nucleus, having chromogenic characters, like the quinonoid grouping in the benzene nucleus. The chromogenic intensity becomes enhanced when bromine is added to the molecule, and the tetrabromide has marked fluorescent properties (see p. 190).

During this investigation, large quantities of furfuraldehyde were used up in abortive attempts to increase the yields of the yellow and orange-coloured compounds, but although the conditions were varied as far as possible, the yields never exceeded 5 per cent. of the calculated amount, except in one instance when an 8 per cent. yield of the yellow substance was obtained. In many other experiments, traces only were produced.

## EXPERIMENTAL.

*Action of Furfuraldehyde on Sodium Succinate in presence of Acetic Anhydride. Formation and Separation of Difurfurylidene-succinic Anhydride and  $\alpha$ -Difurfurylidene-propionic Acid.*

An intimate mixture of furfuraldehyde, thoroughly dried sodium succinate, and freshly distilled acetic anhydride, contained in a flask fitted with an air condenser, was cautiously heated in a paraffin-bath. The reaction commenced at 100° and proceeded so vigorously above this temperature that occasionally, when large quantities were employed, it became uncontrollable, and gave rise to black, resinous products. The most favourable yields were obtained by heating together at 90—100° for 6 hours, 20 grams of furfuraldehyde, 30 grams of sodium succinate and 45 grams of acetic anhydride. It was found necessary to employ the sodium salt in the form of a very fine powder, which was dried at 140° just before the experiment.

During the condensation, small quantities of carbon dioxide were evolved and the contents of the flask darkened, the final semi-solid product having a dark greenish-brown colour. The relative proportion of orange-coloured anhydride and yellow acid produced varied considerably with the conditions (time and temperature), but in general the yellow acid increased at the expense of the anhydride if the temperature was allowed to rise above 100° and if the heating continued for more than 6 hours, whilst in many cases under these circumstances the anhydride was not isolated. It was, moreover, impossible to obtain the anhydride exclusively by working at lower temperatures. These two products were isolated and separated by one or other of the following methods.

1. *Ether Extraction.*—The contents of the flask were treated with ether, and the solid residue, after filtering, further extracted in a Soxhlet apparatus for 4 or 5 hours, this treatment being necessary owing to the sparing solubility of the yellow and orange-coloured substances in ether. The dark ethereal extracts, on evaporation, slowly yielded these two compounds, together with succinic acid and succinic anhydride, the mother liquor containing acetic acid and its anhydride, furfuraldehyde and resin. The crystals, which were much discoloured, assumed a bright orange colour after draining on a porous plate. They were now treated with dilute ammonia, in which the orange-coloured anhydride remained undissolved as a granular powder. This product was purified by recrystallising from hot glacial acetic acid, and finally from hot benzene. The highest yield of difurfurylidene-succinic anhydride thus obtained, after about thirty separate syntheses

had been carried out in order to ascertain the best conditions of treatment, was about 5 per cent. of the calculated amount.

In order to isolate the yellow acid ( $\alpha\gamma$ -difurfurylidenepropionic acid) which accompanies the anhydride, the ammoniacal filtrate from the latter was acidified with hydrochloric acid. A dirty yellowish-brown precipitate of the impure acid was deposited, which was found to be very difficult to purify, owing to the presence of brown, oily resins having an acid nature, these substances were also precipitated, and rendered it almost impossible to dry the product. When gently warmed, the impure material melted to a black tar, which could not be effectually purified. By repeated crystallisation of the dried precipitate from hot benzene, however, it was at length found possible to separate the less fusible, yellow, crystalline acid in a fairly pure condition from the oily resins.

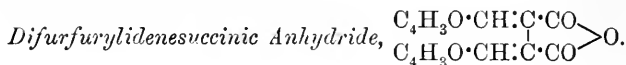

An alternative, and much more satisfactory method of purification was ultimately devised, depending on the fact that the sodium salt of the yellow acid is not very soluble in water and crystallises readily, whilst the sodium salts of the impurities are more soluble and do not crystallise. The impure product, obtained by acidifying the above ammoniacal solution, was therefore washed, dissolved in a slight excess of sodium hydroxide solution, and the resulting dark brown solution of the sodium salts concentrated carefully on the water-bath until crystals commenced to separate. On cooling, the entire mass became crystalline, and the sodium salt, when collected at the pump and dried on a porous plate, was obtained in large, transparent, orange-yellow plates. The mother liquor generally yielded a second crop of crystals.

The  $\alpha\gamma$ -difurfurylidenepropionic acid obtained from this sodium salt by the action of hydrochloric acid was absolutely pure and melted  $5^{\circ}$  higher than that obtained by the foregoing method of crystallisation from benzene. The maximum yield was about 5.5 per cent. of theory, this being obtained only by carrying out the original reaction at  $110^{\circ}$ , so as to diminish the production of the orange-coloured compound.

2. *Treatment with Water.*—A method of treatment similar to that employed by Fittig (*loc. cit.*) was adopted by the authors in a number of experiments made in endeavouring to isolate furylparaconic and furylisocrotonic acids. These acids could, however, not be detected. The steam distillate contained only furfuraldehyde; the residue in the flask contained a large quantity of oily resin, which was filtered off whilst hot. The filtrate was yellow, and on cooling became turbid, and in the course of two to three days a bright yellow, micro-crystalline powder appeared in the form of crusts on the surface of the liquid and sides of the vessel; this substance melted at about  $200^{\circ}$ , and was fairly pure  $\alpha\gamma$ -difurfurylidenepropionic acid. It was crystallised

repeatedly from benzene. The aqueous filtrate from the yellow crusts contained only acetic acid, succinic acids, and their sodium salts.

The tarry matter was also examined, and, although it was found to contain a relatively considerable proportion of the yellow  $\alpha\gamma$ -difurfurylidene- $\beta$ -propiolic acid (which was extracted by repeated treatment with hot water, in which this acid is appreciably soluble), no other acid, except the resin acids, could be obtained from it. The quantity of tarry matter or pitch obtained in all the experiments was very great, and at once explained the very small yields, but it was impossible under any conditions to prevent its formation, although by carefully regulating the temperature at which the condensation was effected its quantity could be more or less minimised. The resin was closely investigated and, by repeated solution in alkali and reprecipitation with acids, was obtained in the form of a brown, amorphous powder, which was distinctly unsaturated, had slightly acid characters, and exhibited properties analogous to the yellow, crystalline  $\alpha\gamma$ -difurfurylidene- $\beta$ -propiolic acid. It had, however, no definite melting point, and evidently consisted of a mixture of several substances (probably polymerised derivatives), and, although numerous attempts were made to separate them by means of solvents, definitely pure compounds could not be isolated. The mixture was instantly oxidised by cold potassium permanganate, giving large quantities of oxalic acid. This investigation was accordingly abandoned.

This acid crystallises in fine, silky needles from benzene, but forms thick prisms when separating slowly from glacial acetic acid; it melts at  $187^\circ$ .

0.1123 gave 0.2684  $\text{CO}_2$  and 0.0351  $\text{H}_2\text{O}$ .  $\text{C} = 65.18$ ;  $\text{H} = 3.47$ .

0.0872 „ 0.2080  $\text{CO}_2$  „ 0.0270  $\text{H}_2\text{O}$ .  $\text{C} = 65.05$ ;  $\text{H} = 3.43$ .

$\text{C}_{14}\text{H}_8\text{O}_5$  requires  $\text{C} = 65.62$ ;  $\text{H} = 3.12$  per cent.

A determination of its molecular weight was carried out by the ebullioscopic method in benzene solution.

	Solute.	Solvent.	Rise of b. p.	M. W.
I.	0.1524	34.168	0.045	264
II.	0.2926	34.168	0.090	254

$\text{C}_{14}\text{H}_8\text{O}_5$  requires M. W. = 256.

Difurfurylidenesuccinic anhydride is only very sparingly soluble in the usual organic solvents, but the solutions have a bright orange colour. In benzene, it is fairly readily soluble in the hot, but only slightly so in the cold solvent (1 part in 350 at  $14^\circ$ ).

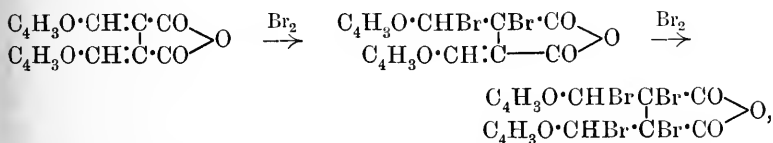

It is insoluble in and unaffected by water, aqueous sodium carbonate, ammonia, &c.; also by cold aqueous sodium hydroxide, but in a boiling solution of this alkali it is slowly attacked and disappears, forming a pale yellow solution of the sodium salt of the corresponding dicarboxylic acid.

Attempts made to reduce difurfurylidenesuccinic anhydride by zinc dust and glacial acetic acid, and other reducing agents gave no satisfactory results, mainly owing to insufficiency of material.

On cautiously oxidising the substance with nitric acid, potassium permanganate, or chromic acid, oxalic acid was formed, this result being due to the presence of the furan nucleus. An appreciable quantity of a syrupy acid was simultaneously formed, but this substance could not be purified or identified owing to its small amount.

*Action of Bromine on Difurfurylidenesuccinic Anhydride.*

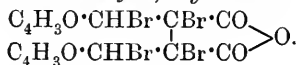

Owing to the markedly unsaturated character of the anhydride and the presence of two furyl groups, bromine interacts with great vigour and its chloroform solution is instantly decolorised. It is probable that the first action consists in adding two and then four atoms of the halogen at the points of double union outside the furyl groups thus :

further addition then taking place in the furan nucleus. The action is further complicated by the fact that substitution simultaneously occurs, with evolution of hydrogen bromide and formation of viscous bromo-derivatives. When, however, the bromine is carefully added, comparatively little substitution occurs until four atoms of bromine have been introduced. Experiments were then made with the view of introducing bromine in successive stages corresponding with 2, 4, 6, and more atoms. A saturated solution of the orange-coloured anhydride in chloroform was treated with the requisite volume of a solution of bromine in the same solvent added drop by drop; the solvent was then allowed to evaporate and the residue purified. It was found impossible to isolate in a pure condition any product other than the tetrabromide. In the experiments in which two atoms of bromine only had been added, a mixture of granular and viscous substances remained which were found to contain the tetrabromide and unchanged difurfurylidenesuccinic anhydride, but no dibromide. From those experiments, also, in which an excess of

bromine had been used, the chief product isolated was the tetrabromide, the remainder being a syrupy mixture from which no definite substance could be isolated.

$\alpha\alpha_1\beta\beta_1$ -Tetrabromo-s-difurfurylsuccinic Anhydride,

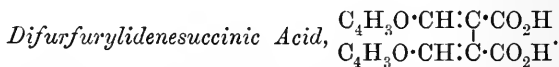

This compound was obtained in largest quantity by the addition of four atoms of bromine to difurfurylidenesuccinic anhydride. The residue, after removing the chloroform, had a brown, vitreous appearance; it was washed several times with cold alcohol and recrystallised from benzene, being then obtained in micro-crystalline, yellow needles melting at 195—196°.

0.1736 gave 0.2270 AgBr. Br = 55.16.

$\text{C}_{14}\text{H}_8\text{O}_5\text{Br}_4$  requires Br = 55.55 per cent.

The tetrabromo-derivative is fairly readily soluble in chloroform, benzene or acetone, but only sparingly so in alcohol; its solutions have a yellow fluorescence, which is destroyed by alkalis and restored by acids.

An attempt was made to obtain the dibromo-derivative by using glacial acetic acid as a solvent for the bromine. On adding water to the product of reaction, a yellow powder was deposited, which, when dissolved in acetic acid and reprecipitated with water, melted indefinitely at about 112° and contained 33.46 per cent. of bromine. The dibromide,  $\text{C}_{14}\text{H}_8\text{O}_5\text{Br}_2$ , requires Br = 38.46 per cent. By further treatment with acetic acid and water, it was obtained apparently pure, and melted at 135°, but unfortunately the quantity was too small for analysis.

The orange-coloured anhydride was digested with about twice the theoretical quantity of a 30 per cent. solution of pure sodium hydroxide in a silver vessel at 100° for several hours until the last traces of orange-coloured needles had disappeared. A slightly yellow solution resulted, which, after cooling, was acidified with hydrochloric acid. A pale yellow, crystalline precipitate was gradually deposited, the total yield being theoretical. The acid was purified by dissolving in aqueous sodium carbonate and reprecipitating with acid. The pure substance melted at 185—187°, but at 185° it rapidly assumed a deep orange colour and then melted to a blood-red liquid, evolving steam and yielding the anhydride (m. p. 187°).

0.0724 gave 0.1639  $\text{CO}_2$  and 0.0244  $\text{H}_2\text{O}$ .  $\text{C} = 61.73$ ;  $\text{H} = 3.74$ .

$\text{C}_{14}\text{H}_{10}\text{O}_6$  requires  $\text{C} = 61.31$ ;  $\text{H} = 3.64$  per cent.

The acid is fairly readily soluble in alcohol and acetone; it dissolves very easily in glacial acetic acid, but is insoluble in benzene and chloroform. It forms a yellow, crystalline sodium salt and a bright yellow, insoluble silver salt.

When the acid is warmed with acetyl chloride, it dissolves, and the colour of the solution rapidly changes from yellow to blood-red, then almost instantaneously the pure anhydride separates as a net-work of bright orange-coloured needles melting at  $187^\circ$ .

*$\alpha\gamma$ -Difurfurylidene- $\beta$ -propionic Acid ( $\alpha$ -Furfurylidene-furylisocrotonic Acid),*  
 $\text{C}_4\text{H}_3\text{O} \cdot \text{CH} : \text{CH}$   
 $\text{C}_4\text{H}_3\text{O} \cdot \text{CH} : \dot{\text{C}} \cdot \text{CO}_2\text{H} \cdot$

The isolation of this compound from the product of interaction of furfuraldehyde, sodium succinate, and acetic anhydride has already been described. An 8 per cent. yield of this acid was obtained by using succinic anhydride as dehydrating agent instead of acetic anhydride. By this method, the formation of difurfurylidene-succinic anhydride was prevented. The use of large quantities was avoided, the preparation being carried out on a small scale. Eight grams of sodium succinate (dried at  $140^\circ$ ), 6 grams of succinic anhydride, and 5 grams of furfuraldehyde were intimately mixed and heated at  $120^\circ$  in a paraffin bath for 4—5 hours. The solid product, which had darkened considerably, was pulverised in a mortar and digested with aqueous sodium carbonate at  $40^\circ$  for about 2 hours. A considerable quantity of brown, insoluble, resinous matter remained, which was filtered off, and the yellow solution, after cooling, acidified with hydrochloric acid. The yellow precipitate, which was somewhat oily, was washed thoroughly and purified by conversion into its sodium salt (compare p. 187), the acid being subsequently liberated by treatment with hydrochloric acid. The purest specimen of the acid obtained in this manner melted at  $213^\circ$ . A number of specimens in the earlier experiments, which had been purified by recrystallisation from benzene and other solvents, melted at  $205^\circ$ , evidently owing to traces of adherent resinous matter.

m. p.  $205^\circ$ . 0.1096 gave 0.2702  $\text{CO}_2$  and 0.0423  $\text{H}_2\text{O}$ .  $\text{C} = 67.23$ ;  $\text{H} = 4.28$ .

m. p.  $205^\circ$ . 0.1858 gave 0.4569  $\text{CO}_2$  and 0.0732  $\text{H}_2\text{O}$ .  $\text{C} = 67.21$ ;  $\text{H} = 4.39$ .

m. p.  $213^\circ$ . 0.2169 gave 0.5419  $\text{CO}_2$  and 0.0865  $\text{H}_2\text{O}$ .  $\text{C} = 68.07$ ;  $\text{H} = 4.43$ .

$\text{C}_{13}\text{H}_{10}\text{O}_4$  requires  $\text{C} = 67.33$ ;  $\text{H} = 4.34$  per cent.

$\alpha\gamma$ -Difurfurylidene- $\beta$ -propiolic acid is practically insoluble in water, slightly soluble in ether, cold alcohol or benzene, but may be crystallised from its hot solution in the last two solvents in long, yellow needles; it is readily soluble in glacial acetic acid, and is reprecipitated by water as a bright yellow precipitate. The acid at once dissolves in aqueous alkali hydroxides, including ammonia, and is slowly soluble in sodium carbonate solution, being reprecipitated from these solutions by mineral acids or acetic acid.

The *sodium* salt is sparingly soluble in water and crystallises in large, transparent, orange-yellow plates, which at  $100^\circ$  lose water and crumble to an opaque, bright yellow powder.

The *silver* salt is precipitated from neutral solutions on adding silver nitrate as a bright yellow, colloidal precipitate.

0.0720 gave 0.0232 Ag.  $\text{Ag} = 32.22$ .

$\text{C}_{13}\text{H}_9\text{O}_4\text{Ag}$  requires  $\text{Ag} = 32.05$  per cent.

In pure water, the salt is fairly soluble, forming a pale yellow solution.

UNIVERSITY OF LIVERPOOL.

## XXIV.—*The Constitution of Epinephrine.*

By HOOPER ALBERT DICKINSON JOWETT.

"EPINEPHRIN," the name given by Abel and Crawford to the active principle of the suprarenal gland, was first isolated by them in an impure condition in 1897 (Johns Hopkins Hospital Bulletin, No. 76), and a similar substance, also more or less impure, but prepared by a different method, was obtained by von Fürth (*Zeit. physiol. Chem.*, 1900, 29, 105), who called it "suprarenin."

In 1901, the active principle was isolated in a crystalline condition by Takamine (*Amer. J. Pharm.*, 1901, 73, 523) and called by him "adrenalin," and shortly afterwards it was prepared by a different method by Aldrich (*Amer. J. Physiol.*, 1901, 5, 457).

The three names "epinephrin," "suprarenin," and "adrenalin," therefore refer to the same substance, although Abel (*Ber.*, 1903, 36, 1839) has since adopted the term "epinephrin hydrate." As this author was the first to isolate the substance, although in an impure condition, it would seem that the name originally assigned by Abel to the active principle should be the one adopted. Takamine, from the results of analyses of crystalline epinephrine, proposed the formula

$C_{10}H_{15}O_3N$ , and showed that, although it acted as a mono-acidic base, it gave no reaction with the usual alkaloidal reagents. Aldrich, however, preferred the slightly different formula  $C_9H_{13}O_3N$ .

Abel, who carefully purified his material, adopted the formula  $C_{10}H_{13}O_3N, \frac{1}{2}H_2O$ , but adduced absolutely no evidence to show that it contained any water of crystallisation. His results agree equally well with Aldrich's formula  $C_9H_{13}O_3N$ . This is seen from the following numbers calculated for each formula :

(Aldrich's formula)  $C_9H_{13}O_3N$  requires C = 59.0 ; H = 7.1 ; N = 7.6.

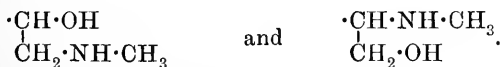

(Abel's formula)  $C_{10}H_{13}O_3N, \frac{1}{2}H_2O$  requires C = 58.8 ; H = 6.9 ; N = 6.9.

Abel actually found C = 58.4 to 58.7 ; H = 6.8 to 7.2 ; N = 7.1 to 7.6 per cent.

Von Fürth (*Monatsh.*, 1903, 24, 261) confirmed the formula  $C_9H_{13}O_3N$  by analyses and molecular weight determinations.

Pauly (*Ber.*, 1903, 36, 2945), from the results of the analysis of very carefully purified material, also confirmed this formula, so that it must be considered the most probable of those proposed. No crystalline salts or derivatives have been described, but von Fürth prepared a tribenzoyl- and a tribenzenesulpho-derivative. He also showed that it contained no methoxyl group, and that it yielded methylamine by treatment with concentrated acids.

Of the degradation products of epinephrine, only protocatechuic acid, formed by fusion with potassium hydroxide, has been positively identified, although substances giving the pyrrole, skatole, or catechol reactions have been obtained by different observers. Von Fürth suggested for the base the partially developed formula  $[CH_3 \cdot NC_2H \cdot OH]C_6H_6(OH)_2$ , and Pauly, who determined its specific rotation, suggested that it contained a hydroxylated benzene residue attached to one of five possible complexes, of which the most probable were the following :

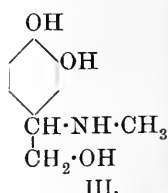

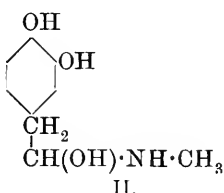

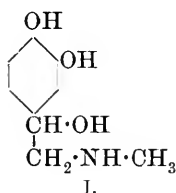

In this way, the formation of catechol, skatole, or pyrrole derivatives would be easily explained.

In the present investigation, I have confirmed the formula  $C_9H_{13}O_3N$ , first proposed by Aldrich, by analyses of carefully purified material and by molecular weight determinations. By fusion with potassium hydroxide, a small quantity of a crystalline substance giving the reactions of protocatechuic acid was isolated, but the amount was so small that it was doubtful whether the presence of this complex in the original substance could be correctly deduced from its formation.

By oxidation with permanganate, oxalic and formic acids and methylamine were obtained.

By methylation and subsequent oxidation with permanganate, trimethylamine and veratric acid were obtained, thus proving the existence of the complexes  $C_6H_3(OH)_2 \cdot C$  and  $NH(CH_3)$  in the original base.

From these results, the following constitutional formulæ of epinephrine may be deduced :

Of these formulæ, I is the more probable, for if II were correct, then, after methylation and subsequent oxidation, we should expect the product to yield homoveratric acid,  $C_6H_3(OH)_2 \cdot CH_2 \cdot CO_2H$ , whereas veratric acid was actually obtained, whilst III would not so readily explain the formation of pyrrole or skatole derivatives. Formula I may therefore be considered to represent correctly the constitution of epinephrine, and it serves to explain the ordinary reactions of the base as well as the formation of pyrrole, skatole, or catechol derivatives as degradation products.

## EXPERIMENTAL.

### *The Formula and Properties of Epinephrine.*

The crude crystalline material was first freed from inorganic impurities by the method previously adopted by other observers, namely, solution of a salt in alcohol and fractional precipitation with ether. It was finally purified by fractional precipitation of the base from the aqueous solution of its hydrochloride by ammonia.

The analyses of four different specimens were sufficient to confirm the formula  $C_9H_{13}O_3N$ .

0.1184 gave 0.2546  $CO_2$  and 0.0798  $H_2O$ .  $C = 58.6$  ;  $H = 7.5$ .

0.1082 „ 0.2306  $CO_2$  „ 0.0720  $H_2O$ .  $C = 58.1$  ;  $H = 7.4$ .

0.1238 „ 0.2642  $CO_2$  „ 0.0816  $H_2O$ .  $C = 58.2$  ;  $H = 7.3$ .

0.0990 „ 0.2136  $CO_2$  „ 0.0644  $H_2O$ .  $C = 58.8$  ;  $H = 7.2$ .

0.1342 „ 9.2 c.c. N at  $15^\circ$  and 755 mm.  $N = 7.8$ .

0.0946 in 24.78 glacial acetic acid gave  $\Delta t - 0.11^\circ$ . M. W. = 135.

$C_9H_{13}O_3N$  requires  $C = 59.0$  ;  $H = 7.1$  ;  $N = 7.6$  per cent. M. W. = 183.

The determination of the specific rotation of the base in dilute acetic acid solution gave the following result :

$$\alpha_D = -10'; l = 0.25 \text{ dcm.}; c = 2.084; [\alpha]_D = -32.0^\circ.$$

Pauly (*loc. cit.*) found  $[\alpha]_D -43^\circ$ , but considering the small observed angle ( $10'$ ) the above figures do not vary beyond the limits of experimental error.

The general statements of previous observers as to the solubility of epinephrine in various solvents and its behaviour towards alkaloidal reagents were confirmed. The base did not react with phenylhydrazine.

#### *Oxidation with Permanganate.*

Five grams of epinephrine were dissolved in dilute sulphuric acid and oxidised at the ordinary temperature with a 1 per cent. solution of permanganate, 30 grams of this reagent being required to produce a permanent colour. The product yielded methylamine, which was identified by its platinichloride.

0.1646 gave 0.0688 Pt.  $\text{Pt} = 41.8$ .

$(\text{CH}_5\text{N})_2, \text{H}_2\text{PtCl}_6$  requires  $\text{Pt} = 41.3$  per cent.

The acids obtained were formic and oxalic acids.

#### *Fusion with Potassium Hydroxide.*

Five grams of epinephrine were added to 25 grams of potassium hydroxide and the mass fused at as low a temperature as possible. The melt was then dissolved in water, acidified, and extracted with ether. The residue, after distilling off the ether, was obtained crystalline and gave the characteristic protocatechuic acid reaction on adding successively ferric chloride and sodium carbonate. The amount obtained was insufficient to admit of further examination.

#### *Methylation and Subsequent Oxidation with Permanganate.*

Four grams of epinephrine were dissolved in 50 c.c. of methyl alcohol in which 1 gram of sodium had been dissolved, and 8 grams of methyl iodide added. The mixture was then heated in a sealed tube at  $100^\circ$  for four hours, the alcohol distilled off, and the operation repeated with the residue. After the second methylation, the residue was dissolved in water and then added to an aqueous solution of 17 grams of silver nitrate, the silver iodide quickly filtered off, and the filtrate saturated with hydrogen sulphide and again filtered. The filtrate was then oxidised with a 2 per cent. solution of perman-

ganate at the ordinary temperature, when 10 grams were required to produce a permanent colour. The product, when worked up in the usual way, yielded a volatile base which was identified as trimethylamine.

0.1588 Pt salt gave 0.059 Pt. Pt = 37.1.

$(C_3H_9N)_2 \cdot H_2PtCl_6$  requires Pt = 37.1 per cent.

The crystalline acid obtained from the ethereal extract was recrystallised from hot water until its melting point was constant; it formed white, acicular crystals, sparingly soluble in cold water and melting sharply at  $179^\circ$ . The aqueous solution gave no reaction with ferric chloride.

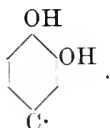

0.1128, dried at  $110-120^\circ$ , gave 0.2446  $CO_2$  and 0.057  $H_2O$ . C = 59.1 H = 5.6.

$C_9H_{10}O_4$  requires C = 59.3; H = 5.5 per cent.

This compound was therefore identified as veratric acid.

#### *The Constitution of Epinephrine.*

Since the product obtained by exhaustive methylation yields veratric acid by oxidation with permanganate, epinephrine must contain the complex :

As it yields trimethylamine by the foregoing treatment and methylamine by oxidation of the original base, it must therefore contain the group  $\cdot NH(CH_3)$ , which, being split off by simple oxidation, is most probably attached to the side-chain and not to the benzene nucleus.

As epinephrine yields tribenzoyl- and tribenzenesulpho-derivatives, it probably contains three hydroxyl groups, of which two are attached to the benzene nucleus.

The only probable formulæ which would comply with the above conditions and also conform to Pauly's hypothesis (*loc. cit.*) are those indicated on p. 194.

Of these, I is the most probable, for if II were correct we should expect after methylation and subsequent oxidation to obtain homoveratric acid and not veratric acid. Moreover, III would not so readily explain the formation of pyrrole or skatole derivatives.

Formula I is therefore the most probable formula for epinephrine, as by it the formation of catechol or protocatechuic acid is easily explained

as well as the reducing properties of the base. It also contains one of the two side-chains regarded as probable by Panly (*loc. cit.*). By the union of the nitrogen atom to the benzene ring, pyrrole derivatives would be formed, as has been stated to be the case.

*Addendum.*—Since this paper was written, a communication by Abel has appeared (*Ber.*, 1904, 37, 368) in which he still adheres to the formula  $C_{10}H_{13}O_3N, \frac{1}{2}H_2O$ . He states, however (*loc. cit.*, 381), that 0.2288 gram of the base, when heated for one hour at  $145^\circ$  and subsequently for one hour at  $155$ – $160^\circ$  in a vacuum, lost only 0.0014 gram or 0.6 per cent. This experiment apparently only affords further evidence that the base contains no water of crystallisation.

THE WELLCOME CHEMICAL RESEARCH LABORATORIES,  
LONDON, E.C.

## XXV.—*The Resolution of $\alpha\beta$ -Dihydroxybutyric Acid into its Optically Active Constituents.*

ROBERT SELBY MORRELL and EDWARD KENNETH HANSON.

THE two inactive  $\alpha\beta$ -dihydroxybutyric acids, obtained by Fittig and Kochs on oxidising the  $\alpha$ - and  $\beta$ -crotonic acids with barium permanganate (*Annalen*, 1892, 268, 8 and 16), are characterised mainly by the different solubilities of their salts in water. If the  $\alpha$ - and

$\beta$ -crotonic acids are represented by the formulæ  $\overset{\text{H}}{\text{CH}_3} \cdot \overset{\text{H}}{\text{C}} = \overset{\text{H}}{\text{C}} \cdot \text{CO}_2\text{H}$  and

$\overset{\text{H}}{\text{CH}_3} \cdot \text{C} = \overset{\text{H}}{\text{C}} \cdot \text{CO}_2\text{H}$ , the two  $\alpha\beta$ -dihydroxybutyric acids ( $\beta$ -methyl-

glyceric and  $\beta$ -methylisoglyceric acids) should have the formulæ

$\overset{\text{H}}{\text{CH}_3} \cdot \overset{\text{H}}{\text{C}} - \overset{\text{H}}{\text{C}} \cdot \text{CO}_2\text{H}$  and  $\overset{\text{HO}}{\text{CH}_3} \cdot \overset{\text{H}}{\text{C}} - \overset{\text{OH}}{\text{C}} \cdot \text{CO}_2\text{H}$ .

In connection with an investigation on the oxidation of carbohydrates which is being carried out by one of us, it seemed advisable to investigate the properties of these acids more completely and to prepare their salts with optically active bases, with the view of resolving the racemic forms into their optically active components.

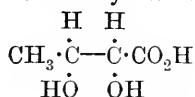

In this paper, we communicate the results of an investigation of the properties of the *l*-modification of  $\alpha\beta$ -dihydroxybutyric acid and of one of the salts of the *d*-modification. In the course of our investigation, we were led to believe that a more complete separation of  $\beta$ -crotonic acid from  $\alpha$ -crotonic acid could be effected, but this portion of the work will form the subject of another paper. The resolution of  $\beta$ -methylglyceric acid can be easily effected by the fractional crystallisation of the quinidine salts. The quinidine *l*- $\beta$ -methylglycerate is sparingly soluble in water and yields the *l*-acid, having a specific rotation of  $-13.5^\circ$ . The barium *l*-salt is more strongly lævoptatory,  $[\alpha]_D -20^\circ$ , and the rotation of this salt is greater than that of calcium glycerate ( $-11.66^\circ$ ), derived from *d*-glyceric acid, which has  $[\alpha]_D^{127} +2.14^\circ$ ; moreover, the rotation of barium *l*- $\beta$ -methylglycerate has the same sign as that of the acid (compare Frankland and Frew, Trans., 1891, 59, 56, 101).

The specific rotation of an aqueous solution of  $\alpha\beta$ -dihydroxybutyric acid is unchanged when allowed to remain for 12 hours, and since it is slightly lower than that of the barium salt there is probably no anhydride present in the solution. In the case of *d*-glyceric acid, there is evidence of the formation of an anhydride on the evaporation of an aqueous solution (Frankland and Frew, Trans., 1891, 59, 56). Comparison with the specific rotation of *l*- $\beta$ -hydroxybutyric acid shows that the introduction of a hydroxyl group lowers the rotation of the acid. The specific rotation of *l*- $\beta$ -hydroxybutyric acid is  $[\alpha]_D -24.8^\circ$ , whilst that of the corresponding sodium salt is  $[\alpha]_D -14.5^\circ$  (Mackenzie, Trans., 1902, 81, 1402). Mackenzie states that the rotations of  $\beta$ -hydroxybutyric acid and its salts are exceptional, in that the salts have lower rotations than that of the free acid. An aqueous solution of  $\beta$ -hydroxybutyric acid contains some anhydride, but the rotation of the anhydride differs very little from that of the free acid (*loc. cit.*)

By the action of lime water on an oxycellulose, Faber and Tollens obtained isosaccharic acid,

and a dihydroxybutyric acid. This dihydroxybutyric acid was found to have a specific rotation  $[\alpha]_D -2.6^\circ$ , in freshly prepared aqueous solution, but after three days the specific rotation had changed to  $+13.7^\circ$  (*loc. cit.*). The acid is probably the optical isomeride of the *l*- $\alpha\beta$ -hydroxybutyric acid obtained by us. The formula

rather than  $\text{CH}_2(\text{OH})\text{CH}_3 > \text{C}(\text{OH})\cdot\text{CO}_2\text{H}$ , ought to be assigned to Faber

and Tollens's acid. The optical isomerism of these two acids perhaps might be considered as affording some slight evidence in favour of the existence of a methylpentose residue in cellulose. The oxycelluloses are characterised in certain cases by the presence of active carbonyl groups, by methoxyl radicles, and by yielding furfuraldehyde as a product of acid hydrolysis (Cross and Bevan, *Cellulose*, p. 82). The production of furfuraldehyde indicates generally the presence of a pentose nucleus, although it may also be obtained from glycuronic acid and glucosone, which are derived from hexoses.

### EXPERIMENTAL.

$\beta$ -Methylglyceric acid, which was prepared from solid crotonic acid by oxidation with barium permanganate according to the directions given by Fittig and Kochs (*loc. cit.*), was converted into its salts with brucine, quinine, strychnine, morphine, and quinidine.

*Brucine  $\beta$ -Methylglycerate.*—This salt is exceedingly soluble in water and fairly soluble in hot absolute alcohol, one part of the salt dissolving in 15 parts of the boiling solvent; it crystallises from a concentrated alcoholic solution in small needles, but if the solution is more dilute, nodular aggregates of needles slowly separate. It melts at  $236^\circ$  with decomposition.

0.2012 gave 9.8 c.c. moist nitrogen at  $22^\circ$  and 765 mm.  $N = 5.58$ .

$C_{23}H_{26}O_4N_2, C_4H_8O_4$  requires  $N = 5.45$  per cent.

The specific rotation of the salt was determined in both alcohol and water.

(1) In alcohol:  $l = 1$ ;  $c = 1.333$ ;  $\alpha_D^{20} - 0.2^\circ$ ;  $[\alpha]_D^{20} - 15^\circ$ .

(2) In water:

$l = 1$ ;  $c = 9.983$ ;  $d = 1.026$ ;  $\alpha_D^{16} - 2.88^\circ$ ;  $[\alpha]_D^{16} - 28.12^\circ$ .

Tykociner found that the specific rotation of a brucine salt of an inactive acid dissolved in water was approximately  $-34^\circ$ . The brucine salt is apparently that of the inactive acid (*Rec. trav. chim.*, 1892, 11, 148). Fractional crystallisation of the salt failed to alter its rotation appreciably, and a determination of the specific rotatory power of the last crop of crystals from the aqueous solution gave the following numbers:

$l = 1$ ;  $c = 10.123$ ;  $d = 1.0277$ ;  $\alpha_D^{16} - 2.89^\circ$ ;  $[\alpha]_D^{16} - 27.8^\circ$ .

The acid was produced by decomposing successively the brucine salt by baryta and the barium salt by the exact amount of sulphuric acid; it crystallised from a mixture of dry acetone and dry ether in

aggregates of needles and was found to be identical with the inactive acid obtained by Fittig and Kochs (*loc. cit.*).

0.1830 (dried in a vacuum over sulphuric acid) gave 0.2695 CO<sub>2</sub> and 0.1125 H<sub>2</sub>O. C = 40.16; H = 6.8.

C<sub>4</sub>H<sub>8</sub>O<sub>4</sub> requires C = 40.0; H = 6.66 per cent.

An aqueous solution of the acid gave :

$$l = 2; c = 6.93; \alpha_D^{20} - 0.13^\circ; [\alpha]_D^{20} - 0.95^\circ.$$

On adding boric acid, in the proportion of 1 gram-molecule of the acid to 1 gram-molecule of the methylglyceric acid, the angle observed was  $-0.18^\circ$ . The specific rotation was now only  $[\alpha]_D^{20} - 1.32^\circ$ .

From these data, it is evident that the solubilities of the *d*- and *l*-brucine salts in alcohol are so nearly equal that their separation by fractional crystallisation is impossible.

*Quinine Methylglycerate.*—This salt is exceedingly soluble in water and absolute alcohol, but very sparingly so in benzene; it melts at  $174^\circ$  without decomposition. The determination of the optical activity in absolute alcohol and in water gave the following numbers respectively :

$$c = 2; l = 1; \alpha_D^{20} - 2.6^\circ; [\alpha]_D^{20} - 130^\circ.$$

$$c = 4.535; l = 1; \alpha_D^{16} - 4.94^\circ; [\alpha]_D^{16} - 108.93^\circ.$$

The specific rotation of quinine in alcohol is  $[\alpha]_D^{20} - 166.6^\circ$  ( $c = 2$ ) (Oudemann's *Annalen*, 1876, 182, 44).

The salt dissolves so sparingly in benzene and is so very soluble in water and alcohol, that it was quite impossible to separate its active components by fractional crystallisation.

The cinchonine, strychnine, and morphine salts are exceedingly soluble in water and in alcohol; the cinchonine salt is sparingly soluble in benzene. We have not as yet obtained the salts of these three bases with  $\beta$ -methylglyceric acid in a crystalline form.

*Quinidine  $\beta$ -Methylglycerate.*—This salt was prepared by neutralising a hot aqueous solution of  $\beta$ -methylglyceric acid with quinidine. On concentrating on the water-bath, the salt separated out in clusters of six-sided plates. The mother liquor gave a second crop of these crystals, but, after further concentration, needle-shaped crystals appeared. The first crop of crystals melted at  $113$ – $114^\circ$  without decomposition, and contained two molecules of water of crystallisation.

0.3 air-dried salt gave 15.6 c.c. moist nitrogen at  $16^\circ$  and 763 mm.

N = 6.08.

0.1823 air-dried salt gave 0.4015 CO<sub>2</sub> and 0.1220 H<sub>2</sub>O. C = 60.06;

H = 7.43.

0.5811 air-dried salt lost  $0.338^\circ$  at  $105^\circ$ .  $\text{H}_2\text{O} = 5.81$ .

$\text{C}_{20}\text{H}_{24}\text{O}_2\text{N}_2\text{C}_4\text{H}_8\text{O}_4, 2\text{H}_2\text{O}$  requires  $\text{N} = 5.71$ .  $\text{C} = 60.0$ ;  $\text{H} = 7.5$ ;  
 $\text{H}_2\text{O} = 7.5$ .

$\text{C}_{20}\text{H}_{24}\text{N}_2\text{O}_2\text{C}_4\text{H}_8\text{O}_4, 1\frac{1}{2}\text{H}_2\text{O}$  requires  $\text{N} = 5.82$ .  $\text{C} = 59.87$ ;  $\text{H} = 7.27$ ;  
 $\text{H}_2\text{O} = 5.73$  per cent.

The specific rotation was determined in aqueous and in alcoholic solutions.

(a) In water.  $l = 1$ ;  $c = 3.310$ ;  $\alpha_D^{16^\circ} + 4.75^\circ$ ;  $[\alpha]_D^{16^\circ} + 143.46^\circ$ .

(b) In alcohol.  $l = 1$ ;  $c = 3.7916$ ;  $\alpha_D^{16^\circ} + 4.72^\circ$ ;  $[\alpha]_D^{16^\circ} = 159.04^\circ$ .  
 $d = 0.772$ .

The specific rotation of quinidine in alcohol is  $+236.8^\circ$ .

After six crystallisations from water, neither the melting point nor optical activity underwent any appreciable change.

The sixth fraction melted at  $114^\circ$ , and had a specific rotation  $[\alpha]_D^{18^\circ} + 142.2^\circ$ .

The determination of the solubility of the salt in water gave the following numbers.

8.2738 grams of a saturated aqueous solution of quinidine  $\beta$ -methylglycerate at  $14.9^\circ$  contained 0.1368 gram of the salt; this result corresponds with a solubility at  $14.9^\circ$  of 1.64 grams in 100 grams of the solution.

### *1- $\beta$ -Methylglyceric Acid.*

The pure quinidine salt (m. p.  $114^\circ$ ) was dissolved in about 10 parts of water, and the quinidine was precipitated by means of baryta solution. The excess of baryta was removed by carbon dioxide, and, after filtration, the solution was found to be strongly laevorotatory.

The solution of the barium salt was concentrated to a small bulk *in vacuo* at  $50^\circ$  and poured into absolute alcohol. The precipitated barium salt is somewhat soluble in alcohol, and, on evaporating off this solvent, a further quantity of the salt was obtained; it was purified by recrystallisation from a very small volume of water, when it separated in fine needles and dried at  $110^\circ$ .

0.2032 gave 0.1267  $\text{BaSO}_4$ .  $\text{Ba} = 36.52$ .

$(\text{C}_4\text{H}_7\text{O}_4)_2\text{Ba}$  requires  $\text{Ba} = 36.53$  per cent.

The determination of the specific rotation gave the following numbers:

$l = 1$ ;  $c = 6.2683$ ;  $\alpha_D^{16^\circ} - 1.36^\circ$ ;  $[\alpha]_D^{16^\circ} - 20.63^\circ$ ;

and after 12 hours the rotation was unchanged.

To obtain the free acid, the barium salt was decomposed exactly by dilute sulphuric acid; the filtrate from the barium sulphate was

evaporated at  $50^\circ$  under diminished pressure to a syrup, which was extracted with dry acetone; the solution was filtered and the filtrate treated with dry ether until a permanent turbidity ensued.

The ether-acetone solution was poured off from the syrup which separated, and allowed to evaporate at the ordinary temperature. The acid, which was left as a syrup, after being stirred with a glass rod became solid. The white, crystalline solid was washed with dry ether and dried in a vacuum over sulphuric acid until its weight became constant. It was found to be quite free from ash. The *l*-methylglyceric acid crystallises in hexagonal plates and melts at  $74\text{--}75^\circ$ . Fittig and Kochs (*loc. cit.*) give the same melting point for the inactive acid.

0.1808 gave 0.2655  $\text{CO}_2$  and 0.1122  $\text{H}_2\text{O}$ .  $\text{C} = 40.05$ ;  $\text{H} = 6.89$ .

$\text{C}_4\text{H}_8\text{O}_4$  requires  $\text{C} = 40.0$ ;  $\text{H} = 6.66$  per cent.

The determination of the specific rotation gave the following numbers:

$l = 1$ ;  $c = 5.9937$ ;  $d = 1.023$ ;  $\alpha_D^{16^\circ} = 1.17^\circ$ ;  $[\alpha]_D^{16^\circ} = 13.51^\circ$ .

The acid is exceedingly hygroscopic; it is very soluble in alcohol and acetone, and dissolves very sparingly in dry ether.

#### *d*- $\beta$ -Methylglyceric Acid.

The mother liquors from the quinidine *l*-salt contain the more soluble *d*-salt. It was found impossible to separate the *l*-salt completely from the *d*-salt by fractional crystallisation. Since the barium *l*-salt is somewhat soluble in alcohol and the inactive barium salt is insoluble in that solvent, it was thought that a separation of the barium *d*-salt from the racemic salt might be effected by means of alcohol.

The impure quinidine *d*-salt was decomposed by baryta, and after filtration from the precipitated quinidine the concentrated solution of the barium salt was poured into absolute alcohol. The salt which separated out was quite inactive, and contained 36.5 per cent. of barium. The alcoholic filtrate was concentrated to a syrup, which soon became solid. After digestion with rectified spirit, the inactive salt was left undissolved, and from the alcoholic filtrate, the *d*-salt was obtained as an uncrystallisable syrup. In order to remove as much as possible of the inactive salt, the treatment with rectified spirit was repeated twice and the syrup was dried at  $130^\circ$  and analysed.

0.21479 gave 0.1350  $\text{BaSO}_4$ .  $\text{Ba} = 36.95$ .

$\text{Ba}(\text{C}_4\text{H}_7\text{O}_4)_2$  requires  $\text{Ba} = 36.53$  per cent.

A determination of the specific rotatory power gave the following numbers :

$$l = 1 ; c = 7.058 ; d = 1.040 ; \alpha_D^{15} + 1.25^\circ ; [\alpha]_D^{20} + 17.03^\circ.$$

The specific rotation of the barium *d*- $\beta$ -methylglycerate agrees fairly well with the value obtained for that of the barium *l*-salt.

The yield of the barium *d*-salt was so small, owing to the difficulty in separating it from the inactive salt, that the *d*-methylglyceric acid could not be isolated.

The racemic barium methylglycerate is much less soluble in water than either the *d*- or *l*-salt, and crystallises from a concentrated aqueous solution in stellar aggregates of obliquely terminated needles ; it contains two molecules of water of crystallisation, which are expelled at  $110^\circ$ .

0.6456 (air-dried) lost 0.0544  $\text{H}_2\text{O}$ .  $\text{H}_2\text{O} = 8.4$ .

$\text{Ba}(\text{C}_4\text{H}_7\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$  requires  $\text{H}_2\text{O} = 8.75$  per cent.

We are under very great obligations to Mr. A. E. Bellars for valuable assistance in the experimental part of the paper.

Our thanks are due to the Research Fund Committee of the Chemical Society for a grant defraying the cost of the materials used in this investigation.

## XXVI.—*The Chemical Reactions of Nickel Carbonyl.* *Part I. Reactions with the Halogens and other* *Inorganic Substances.*

By JAMES DEWAR and HUMPHREY OWEN JONES.

THE previous investigation of the physical properties and stability of nickel carbonyl (*Proc. Roy. Soc.*, 1903, 51, 427) having shown that the compound was much more stable than had hitherto been supposed, it was thought of interest to study its chemical reactions and stability more fully.

A few of the simpler decompositions of the compound were observed by Dr. Mond and his collaborators (*Trans.*, 1890, 57, 749), some further observations were recorded by Berthelot (*Compt. rend.*, 1891, 113, 679), and the product of oxidation in moist air has been studied by the last-mentioned chemist and by Lenher and Loos (*Amer. Chem. J.*, 1899, 22, 114).

The authors have studied a number of the reactions of the compound with the view of throwing further light on its chemical nature and structure, and its possible use as a synthetical agent. The present paper contains an account of its interactions with certain elements and simple inorganic compounds, studied mainly from a thermochemical point of view.

The heat of formation of liquid nickel carbonyl from metallic nickel and gaseous carbon monoxide, as determined by Mittasch (*Zeit. Physikal. Chem.*, 1902, 40, 49), lies between 51 and 55 Cal., the mean value being 52.17 Cal. Reicher had previously obtained the value 59.5 Cal. from the combustion of the compound. Taking the lower value and Thomsen's values for other nickel compounds, it might be expected that nickel carbonyl would be readily decomposed by chlorine or bromine, but not by iodine or sulphur, whereas it is actually decomposed completely by the four elements with the production of the corresponding nickel compounds and carbon monoxide.

In no case in which nickel carbonyl has been decomposed by elements has any combination of the carbon monoxide with the element been observed. This is remarkable since it might be expected that combination would take place more readily when the monoxide was in the so-called 'nascent' state.

Again, in the decomposition with hydrogen iodide and hydrogen sulphide, carbon monoxide is set free, and combination with hydrogen does not occur to any appreciable extent, if at all.

### *The Halogens and their Compounds.*

The reaction with the halogens was investigated in solution in pure, dry carbon tetrachloride, the mode of procedure being briefly as follows. Standard solutions of the carbonyl derivative and the halogen were made, varying in strength from normal to decinormal, 1—10 c.c. of the carbonyl solution were introduced into a Lunge nitrometer over mercury followed successively by some tetrachloride and a very slight excess of the solution of the halogen, the mixture being then shaken and the volume of gas evolved measured after the reaction was completed. This volume was then corrected to normal temperature and pressure by comparison with another nitrometer containing a known volume of air enclosed over carbon tetrachloride, and the gas was afterwards examined to ascertain whether it was pure carbon monoxide.

Experiments were also made at low temperatures to see whether the liquid or solid halogens had any action on solid nickel carbonyl.

*Chlorine.*

On mixing normal solutions in carbon tetrachloride, a brisk evolution of gas takes place at once and a grey solid is precipitated. From 1 c.c. of normal nickel carbonyl solution and 1.1 c.c. of normal chlorine solution, 49.0 c.c. of gas at 16° and 755 mm. were evolved, the volume when corrected to 0° and 760 mm. being 45.2 c.c.

The volume of carbon monoxide theoretically obtainable being 44.8 c.c., it is clear that complete decomposition has taken place into carbon monoxide or a mixture of this gas and carbonyl chloride. The gas, when tested for carbonyl chloride by treatment with water or aqueous sodium carbonate, gave indications that at most only a trace of the gas was formed, even when a considerable excess of chlorine had been used.

The solid product when collected and analysed was found to be pure anhydrous nickel chloride.

The heat of the reaction  $[\text{Ni}, \text{Cl}_2]$  is given by Thomsen (*Thermochemische Untersuchungen*, 3, 307) as 74.53 Cal., hence the reaction  $[\text{Ni}(\text{CO})_4, \text{Cl}_2]$  should occur with the evolution of 22.36 Cal.: a considerable rise of temperature does occur during the reaction.

No action occurs in a mixture of solid chlorine and solid nickel carbonyl, but when the chlorine becomes liquid the reaction seems to begin and to proceed steadily.

*Bromine.*

The reaction between normal solutions in carbon tetrachloride takes place rapidly and ends almost immediately after complete mixture, as in the case of chlorine.

The gas evolved was pure carbon monoxide and the solid on analysis was found to be pure anhydrous nickel bromide.

One c.c. of nickel carbonyl solution and 1.1 c.c. of normal bromine solution gave 47.2 c.c. of gas at 12° and 758 mm. The corrected volume of the gas is 44.5, whereas theory requires 44.8 as before.

Thomsen (*loc. cit.*) gives the heat of the reaction  $(\text{Ni}, \text{Br}_2, \text{aq})$  as 71.82 Cal., so that, unless the heat of hydration of nickel bromide is exceptionally great and the heat of solution exceptionally small, the reaction  $[\text{Ni}(\text{CO})_4, \text{Br}_2]$  should nevertheless occur with evolution of heat, as is actually found to be the case: a distinct rise of temperature takes place during the reaction.

Solid nickel carbonyl and solid bromine did not react, and when the mixture was gradually warmed it underwent no change until the bromine became liquid, when the reaction between the solid carbonyl and the liquid bromine proceeded rapidly.

*Iodine.*

When a normal solution of nickel carbonyl in carbon tetrachloride was mixed with an  $N/5$  or  $N/10$  solution of iodine in the same solvent, a brown or black solid was deposited and carbon monoxide was slowly evolved. On examination the solid proved to be nickel iodide. The reaction between 1 c.c. of the carbonyl solution and 5 c.c. of  $N/5$  iodine solution was completed in about half an hour, and the theoretical quantity of carbon monoxide was produced, as in the other cases.

Analysis of the solid, after heating at  $100^\circ$ , gave  $\text{Ni}=18.9$ .  $\text{I}=80.6$ . Calculated for  $\text{NiI}_2$ ,  $\text{Ni}=18.9$ .  $\text{I}=81.1$  per cent.

Thomsen (*loc. cit.*) gives the heat of the reaction  $(\text{NiI}_2, \text{aq})$  as 41.4 Cal. Now, unless the sum of the heats of hydration and solution of nickel iodide is negative, the reaction  $[\text{Ni}(\text{CO})_4, \text{I}_2]$  should be endothermic. A rough experiment was made which showed that the combined heat of solution and hydration of nickel iodide was positive, but small, being approximately 614 cal.

It was therefore important to determine whether any considerable fall of temperature occurred during the reaction. Experiments were made in which a definite volume of normal nickel carbonyl solution in different solvents was placed in a bulb, which was broken in an excess of  $N/10$  iodine dissolved in the same solvent and contained in a bottle, insulated as far as possible from extraneous sources of heat. The mixture was stirred, and the change of temperature observed by means of an accurate thermometer.

A mixture of 80 c.c. of  $N/5$  iodine and 8 c.c. of normal nickel carbonyl in carbon tetrachloride, was initially at  $15^\circ$ , and in the course of 13 minutes the temperature fell to  $13.8^\circ$ , the reaction being by that time nearly completed.

A mixture of 80 c.c. of  $N/10$  iodine, and 7 c.c. of normal nickel carbonyl in alcohol, was initially at  $15.4^\circ$ , but after 23 minutes, when the reaction was practically completed, the temperature had fallen to  $14.7^\circ$ .

In both these cases the fall is scarcely greater than would be expected to occur by the evaporation of a quantity of the liquid necessary to saturate the carbon monoxide evolved with its vapour at the temperature of the experiment. Sufficient data are not available to calculate the expected fall of temperature accurately, but the rough estimate which can be made with the incomplete data obtainable is of the above order.

It became, therefore, interesting to ascertain the source of the energy necessary to carry out the reaction. Experiments described

below on the velocity of the evolution of the carbon monoxide show that the reaction proceeds steadily at the ordinary temperature, and is a normal bimolecular reaction, as might be expected. The energy cannot be derived from radiant light or heat, since the reaction proceeds quite as rapidly when such radiations are screened off as completely as possible.

An indication of the possible source of the energy was obtained when the reaction was carried out in ethereal solution. In this case the nickel iodide is usually first deposited as a viscid brown liquid, which then changes into a mass of large pale green, tabular crystals, but very occasionally the green crystals seem to be formed directly. These crystals, when filtered off rapidly, change to the black iodide, and give off ether in the process; they may therefore be considered as consisting of nickel iodide united with ether of crystallisation.\* The loss of ether is so rapid when the crystals are taken out of the solvent, that it is quite impossible to analyse them. Somewhat similar phenomena have also been observed in other solvents, for example, in chloroform the iodide is deposited in brown, tabular crystals, which rapidly change when removed from the solution, and it is therefore probable that the nickel iodide forms molecular complexes either with the solvent or with iodine, even when there is no visible evidence of their existence, and thus gains the energy necessary to carry out the reaction. However, the tendency to form these complexes cannot be very great, since the anhydrous iodide does not combine with these solvents when mixed with them at the ordinary temperature.

This hypothesis as to the source of the energy required receives some slight support from the fact that solid iodine has scarcely any action on liquid nickel carbonyl, although this is partly due to the fact that the halogen is insoluble in the latter.

### *The Order of the Reaction and its Velocity in Chloroform.*

On investigating the velocity of the reaction in chloroform solution by observing the rate of evolution of carbon monoxide, it was found that the reaction proceeded quite normally at the ordinary temperature and, by altering the concentration, it was found that the reaction was of the second order as might be expected from the equation  $\text{Ni}(\text{CO})_4 + \text{I}_2 = \text{NiI}_2 + 4\text{CO}$ , providing that the iodine molecules are diatomic in chloroform solution. The experiments were made as simple as possible, the object being merely to see that the reaction proceeded steadily.

Three experiments are quoted and the results are shown by the appended curves, in which the ordinates represent the number of cubic

\* Compare the formation of  $\text{MgBr}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$  and  $\text{MgI}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$  (*Compt. rend.*, 1901, 132, 835) and (*J. Russ. Phys. Chem. Soc.*, 1903, 35, 610).

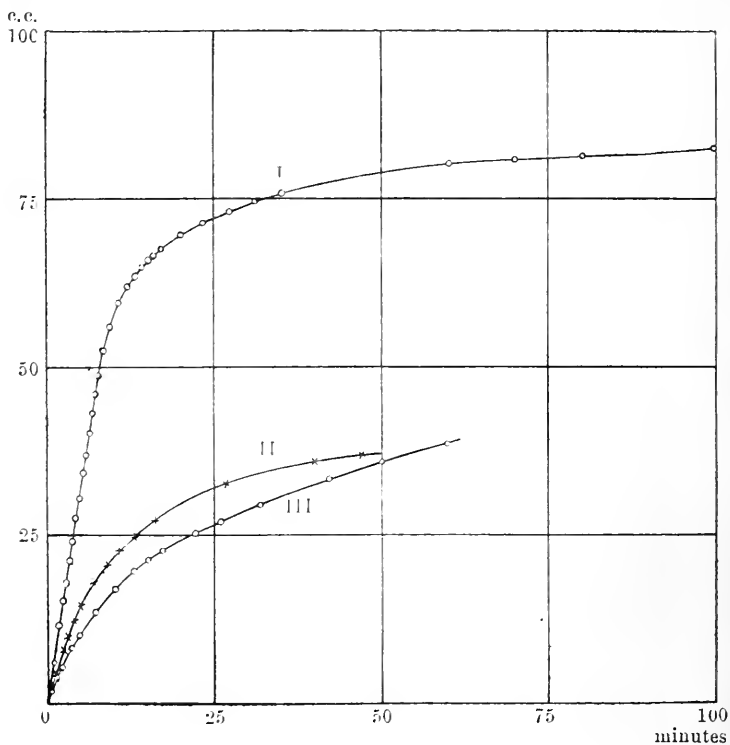

centimetres of gas evolved and the abscissæ represent the time in minutes, the temperature being  $12^{\circ}$ .

Curve I, 10 c.c.  $N/5$   $Ni(CO)_4$  + 30 c.c.  $N/10$  iodine in 50 c.c.

„ II, 5 „  $N/5$   $Ni(CO)_4$  + 30 „  $N/10$  iodine in 50 „

„ III, 5 „  $N/5$   $Ni(CO)_4$  + 15 „  $N/10$  iodine in 50 „

It is readily seen that the evolution of gas proceeds steadily without cessation from the beginning to the time when the observations ceased.

The order of the reaction was calculated by means of the formula

$$n = \frac{\log dC_1/dt / dC_2/dt}{\log C_1/C_2}$$

for three pairs of experiments I and III, and the following three values of  $n$  were obtained, 2.03, 2.20, and 2.00, so that the reaction is evidently one of the second order.

In calculating the velocity constant, very satisfactory results cannot

be obtained, probably owing either to some lag in the evolution of the gas from the solvent or to some disturbing side reactions. The value of  $k$ , however, appears to be about 0.0005, the unit of time being a minute.

### *Cyanogen.*

Gaseous cyanogen appears to have no action on gaseous or liquid nickel carbonyl. Cyanogen gas, enclosed in a Lunge nitrometer over mercury, when mixed with a little nickel carbonyl immediately increased in volume owing to the high vapour pressure of the carbonyl; but afterwards the volume remained constant for several days and no solid was deposited.

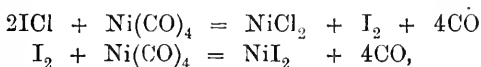

With an alcoholic solution of cyanogen, however, a reaction took place with moderate ease, nickel cyanide and carbon monoxide being produced. The reaction proceeded to the end, and the theoretical quantity of gas was evolved.

The heat of formation of hydrated nickel cyanide is 50.5 Cal. (Varet, *Compt. rend.*, 1896, 122, 1123), it is therefore slightly greater than that of nickel iodide, so that the reaction here, again, must be promoted by the formation of molecular complexes as in the case of the iodide.

### *Iodine Monochloride.*

When the brown solution of iodine monochloride in chloroform is mixed with a solution of nickel carbonyl in the same solvent, a violent reaction immediately takes place, a light brown solid is precipitated, and the solution becomes purple. The rate of evolution of gas then diminishes appreciably and the purple colour of the solution gradually disappears. The gas evolved is carbon monoxide, and the solid product of the reaction is a mixture of nickel chloride and iodide.

The reaction obviously proceeds in two distinct stages according to the equations

the first stage taking place rapidly with liberation of iodine, which then reacts more slowly with a further quantity of nickel carbonyl.

### *Iodine Trichloride.*

The reaction here proceeds exactly as in the case of the monochloride. The brown solution in chloroform or carbon tetrachloride at once becomes purple and gas is evolved very rapidly; the evolution of gas then becomes slower and the purple colour gradually disappears. The

reaction clearly occurs in two distinct stages, as in the case of the monochloride, the chloride being formed in preference to the iodide as would be expected from their respective heats of formation.

### *Cyanogen Iodide.*

When the colourless alcoholic solution of cyanogen iodide is mixed with a similar solution of nickel carbonyl, a light drab precipitate is at once formed, carbon monoxide is evolved and the solution turns brown. The precipitate is nickel cyanide and free iodine remains in the solution. The evolution of gas continues, and a darker precipitate is produced which now consists of nickel iodide.

A chloroform solution of cyanogen iodide, which is also colourless, behaves similarly, gas is evolved and a light drab precipitate produced, the solution becoming purple and containing free iodine. The evolution of gas continues and the precipitate turns black, or, if the tube is not shaken, a black precipitate of nickel iodide settles on the top of that first formed.

Here, again, it is clear that the reaction proceeds in stages, nickel cyanide and free iodine being first formed according to the equation

and then the iodine reacts with a further quantity of nickel carbonyl to produce nickel iodide. This shows clearly that the heat of formation of nickel cyanide is greater than that of the iodide in alcoholic or chloroform solutions, just as in aqueous solution.

### *The Hydrides of the Halogens.*

Dry hydrogen chloride or bromide, when mixed with nickel carbonyl over mercury, at once increases in volume owing to the vapour pressure of the carbonyl, the increase being exactly that amount which would be expected from the known value of the vapour pressure. Practically no further change could be observed on allowing the mixture to remain for several days. A minute amount of solid was deposited in some cases, but there was obviously no extensive reaction.

The reaction between hydrogen iodide and nickel carbonyl was investigated as follows, the use of mercury being inadmissible on account of its action on the acid gas. A glass bulb was carefully exhausted and then filled with hydrogen iodide at a slightly reduced pressure, a little nickel carbonyl was then admitted, excess being avoided at first. The gases soon reacted with the deposition of a black solid, the gaseous products were examined by passing through a U-tube immersed in liquid air and collecting the uncondensable gas and afterwards fractionating the condensed portions. The uncondensed gases

consisted of hydrogen and carbon monoxide, the condensable part being hydrogen iodide and nickel carbonyl. No formaldehyde could be detected. The solid produced was pure nickel iodide and contained no free iodine.

A solution of hydrogen iodide in chloroform reacts very rapidly with a similar solution of nickel carbonyl, producing carbon monoxide and a mixture of solids containing nickel iodide and free iodine, which has not yet been fully examined.

### *Sulphur.*

A solution of sulphur in carbon disulphide reacts slowly with nickel carbonyl in the absence of air, evolving a gas and forming a black solid. The gas evolved is not immediately absorbed by an alcoholic potash solution and therefore contains no carbon oxysulphide, it is, however, taken up by a solution of cuprous chloride in hydrochloric acid and is therefore practically pure carbon monoxide. The solid contains nickel and sulphur. A similar reaction occurs with a solution of sulphur in xylene, but in both cases it takes place very slowly.

With 1.5 c.c. of a normal solution of nickel carbonyl and an excess of a solution of sulphur in carbon disulphide, gas was steadily evolved for four days until about 78 c.c. had been collected, this being approximately the amount to be expected.

The heat of the reaction ( $\text{Ni}_3\text{S}_2.n\text{H}_2\text{O}$ ) is given by Thomsen (*loc. cit.*) as 19.4 Cal., so that the reaction  $[\text{Ni}(\text{CO})_4]\text{S}$  might therefore be strongly endothermic. However, there is no marked fall of temperature during the reaction, no energy can be obtained from radiant light since the black deposit rapidly renders the walls of the vessel quite opaque, and moreover, the reaction proceeds in the dark. The solid, on examination, was found to be a higher sulphide than  $\text{NiS}$ , having, in fact, a composition closely corresponding to  $\text{Ni}_2\text{S}_3$ . Found  $\text{Ni} = 54.8$ .  $\text{Ni}_2\text{S}_3$  requires  $\text{Ni} = 54.5$  per cent. Hence the necessary energy may be derived from the formation of this more complex compound.

### *Hydrogen Sulphide.*

Hydrogen sulphide mixed with excess of nickel carbonyl reacts very slowly, depositing a black solid and liberating hydrogen and carbon monoxide. In about a week only about 40 per cent. of the sulphide had reacted.

In alcoholic solution, the reaction proceeds more quickly, and the black precipitate first formed acquires a bronze lustre. On analysis, this solid proved to be the monosulphide,  $\text{NiS}$ . Found  $\text{Ni} = 64.4$ .  $\text{NiS}$  requires  $\text{Ni} = 64.7$  per cent.

The gases evolved contained hydrogen and carbon monoxide, and no formaldehyde could be identified with certainty among the products of reaction.

*Sulphuric Acid.*

Berthelot (*Compt. rend.*, 1891, 112, 1343) states that nickel carbonyl in contact with concentrated sulphuric acid detonates after a few minutes. This is quite contrary to our experience, for even when slightly moist nickel carbonyl was used, the reaction always took place slowly without any great evolution of heat.

Some nickel carbonyl and sulphuric acid were sealed up in a tube, a reaction went on very slowly during several weeks. The tube was opened from time to time and examined. Considerable pressure was developed and a yellow precipitate was formed. The gas evolved was a mixture of carbon monoxide and hydrogen, a little hydrogen sulphide was observed later, and the yellow solid proved to be nickel sulphate, so that the reaction seems to proceed according to the equation:

*Phosphorus.*

Nickel carbonyl, when mixed with a solution of phosphorus in carbon disulphide and left out of contact with air, undergoes no change after several weeks. If, however, dry air has access to the mixture, a reaction slowly occurs with the evolution of gas and the formation of a black solid which contains nickel and phosphorus, but which has not yet been fully examined.

CAMBRIDGE.

XXVII.—*The Chemical Reactions of Nickel Carbonyl.*  
*Part II. Reaction with Aromatic Hydrocarbons*  
*in presence of Aluminium Chloride. Synthesis of*  
*Aldehydes and Anthracene Derivatives.*

By JAMES DEWAR and HUMPHREY OWEN JONES.

NICKEL carbonyl does not react with aluminium chloride or most of the other metallic chlorides, nor has it by itself any action on aromatic hydrocarbons. If, however, a mixture of nickel carbonyl and a hydrocarbon, such as benzene or toluene, is treated with aluminium chloride

in the cold, a rapid evolution of hydrogen chloride at once occurs, while the mixture darkens in colour and becomes viscid. It is remarkable that during this apparently violent reaction there is no perceptible rise of temperature.

The reaction was allowed to proceed in the cold and also at  $100^{\circ}$ , and the products investigated. In the former case, an aldehyde was produced, the reaction being very similar to that effected by a mixture of carbon monoxide and hydrogen chloride in the presence of aluminium chloride (Gattermann and Koch, *Ber.*, 1897, 30, 1622; 1898, 31, 1149), and little or no nickel chloride could be detected. In the latter case, the aldehyde had almost entirely disappeared; an anthracene derivative was found to have been produced whenever possible, and a considerable quantity of nickel chloride appeared among the reaction products. The mechanism of this reaction is obscure, and although it is probable that the anthracene is formed by the condensation of two molecules of the aldehyde with the elimination of the elements of hydrogen peroxide, a change which may be effected by the metallic nickel present, yet numerous experiments made with the view of throwing further light on the process have given negative results.

The aldehyde produced from toluene is *p*-tolualdehyde, and the dimethylantracene formed must then be 2:6-dimethylantracene.

*m*-Xylene gives 2:4-dimethylbenzaldehyde, and the tetramethylantracene is therefore the 2:4:6:8-derivative, since the aldehyde can only condense in one way so as to give an anthracene compound. This tetramethylantracene is identical with that produced by Anschütz from *m*-xylene. Consequently the other produced from *m*-xylene by Friedel and Crafts must be the 1:3:6:8-isomeride, since there are only two such compounds which can be derived from *m*-xylene.

Mesitylene gives the aldehyde and no condensation product, the formation of an anthracene derivative being impossible in this case.

Naphthalene behaves in an entirely different manner from the above benzene derivatives; no aldehyde could be detected, and the product contains a hydrocarbon,  $C_{16}H_{12}$ , apparently identical with that obtained from ruficoccin by distillation with zinc dust and also by the action of methyl chloride and aluminium chloride on naphthalene. In this case, it would appear that carbon rings have been formed directly from carbon monoxide.

#### *Benzene.*

A mixture of benzene (4 mols.), aluminium chloride (4 mols.), and nickel carbonyl (1 mol.) was allowed to react in the cold either in a flask provided with a calcium chloride tube with a very small orifice as outlet for the gas, or in a sealed tube, which was opened from time to time to relieve the pressure. After a few days, the dark mass was

decomposed by means of ice-water (the aqueous layer contained only mere traces of nickel in solution), and after the addition of hydrochloric acid was submitted to distillation in a current of steam. The distillate and residue were extracted with benzene, dried over calcium chloride, and distilled. The distillate in steam was found to consist almost entirely of benzaldehyde, which was further identified by oxidation to benzoic acid and by the formation of its phenylhydrazone. The yield obtainable is not large, not exceeding 25 per cent. of the weight of the benzene used. The residue not volatile in steam was found to contain only a small quantity of viscid oil, which was not further examined.

On heating a mixture of the reagents, in the same proportions as above, at  $100^{\circ}$  in a sealed tube for periods varying from half an hour to several hours, the result was invariably the same, a dark mass was formed, considerable pressure developed, and a certain amount of the three reagents was found to be still present.

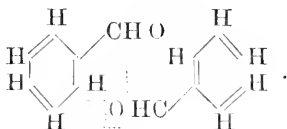

The product of the reaction was mixed with ice-water and treated as already described; the aqueous layer now contained considerable quantities of nickel in solution. The distillate in steam yielded a small quantity of benzaldehyde and a trace of a crystalline solid, which was afterwards found to be identical with the substance isolated from the part not volatile in steam. The dark, tarry solid left in the flask after the distillation in steam was taken up in hot benzene and the solution dried over calcium chloride and distilled under reduced pressure. A crystalline solid having a pale yellow colour distilled over between  $250^{\circ}$  and  $260^{\circ}$  under 10 mm. pressure, leaving behind a small amount of tarry residue, which was not further investigated. In one experiment, 12 grams of the solid were obtained, together with a small amount of benzaldehyde, from 17 grams of nickel carbonyl and 31.2 grams of benzene.

The solid, which was repeatedly crystallised from hot alcohol or benzene, was finally obtained in colourless, lustrous plates melting at  $211^{\circ}$  (uncorr.), and showing a beautiful violet fluorescence; it was identified as anthracene by ultimate analysis and vapour density determinations, and was further characterised by the formation of its picrate (m. p.  $136-137^{\circ}$ ) and anthraquinone.

Moreover, it was found that both this product and pure anthracene dissolved in pure sulphuric acid to a pale yellow solution, but if a trace of nitric acid were present—as is always the case with the ordinary 'pure' acid—a brilliant, dark green coloration was produced, and on adding potassium dichromate or a larger amount of nitric acid, the colour changed to a brilliant, reddish-purple, and finally to brown. This reaction, which we have never seen described, constitutes an ex-

ceedingly delicate test for anthracene and its homologues, and serves to distinguish this series from allied substances.

Anthracene is therefore the principal product of the action of nickel carbonyl on benzene in the presence of aluminium chloride at  $100^{\circ}$ , and it seems that benzaldehyde is certainly an intermediate product. The mechanism of this reaction, if benzaldehyde is assumed to be the intermediate product, consists in the elimination of the elements of hydrogen peroxide.

This change is of considerable interest, and several experiments have been made with the object of elucidating it; but, unfortunately, little information has been gained. The metallic nickel, produced by the decomposition of its carbonyl derivative, is very probably the reducing agent which effects the change, since it is only dissolved in any quantity when anthracene is produced.

(1) Benzaldehyde, when heated with aluminium chloride alone or with benzene and aluminium chloride, produced no anthracene, but only benzoic acid and a solid melting at  $90^{\circ}$ .

(2) On heating with aluminium chloride and zinc dust, benzaldehyde yielded a solid not volatile in steam; this product dissolved in hot alcohol and crystallised in needles melting at  $134^{\circ}$ .

0.1223 gave 0.356  $\text{CO}_2$  and 0.0625  $\text{H}_2\text{O}$ .  $\text{C} = 78.8$ ;  $\text{H} = 5.6$ .

$(\text{C}_6\text{H}_5 \cdot \text{CHO})_x$  requires  $\text{C} = 79.2$ ;  $\text{H} = 5.6$  per cent.

The substance is identified as being benzoin by the foregoing analysis and by a comparison of its melting point with that of the pure substance.

(3) A mixture of benzaldehyde, aluminium chloride, and finely-divided metallic nickel (reduced at a low temperature), when left in the cold became hot, and a small quantity of gas was produced. The product was heated at  $100^{\circ}$  for 5 hours and then examined in the manner already described. There was a slight pressure in the tube, and the aqueous solution contained nickel chloride. The steam distillate contained benzaldehyde and benzoic acid, but no anthracene could be obtained.

Hydrogen chloride, in benzene solution, was found to have only a very slight action on nickel carbonyl. Zinc chloride and anhydrous ferric chloride cause the production of a small amount of hydrogen

chloride, but the action is very slight and the liquid remains clear and colourless even after prolonged heating.

### *Toluene.*

On mixing nickel carbonyl (1 mol.) with toluene (4 mols.) and aluminium chloride (4 mols.), torrents of hydrochloric acid were immediately evolved, and the evolution of gas from the mixture continued slowly for several days. The reaction product was treated successively with ice-water and hydrochloric acid, being then submitted to steam distillation and worked up as already described. The aqueous solution contained only a trace of nickel chloride. Toluene distilled over first, and then a small quantity of oil boiling at  $204^{\circ}$  was obtained, the yield being about 16 per cent. of the toluene used. This product was identified as *p*-tolualdehyde by the preparation of methyl terephthalate from the product of its oxidation. The phenylhydrazone of this aldehyde was prepared; it separated from alcoholic solution in almost colourless plates which melt at  $114$ – $115^{\circ}$  and readily turn pink on exposure to sunlight. There was a small amount of non-crystallisable oil with a high boiling point, which was not further examined.

The product of the reaction at  $100^{\circ}$ , worked up in a similar way, gave about 9 per cent. of the aldehyde, and then the residue gave a solid, which, on crystallising from hot alcohol, separated in plates melting at  $215$ – $216^{\circ}$ .

0.1566 gave 0.5330  $\text{CO}_2$  and 0.099  $\text{H}_2\text{O}$ .  $\text{C} = 92.9$  ;  $\text{H} = 7.02$ .

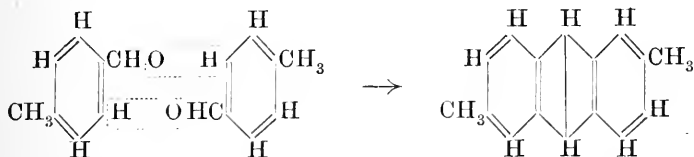

$\text{C}_{10}\text{H}_{14}$  requires  $\text{C} = 93.2$  ;  $\text{H} = 6.8$  per cent.

The substance is therefore a *dimethylantracene*.

This hydrocarbon gives the same colour reactions as anthracene with sulphuric and nitric acids, the colour being a little more intense. On oxidation with an acetic acid solution of chromic acid, it gave a quinone which melted at  $159$ – $160^{\circ}$ .

Elbs and Wittich (*Ber.*, 1885, 18, 348), by the action of chloroform and aluminium chloride on toluene in carbon disulphide solution, obtained a dimethylantracene melting at  $215$ – $216^{\circ}$ , and producing a quinone melting at  $161$ – $162^{\circ}$ . This hydrocarbon is probably identical with that described above. A similar hydrocarbon melting at  $231$ – $232^{\circ}$ , usually assumed to be identical with that of Elbs and Wittich, has been prepared by Friedel and Crafts (*Ann. Chim. Phys.*, 1884, [vi], 1, 482) by the action of benzyl chloride and aluminium chloride on toluene, and also by the action of methylene chloride and aluminium chloride on toluene (*loc. cit.*, 11, 266). The constitution of the dimethylantracene prepared by these methods has not been determined.

If, as is probable, *p*-tolualdehyde is an intermediate product in the formation of the anthracene derivative, then the constitution of the dimethylantracene thus produced, and consequently that of Elbs and Wittich, is at once fixed, since *p*-tolualdehyde can only condense in one way giving 2 : 6-dimethylantracene,

This dimethylantracene is therefore probably not the same as that obtained by Louise (*Ann. Chim. Phys.*, 1885, [vi], 6, 18); this substance, which melted at 218–219° and yielded a quinone melting at 170°, was prepared by passing benzylmesitylene through a red hot tube. These two hydrocarbons could not, however, be identical unless some profound molecular rearrangement had taken place.

#### *m*-Xylene.

A mixture of *m*-xylene, nickel carbonyl, and aluminium chloride in the proportions employed in the preceding examples at once darkened and a rapid evolution of hydrogen chloride occurred. The reaction product was allowed to remain for several days and then worked up in the manner already described. The distillate in steam gave an approximately 20 per cent. yield of an aldehyde boiling at 215–220°, and a very small quantity of an oil with a high boiling point; there was a small amount of tarry residue left in the distillation flask.

The aldehyde, on oxidation with chromic or nitric acids or when left exposed to the air, gave an acid which, after recrystallisation from hot water, was obtained as long, lustrous prisms melting at 126°.

0.1355 gave 0.3560 CO<sub>2</sub> and 0.0838 H<sub>2</sub>O. C = 71.66; H = 6.87.

C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)<sub>2</sub>·CO<sub>2</sub>H requires C = 72.0; H = 6.7 per cent.

The acid is therefore 2 : 4-dimethylbenzoic acid (xylic acid), identical with that produced by the action of carbonyl chloride and aluminium chloride on *m*-xylene (Ador and Meier, *Ber.*, 1879, 12, 1968). Accordingly the aldehyde is 2 : 4-dimethylbenzaldehyde, identical with that produced by the action of carbon monoxide, hydrogen chloride, and aluminium chloride on *m*-xylene by Gattermann and Koch (*loc. cit.*). The phenylhydrazone of this aldehyde crystallises from alcohol in pale yellow, rhombic plates melting at 82–84°. It has a great tendency to separate as an oil, and decomposes rapidly in sunlight, becoming coloured and gummy.

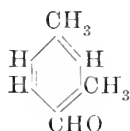

The mixture was also heated at  $100^{\circ}$  for several hours in a sealed tube and the products worked up as before. The part which volatilised in steam gave an approximately 20 per cent. yield of the aldehyde, just as if the reaction had proceeded in the cold. The residue in the distilling flask yielded a quantity of a solid boiling above  $280^{\circ}$  under 20 mm. pressure and a non-crystallisable oil with a higher boiling point. The solid was crystallised successively from hot benzene and from hot acetic acid, and was obtained in beautiful, lustrous plates melting at  $280^{\circ}$  and having a slight yellow tinge with a brilliant green fluorescence. This hydrocarbon is sparingly soluble in cold ether, alcohol, benzene and acetic acid, but more soluble in the hot solvents; it is fairly soluble in cold chloroform.

0.2698 gave 0.9097  $\text{CO}_2$  and 0.1875  $\text{H}_2\text{O}$ .  $\text{C} = 91.9$ ;  $\text{H} = 7.72$ .

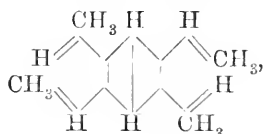

$\text{C}_{18}\text{H}_{18}$  requires  $\text{C} = 92.3$ ;  $\text{H} = 7.7$  per cent.

The compound gives a yellowish-brown coloration when dissolved in sulphuric acid with a trace of nitric acid; the solution, on further addition of the latter acid, assumes a claret, or an intense reddish-purple colour. On oxidation with chromic acid dissolved in acetic acid, a quinone was obtained, which, on recrystallisation from hot alcohol or acetic acid, formed pale yellow prisms melting at  $228$ — $230^{\circ}$ .

The hydrocarbon is therefore a *tetramethylanthracene*, and appears to be identical with that prepared by Anschütz (*Annalen*, 1886, 235, 174) by the action of acetylene tetrabromide and aluminium chloride on *m*-xylene. Since the aldehyde

can only condense in one way, the compound produced must be 2:4:6:8-tetramethylanthracene having this constitution:

unless, during the reaction, a considerable transformation has taken place resulting in the change of position of the methyl groups.

The quinone described above is therefore 2:4:6:8-tetramethylanthraquinone.

Friedel and Crafts (*Ann. Chim. Phys.*, 1887, [vi], 11, 268) obtained a tetramethylanthracene by the action of methylene chloride and

aluminium chloride on *m*-xylene, which is certainly different from that obtained by the authors and by Anschütz, since it melts at 162—163° and gives a quinone melting at 235°. This hydrocarbon must be 1 : 3 : 6 : 8-tetramethylanthracene, since this is the only other possible derivative obtainable from *m*-xylene.

### *Mesitylene.*

Mixtures of mesitylene (4 mols.), aluminium chloride (4 mols.), and nickel carbonyl (1 mol.) were either allowed to remain in the cold or heated in sealed tubes for several hours at 100°. The result in both cases was the same. On opening the tubes, there was but little pressure due to hydrogen chloride as compared to that observed with benzene and toluene, and on treating with water only a comparatively small quantity of nickel went into solution. After acidification, the liquid was submitted to distillation in steam, when the whole of the oil passed over leaving only a very small quantity of tarry matter in the distilling flask. The distillate was extracted with ether, dried over calcium chloride, and submitted to fractional distillation. The main portion of the liquid was found to be unchanged mesitylene, the remainder was an oil boiling at 234—240° and having the characteristics of an aldehyde. This oil, when oxidised with the calculated quantity of potassium permanganate in an alkaline solution, yielded an acid which was sparingly soluble in cold water and, on crystallisation from hot water, melted at 152°.

0.1072 gave 0.2865 CO<sub>2</sub> and 0.0725 H<sub>2</sub>O. C = 72.89 ; H = 7.51.

C<sub>6</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>3</sub>·CO<sub>2</sub>H requires C = 73.17 ; H = 7.32 per cent.

The substance is therefore mesitylenecarboxylic acid (m. p. 152°), the aldehyde being 2 : 4 : 6-trimethylbenzaldehyde, the boiling point of which is given as 235—240° by Feith (*Ber.*, 1891, 24, 3544); this compound cannot condense to form an anthracene derivative.

In the present instance, the reaction is very incomplete, thus, after heating at 100° for 6 hours, only 2 grams of the aldehyde were obtained from 24 grams of mesitylene. In a similar experiment, in which the heating lasted 16 hours, only a small quantity of aldehyde was obtained, but a little mesitylenecarboxylic acid was also produced (compare the formation of benzoic acid, page 215).

### *Naphthalene.*

Mixtures of naphthalene, nickel carbonyl, and aluminium chloride in the proportions indicated in the preceding experiments, when allowed to remain in the cold, gradually became very dark and slowly

evolved hydrogen chloride. After about a week, the mass was worked up in the manner already described. The distillate in steam which solidified was found to be practically pure naphthalene, and no product of an aldehydic nature was found. The black solid left in the distilling flask was dissolved in benzene, dried over calcium chloride, and, after evaporating off the benzene, was distilled under diminished pressure. At first a small amount of naphthalene distilled over, at about  $280^{\circ}$  under 17 mm. pressure an oil distilled which afterwards solidified, then above  $300^{\circ}$  the oily fraction, which had an orange colour, only partially solidified, and a small amount of black residue was left in the distilling flask.

When the same mixture had been heated at  $100^{\circ}$  for a few hours in a sealed tube and worked up as before, the same products were obtained, but in different proportions. There was now only a small quantity of naphthalene, together with a certain amount of the solid distillate and more of the oily fraction, but the main product remained in the distilling flask as a hard, black, resinous residue decomposing at the temperature at which the glass began to soften. The two last-mentioned substances still await further investigation.

The principal solid product obtained when the reaction was carried out in the cold or when the heating only continued for a very short time, was purified by repeated crystallisation from hot benzene, and was then isolated in lustrous plates having a yellow tinge and melting at  $180-181^{\circ}$ . This substance is very sparingly soluble in cold alcohol, benzene and acetic acid, much more so in the hot solvents, and especially in benzene or ethylene dibromide; its solutions are fluorescent. The colour of the hydrocarbon was diminished by crystallisation from hot alcohol with the addition of animal charcoal, but the melting point remained unchanged. From its solution in ethylene dibromide, the compound was obtained in colourless plates melting at  $180-181^{\circ}$ , the fluorescence of which still persists.

0.1203 gave 0.4100  $\text{CO}_2$  and 0.0610  $\text{H}_2\text{O}$ .  $\text{C} = 93.7$ ;  $\text{H} = 5.63$ .

0.1371 „ 0.4722  $\text{CO}_2$  „ 0.0711  $\text{H}_2\text{O}$ .  $\text{C} = 93.9$ ;  $\text{H} = 5.76$ .

$(\text{C}_5\text{H}_4)_x$  requires  $\text{C} = 93.75$ ;  $\text{H} = 6.25$ .

$(\text{C}_4\text{H}_3)_x$  „  $\text{C} = 94.11$ ;  $\text{H} = 5.89$ .

$(\text{C}_4\text{H}_4)_x$  „  $\text{C} = 92.7$ ;  $\text{H} = 7.3$  per cent.

A determination of the vapour density was made by V. Meyer's method, using a lead bath heated to a high temperature.

0.0712 gave 8.4 c.c. at  $12^{\circ}$  and 774 mm.  $\text{M. W.} = 196.4$ .

After cooling the apparatus, it was found that the hydrocarbon had sublimed in lustrous plates without charring.

Several determinations of the molecular weight were made by the

cryoscopic method with carefully purified ethylene dibromide as solvent. Test experiments with naphthalene and anthracene served to show that the solvent was pure and gave very satisfactory numbers. The experimental errors in the determination of the depression are necessarily large, since with solutions nearly saturated, as, for example, with 0.11 gram of the substance in 41 grams of solvent, the depression was only  $0.16^\circ$ , so that accurate results could not be expected. The following values were obtained: M. W. = 193. 198. 214. 227.

Attempts were made to use acetic acid or benzene for the cryoscopic method, but the hydrocarbon was too sparingly soluble in these solvents. With phenol, the value 215 was obtained, but the depression observed with a nearly saturated solution was only  $0.08^\circ$ . By the ebullioscopic method with alcohol as solvent, the elevation was too small to give reliable results, but in benzene the values 263 and 234 were obtained.

Mr. G. Barger, B.A., of King's College, kindly determined the molecular weight of the hydrocarbon by means of his microscopic method (this vol, p. 286). The sparing solubility again makes the determinations difficult, and largely increases the experimental error.

A solution in benzene containing 9.07 grams to the litre was found to be isotonic with a benzil solution containing 0.0345 gram-molecule per litre, hence the molecular weight is 263.

A solution in ethylene dibromide containing 11.5 grams per litre was isotonic with a solution containing between 0.057 and 0.064 gram-molecule of triphenylmethane per litre. Hence molecular weight is 180—202, giving 191 as a mean value. A solution containing 12.7 grams per litre was isotonic with a solution containing between 0.055 and 0.066 gram-molecule of benzil per litre, hence the molecular weight is 192—231, the mean being 211.

The analyses and molecular weight determinations correspond best with the formula  $C_{16}H_{12}$ , and the properties of the hydrocarbon correspond fairly well with those of a hydrocarbon having this formula, which had already been prepared by several chemists.

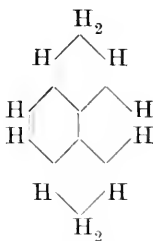

Liebermann and Dorp (*Annalen*, 1872, 163, 112), by the distillation of ruficoccin with zinc dust, obtained a hydrocarbon,  $C_{16}H_{12}$ , melting at  $183-188^\circ$ , and giving a quinone melting at  $250^\circ$ . The constitution

$C_{14}H_8 \begin{matrix} < CH_2 \\ & | \\ < CH_2 \end{matrix}$  is suggested by these authors for this hydrocarbon. By distilling either coccin or carmine with zinc dust, Fürth (*Ber.*, 1883, 16, 2169) obtained a hydrocarbon having this formula and melting at  $186-187^\circ$ .

Bischoff (*Ber.*, 1890, 23, 1905 and 3200), by the action of methyl chloride on naphthalene in the presence of aluminium chloride, obtained,

among other products, a hydrocarbon, boiling at about  $360^{\circ}$ , from which a crystalline substance was isolated having the empirical formula  $C_4H_3$  and melting at  $179-181^{\circ}$ .

The melting point and solubility of Bischoff's compound correspond exactly with those of the compound prepared by the authors. It may or may not be identical with the compound from ruficoccin. Bischoff put forward the following formula :

for his hydrocarbon, suggesting that it might be derived from 1 : 4 : 5 : 8-tetramethylnaphthalene.

Whatever the formula of the hydrocarbon may be, it is clear that unless the highly improbable assumption is made that some of the naphthalene molecules are partially broken down, and the hydrocarbon then built up from intact naphthalene molecules and the degradation products, it must be concluded that a carbon ring has been synthesised from carbon monoxide. The only other case in which this has been shown to occur is in the production of potassium hexaoxybenzene by the action of carbon monoxide on potassium.

*Reaction of Nickel Carbonyl with Benzene in the Presence of Aluminium Bromide.*

In this case, a reaction readily takes place, and the product was treated in the manner already described for aluminium chloride. No benzaldehyde and no anthracene could be detected, but a crystalline product distilling at  $300^{\circ}$  under 30 mm. pressure, and an uncrystallisable oil with a higher boiling point were obtained. The crystalline product, on repeated crystallisation from hot alcohol, was obtained in lustrous plates melting at  $181-181.5^{\circ}$ , and appeared to be identical in every respect with that obtained from naphthalene, a mixture of the two substances melting at  $181-181.5^{\circ}$ .

The authors desire to express their thanks to Dr. Mond for his aid in supplying the means for the conduct of these investigations.

CAMBRIDGE.

## XXVIII.—*Optically Active Nitrogen Compounds. d- and l-Phenylbenzylmethylethylammonium Salts.*

By HUMPHREY OWEN JONES.

THE first definite proof of the existence of optically active compounds in which the optical activity is due to asymmetric atoms other than carbon atoms was given by Pope and Peachey (*Trans.*, 1899, **75**, 1127), when they resolved Wedekind's  $\alpha$ -phenylbenzylmethylallylammonium iodide into dextro- and ævo-rotatory forms in which the activity is caused by the asymmetry of the quinquivalent nitrogen atom. Up to the present time, the salts then described, together with those described later by Pope and Harvey (*Trans.*, 1901, **79**, 828), derived from the same substance, are the only active nitrogen compounds known.

The  $\alpha$ - and  $\beta$ -phenylbenzylmethylallylammonium salts are also unique in that they are the only ones which have been shown to exist in *definite* stable isomeric forms. The phenomena observed in the phenylmethylethylallylammonium iodides by Wedekind (*Ber.*, 1903, **36**, 3791), if they can be considered as due to isomerism at all, are of quite a different order, since the differences vanish when the compounds separate from solution and the amorphous product becomes crystalline. It becomes therefore a matter of importance to determine whether the existence of optical activity is in any way connected with the existence of isomerides or whether it is dependent on the presence of any special radicles.

The resolution of one of these compounds was undertaken by the author in order to show that the negative result of the attempts to prepare active forms of salts of the type  $\text{NR}'\text{R}''\text{R}_2'''\text{X}$  was not due to the absence of ordinary isomerides or to the particular radicles used. A preliminary notice of the partial resolution of phenylbenzylmethylethylammonium compounds has already been published (*Trans.*, 1903, **83**, 1419).

This subject acquired additional interest after the publication of a paper by Wedekind (*Zeit. physikal. Chem.*, 1903, **46**, 235), in which unsuccessful attempts to resolve two salts, namely, *p*-tolylbenzylmethylallylammonium and *p*-tolylmethylethylallylammonium *d*-camphorsulphonates, are described.

The question of the existence of isomerides of phenylbenzylethylmethylammonium iodide was first investigated by preparing this compound in the three possible ways and carefully comparing the properties of the products.

*Phenylbenzylmethylethylammonium Iodide.*

(1) A mixture of methylethylaniline (27 grams) and benzyl iodide (43 grams) in molecular proportion set almost completely to a solid gum in the course of about two hours. The gummy mass, when dissolved in rectified spirit, crystallised slowly; the crystals which separated were short, almost colourless prisms melting at  $139\text{--}140^\circ$ , the melting point being slightly raised by repeatedly crystallising the substance from alcohol. Unfortunately, with this compound, as with some of the other substituted ammonium salts previously investigated, the melting point is not a constant, but depends on the rate of heating, and was sometimes found to have been lowered a degree or two when the substance was left for some time in a stoppered tube, although in this case no visible change had taken place. The carefully purified salt, when slowly heated, becomes slightly brown at  $140^\circ$ , and melts either at, or just below,  $144\text{--}145^\circ$ . If, however, the tube containing the salt is not introduced until the bath is at about  $140^\circ$ , the salt may not melt below  $146\text{--}148^\circ$ . These differences are apparently due to partial decomposition below the melting point. Hence, in the comparison of melting points described below, two tubes containing the substances to be compared were always heated side by side in the same bath.

(2) Benzylethylaniline, which was prepared as described by Friedländer (*Ber.*, 1889, 22, 588) by the action of ethyl iodide on benzylaniline at  $100^\circ$ , boiled at  $286\text{--}288^\circ$  under 750 mm. and at  $190^\circ$  under 20 mm. pressure.

A mixture of this base (14.4 grams) with methyl iodide (10 grams) in molecular proportion gradually deposited the ammonium iodide in a crystalline form, yielding about 1.6 per cent. after three days. The cold alcoholic solution, when diluted with ether, slowly deposited prismatic crystals which melted at  $145^\circ$  when slowly heated and at  $147\text{--}148^\circ$  when quickly heated, or a little higher than the compound produced by method (1). A mixture of the two preparations melted at the same temperature as the product of the second method; moreover, the crystalline form of the two products is the same, so that the two are apparently identical.

(3) A mixture of benzylmethylaniline (19.6 grams) and ethyl iodide (15.6 grams) in molecular proportion deposited, with extreme slowness, a crystalline solid and a little gummy matter, not more than about 2 per cent. of the salt being obtained after about a fortnight. The melting point of the crude substance was  $135\text{--}137^\circ$ , and on recrystallisation from alcohol the melting point rose to  $143\text{--}144^\circ$ , being identical with that of the product from the first method; a mixture of the two melted at

the same temperature, so that they are evidently the same. The quantity of material available was insufficient to furnish crystals large enough for crystallographic examination.

Hence no definite stable isomerides can be produced in this way. It is possible that the gummy product produced at first by method (1) and also the amorphous phenylmethylethylallylammonium iodide of Wedekind (*Ber.*, 1903, 36, 3791) may represent the untransformed, and, in these cases, the unstable addition product, which, when deposited from solution, undergoes transformation into the more stable form, but which is stable under special conditions, as in the case of certain compounds investigated by Kipping, and the  $\alpha$ - and  $\beta$ -phenylbenzylmethylallylammonium compounds of Wedekind (compare *Trans.*, 1903, 83, 1405).

A specimen dried in a vacuum desiccator was employed in the following analysis:

0.1350 gave 0.2695  $\text{CO}_2$  and 0.0691  $\text{H}_2\text{O}$ .  $\text{C} = 54.4$ ;  $\text{H} = 5.60$ .

$\text{C}_{16}\text{H}_{20}\text{NI}$  requires  $\text{C} = 54.4$ ;  $\text{H} = 5.66$  per cent.

#### *Resolution of the d- and l-Camphorsulphonates.*

The camphorsulphonates were made in the usual manner by boiling the silver salt of the acid with the calculated quantity of the ammonium iodide prepared by method (1), and a mixture of ethyl acetate and a little alcohol. *l*-Camphorsulphonic acid was prepared from *l*-borneol as described by Pope and Harvey (*Trans.*, 1901, 79, 76) and was found to melt at  $193^\circ$ ; its ammonium salt in aqueous solution gave  $[\text{M}]_D = 51.5^\circ$ . The *l*-camphorsulphonate of the *l*-base was prepared both from the inactive iodide and from crude *l*-iodide obtained from the most soluble portions of the *d*-camphorsulphonate.

The camphorsulphonates crystallise readily, are very sparingly soluble in acetone and ethyl acetate, even when hot, but dissolve quite readily in methylene diethyl ether (ethylal); a mixture of this with ethyl acetate was therefore used as solvent. The crystallisation was carried out at a comparatively low temperature, as it was found that prolonged heating induced a distinct retrogression in the rotatory power of the salt, most probably due to racemisation. Several crystallisations (6—8) were found to be necessary before the rotatory power of the salts became constant; the resolution therefore proceeds somewhat slowly and is not effected quite so readily as in the case of the phenylbenzylmethylallylammonium salts resolved by Pope and Peachey (*loc. cit.*).

The rotatory power of the salts is small compared with that of the last-mentioned compounds, so that on this account a much larger quantity of material must be worked up (about 30—40 grams of the

camphorsulphonates were employed), so that for this reason, and on account of the slight solubility of the salts and the necessity for keeping down the temperature, the process is somewhat tedious. The amount of the rotation observed was in all cases small even with comparatively concentrated solutions, consequently the experimental error is necessarily large, and great care had to be exercised in order to secure the highest degree of accuracy.

*d-Phenylbenzylmethylethylammonium d-Camphorsulphonate.*

This salt formed lustrous, prismatic crystals melting sharply at  $180-181^{\circ}$ ; its rotatory power in aqueous solution was determined several times during the process of fractional crystallisation, and  $[M]_D$  was found to approach a constant value of about  $71^{\circ}$ . A specimen was then dissolved in a mixture of ethyl acetate and ethylal, the solution allowed to evaporate slowly in a desiccator, and the successive fractions examined. The identity of the two results given below shows, within the limits of experimental error, that the compound is pure.

First fraction: 1.086 in 25 c.c. gave  $\alpha_D = 1.35^{\circ}$  in a 200 mm. tube,\* hence  $[\alpha]_D = 15.54^{\circ}$  and  $[M]_D = 71.0^{\circ}$ .

Third fraction: 1.063 in 25 c.c. gave  $\alpha_D = 1.32^{\circ}$ , hence  $[\alpha]_D = 15.52^{\circ}$  and  $[M]_D = 70.94^{\circ}$ .

0.1355 gave 0.3385  $\text{CO}_2$  and 0.0935  $\text{H}_2\text{O}$ .  $\text{C} = 68.1$ ;  $\text{H} = 7.7$ .

$\text{C}_{26}\text{H}_{35}\text{O}_4\text{NS}$  requires  $\text{C} = 68.2$ ;  $\text{H} = 7.6$  per cent.

*l-Phenylbenzylmethylethylammonium l-Camphorsulphonate.*

The salt has exactly the same properties as the corresponding *dd*-salt, crystallising in similar lustrous prisms and melting at  $180-181^{\circ}$ ; its molecular rotatory power in aqueous solution gradually became constant at about  $71^{\circ}$ . A specimen was then dissolved in a mixture of ethyl acetate and ethylal, the solution allowed to evaporate slowly in a desiccator, and the rotatory power of the successive fractions examined. The practical identity of the numbers obtained with one another and with those already given for the dextrorotatory isomeride shows that the salt is homogeneous.

First fraction: 0.583 in 25 c.c. gave  $\alpha_D = -0.73^{\circ}$ , hence  $[\alpha]_D = -15.6^{\circ}$  and  $[M]_D = -71.5^{\circ}$ .

Second fraction: 1.027 in 25 c.c. gave  $\alpha_D = -1.27^{\circ}$ , hence  $[\alpha]_D = -15.46^{\circ}$  and  $[M]_D = -70.7^{\circ}$ .

\* All the following determinations of  $\alpha_D$  were carried out in a 200 mm. tube.

Third fraction: 1.076 in 25 c.c. gave  $\alpha_D = -1.33^\circ$ , hence  $[\alpha]_D = -15.45^\circ$  and  $[M]_D = -70.6^\circ$ .

Fourth fraction: 1.002 in 25 c.c. gave  $\alpha_D = -1.27^\circ$ , hence  $[\alpha]_D = -15.8^\circ$  and  $[M]_D = -72.3^\circ$ .

0.1930 gave 0.4829  $\text{CO}_2$  and 0.1330  $\text{H}_2\text{O}$ . C = 68.2; H = 7.66.

$\text{C}_{26}\text{H}_{35}\text{O}_4\text{NS}$  requires C = 68.2; H = 7.6 per cent.

The molecular rotatory power of the *d*-phenylbenzylmethylethylammonium *d*-camphorsulphonate is therefore  $+71.0^\circ$  (mean), and that of the corresponding *l*-salt is  $-71.2^\circ$  (mean). Since the molecular rotatory powers of the *d*- and *l*-camphorsulphonate ions are respectively  $+51.7^\circ$  and  $-51.6^\circ$ , the molecular rotatory powers of the *d*- and *l*-phenylbenzylmethylethylammonium ions are  $+19.3^\circ$  and  $-19.6^\circ$  respectively. The value for the *d*-phenylbenzylmethylethylammonium *d*-camphorsulphonate agrees fairly well with that already given, namely,  $+69^\circ$  (*loc. cit.*, 1419). The molecular rotatory powers of the *d*- and *l*-phenylbenzylmethylallylammonium ions are  $+166.4^\circ$  and  $-159^\circ$  respectively (Pope and Harvey, *loc. cit.*).

The remarkably low value obtained for these compounds, which only differ from those last mentioned by the introduction of an ethyl instead of an allyl radicle, is therefore very surprising. It is difficult to see why such a small difference as this could produce such an enormous change in the rotatory powers were it not that it has been repeatedly shown that an ethylene linking exerts a very marked influence in increasing the rotatory power. An attempt was made to confirm these values by the examination of the bromocamphorsulphonates, but unfortunately these have not been obtained crystalline. Even when the *d*-iodide of the base, obtained from the *d*-camphorsulphonate, was converted into the *d*-bromocamphorsulphonate, the salt still remained a gum and could not be induced to crystallise.

#### *d*-Phenylbenzylmethylethylammonium Iodide.

The *d*-iodide of the base was obtained in a crystalline form by adding the calculated quantity of a concentrated aqueous solution of potassium iodide to an aqueous solution of the *d*-camphorsulphonate. The crystalline salt thus obtained, dried in a vacuum desiccator, was found to melt at practically the same temperature as the inactive iodide, admixture with which did not appreciably change the melting point.

The specimen for analysis was crystallised from cold alcohol in the dark.

0.1334 gave 0.2655  $\text{CO}_2$  and 0.0700  $\text{H}_2\text{O}$ . C = 54.28; H = 5.82.

$\text{C}_{16}\text{H}_{20}\text{NI}$  requires C = 54.39; H = 5.66 per cent.

The determinations of the rotatory power of the iodide offer considerable difficulties. The salt has a very small rotatory power and is very sparingly soluble in alcohol, so that, even with practically saturated solutions, the rotations observed were very small, for example,  $0.3-0.4^\circ$ , and hence the experimental error is very large. Chloroform dissolves a little more of the salt, but the solution shows a peculiar supersaturation phenomenon, the salt first dissolves and then partly crystallises out, in most cases rapidly, but sometimes more slowly, leaving a solution which gives a rotation of about the same magnitude as that of an alcoholic solution. Racemisation also occurs slowly in a chloroform solution, and consequently its use was abandoned.

Several determinations were made in alcoholic solution at a concentration of about 2 per cent., which represents a nearly saturated solution at the ordinary temperature. The following data represent three of these determinations:

0.5620 in 25 c.c. absolute alcohol gave  $\alpha_D = 0.37^\circ$ , hence  $[\alpha]_D = 8.23^\circ$  and  $[M]_D = 29.0^\circ$ .

0.5455 in 25 c.c. gave  $\alpha_D = 0.36^\circ$ , hence  $[\alpha]_D = 8.25^\circ$  and  $[M]_D = 29.1^\circ$ .

0.5560 in 25 c.c. gave  $\alpha_D = 0.38^\circ$ , hence  $[\alpha]_D = 8.5^\circ$  and  $[M]_D = 30.1^\circ$ .

It may therefore be concluded that the value of  $[\alpha]_D$  for the *d*-iodide is about  $8.3^\circ$ , although no very great reliance can be placed on these numbers owing to the very large experimental error.

#### *1-Phenylbenzylmethylethylammonium Iodide.*

This iodide was prepared from the corresponding camphorsulphonate in the manner already described for the *d*-iodide. The salt, after recrystallisation from cold alcohol in the dark, was found to melt, when slowly heated, at the same temperature as the *l*- and *d*-iodides, and mixtures of the *l*- and inactive iodides also melted at the same temperature.

The following analysis was made on a specimen dried in a vacuum desiccator.

0.1862 gave 0.3701  $\text{CO}_2$  and 0.0975  $\text{H}_2\text{O}$ .  $\text{C} = 54.2$ ;  $\text{H} = 5.81$ .

$\text{C}_{16}\text{H}_{20}\text{NI}$  requires  $\text{C} = 54.39$ ;  $\text{H} = 5.66$  per cent.

The rotatory power was determined in alcoholic solution in the same way as that of the *d*-iodide, with the following results:

0.547 in 25 c.c. absolute alcohol gave  $\alpha_D = -0.38^\circ$ , hence  $[\alpha]_D = -8.68^\circ$  and  $[M]_D = -30.8^\circ$ .

0.514 in 25 c.c. absolute alcohol gave  $\alpha_D = -0.34^\circ$ , hence  $[\alpha]_D = -8.27^\circ$  and  $[M]_D = -29.2^\circ$ .

0.526 in 25 c.c. absolute alcohol gave  $\alpha_D = -0.35^\circ$ , hence  $[\alpha]_D = -8.32^\circ$  and  $[M]_D = -29.4^\circ$ .

The specific rotatory power of the *l*-iodide in alcoholic solution is therefore numerically identical, within the limits of experimental error, with that of the corresponding *d*-salt, namely, about  $-8.4^\circ$ .

*Autoracemisation of the Phenylbenzylmethylethylammonium Salts.*

The camphorsulphonates retain their rotatory power practically unchanged for weeks in aqueous solution and also in cold alcoholic or ethylal solutions. If, however, the solutions are heated, the aqueous solution becomes turbid, the rotatory power of the other solutions diminishes, and the salt deposited from them has a distinctly low rotatory power. In one experiment, a specimen of *d*-phenylbenzylmethylethylammonium *d*-camphorsulphonate, having  $[M]_D = 71.4^\circ$ , was recrystallised from a hot mixture of ethyl acetate and acetone, the solution being heated for about 10 minutes in order to bring all the salt into solution; the salt which was deposited on cooling had a much lower rotatory power, namely,  $[M]_D = 56.0^\circ$ . Boiling in ethyl acetate solution had therefore caused almost complete racemisation of the basic part of the molecule.

In the fractional crystallisation of these salts, it is consequently necessary to avoid heating the solutions, and in practice the temperature was usually not raised above about  $40^\circ$ . The solutions of the iodides in alcohol retain their rotatory power in the cold for a long time, especially when left in the dark. On heating, however, the rotatory power diminishes, so that when recrystallising these compounds from alcohol the process must be carried out at as low a temperature as possible. In chloroform solution, racemisation takes place slowly in the cold and in absence of light.

On one occasion, a fairly strong chloroform solution of the *d*-iodide (not quite pure), when put into the tube, did not deposit the excess of iodide as all other chloroform solutions did, and was observed to be in the supersaturated state for about a week. The rest of the solution in the flask soon deposited crystals just as the other chloroform solutions had done.

0.859 in 25 c.c. chloroform gave  $\alpha_D = 0.64^\circ$ , hence  $[\alpha]_D = 9.31^\circ$ ;  $[M]_D = 33.8^\circ$ .

The rotatory power diminished gradually at first at the rate of about  $0.1^\circ$  per day, until it became practically inactive after a little more than a week. These salts therefore behave much in the same way as

the  $\alpha$ -phenylbenzylmethylallylammonium salts investigated by Pope and Harvey (*loc. cit.*).

The effect of chloroform in causing racemisation may be due, as suggested by these authors, to a dissociation of the ammonium salt into the tertiary amine and alkyl iodide and subsequent recombination to form the quaternary compound. This hypothesis is supported by an experiment made by the authors, which showed that the rate of formation of the salt in chloroform solution is large compared with that in alcohol or ether. Wedekind (*Zeit. physikal. Chem.*, 1900, 6, 23), on determining the molecular weight of the iodide in chloroform solution by the ebullioscopic method, obtained values about one-third of the calculated value indicating dissociation of the salt into its constituents.

It is difficult to see how the iodide could dissociate into three substances, the results therefore seem to indicate that the ebullioscopic method is inapplicable here. Moreover, the slow rate of racemisation indicates dissociation to a slight extent only; were the dissociation complete, the racemisation ought to be instantaneous.

The molecular weights of phenylbenzylmethylallylammonium iodide and phenylbenzylmethylethylammonium iodide in chloroform solution were determined by Mr. G. Barger, B.A., of King's College, who used his microscopic method. The author is glad to take the opportunity of expressing his thanks to Mr. Barger for the care and trouble which he expended on these determinations (compare this vol., p. 286).

#### *Phenylbenzylmethylethylammonium Iodide.*

A solution containing 23.9 grams per litre was found to be isotonic with a solution of triphenylmethane containing 0.075 gram-molecule per litre, whence the molecular weight is 319. A solution containing 25.1 grams per litre was found to be isotonic with a solution of azobenzene containing 0.0725 gram-molecule per litre, which gives a molecular weight 346. The calculated molecular weight is 353, so that at the ordinary temperature the molecular weight is approximately normal.

#### *$\alpha$ -Phenylbenzylmethylallylammonium Iodide.*

This salt, being much more soluble in chloroform than the foregoing compound, gives better results. A solution containing 59.0 grams per litre was found to be isotonic with a solution of triphenylmethane containing 0.16—0.17 gram-molecule per litre. Hence the molecular weight of the iodide lies between 335 and 381 (mean 358). The calculated value for  $C_{17}H_{20}NI$  is 365. So that the molecular

weight at the ordinary temperature gives no indication of extensive dissociation.

A peculiar phenomenon was observed in the case of both salts, which was, however, more marked with the phenylbenzylmethylallyl-ammonium iodide than with the other. In the freshly prepared solution, the molecular weight always appeared slightly too high; it then gradually diminished, became normal, and went on diminishing until it was somewhat too low. The rate of diminution was much increased by raising the temperature. This behaviour is being investigated, as it may throw light on the cause of the racemisation, and is probably the cause of the anomalous results obtained by the ebullioscopic method.

The above results, which show that in both cases there is only a very slight dissociation of the salts in chloroform solution at the ordinary temperature, thus account for the slow rate of racemisation.

*i*-Phenylbenzylmethylethylammonium Bromide.—This salt was prepared from the iodide by digesting an alcoholic solution with silver bromide. It crystallises from alcohol in prisms closely resembling those of the iodide, which melt sharply at 155–156°. The melting point of the bromide does not depend on the rate of heating in the same way as the iodide.

*l*-Phenylbenzylmethylethylammonium bromide is not precipitated from the aqueous solution of the camphorsulphonate by the addition of a concentrated aqueous solution of potassium bromide, and consequently had to be prepared by the same method as the inactive compound. It crystallises from alcohol in long prisms melting at 155–156°. A mixture of the *l*- and *i*-bromides also melts sharply at the same temperature.

A determination of the rotatory power in alcoholic solution was made with the following result:

0.634 in 25 c.c. gave  $\alpha_D = -0.68^\circ$ ; hence  $[\alpha]_D = -13.4^\circ$  and  $[M]_D = -41.1^\circ$ .

The rotatory power is greater than that of the corresponding iodide, just as the rotatory power of the active  $\alpha$ -phenylbenzylmethylallyl-ammonium bromide is greater than that of the iodide. The rotatory power of the bromide diminishes on recrystallising from alcohol.

0.212 gave 0.4850 CO<sub>2</sub> and 0.1200 H<sub>2</sub>O. C = 62.36; H = 6.4.

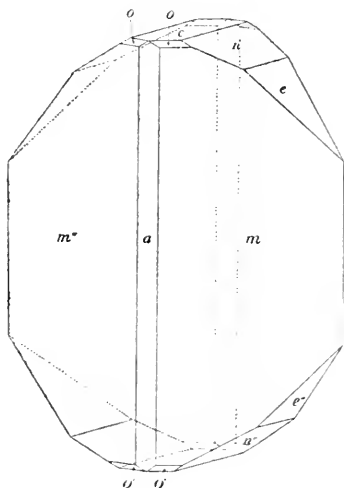

C<sub>16</sub>H<sub>20</sub>NBr requires C = 62.7; H = 6.53 per cent.

*Crystalline Form of the d-, l-, and i-Phenylbenzylmethylethylammonium Iodides.*

The crystallographic examination was undertaken in order to decide whether the inactive form was a racemic compound or merely an inactive mixture. These salts crystallise from alcoholic solutions in beautiful, lustrous prisms, the faces of which, although appearing quite bright, nevertheless give bad reflections on a goniometer, so that it was found difficult to get good measurements. The crystals could only be obtained of very small size, 1—2 mm. in length, and were therefore troublesome to measure.

The dominant form was always the prism  $m\{110\}$ , the pinacoid

FIG. 1.

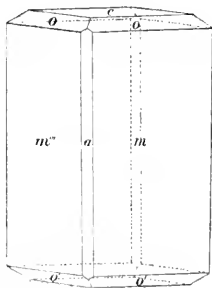

$a\{100\}$  was sometimes present as a very narrow face, but  $b\{010\}$  was never observed. Two distinct types of crystals were observed, see Figs. 1 and 2, one sort exhibited the domes  $e\{011\}$  and  $n\{012\}$  with the basal plane  $c\{001\}$ , often as a mere line, and  $o\{112\}$  was sometimes present; the other kind showed a well-developed basal plane and no domes, but  $o\{112\}$  was always present, and  $a\{100\}$  was occasionally observed. No general forms were present, so that the question of hemihedrism could not be definitely settled. From analogy with the  $\alpha$ -phenylbenzylmethylallylammonium salts and the phenylmethylethylallylammonium salts which belong to the sphenoidal class of the prismatic system, it is probable that this salt also belongs to the same class;

this is supported by the scanty evidence which was obtained by examining the etched figures produced on the faces  $m\{110\}$  and  $m'''\{1\bar{1}0\}$  by dilute alcohol. The few definite figures observed were devoid of a plane of symmetry, and those on  $m$  and  $m'''$  were interchangeable by rotation about the dyad axis.

The crystals of the *d*-, *l*-, and *i*-salts are similar in habit and appearance and have identical angles, so that the inactive salt is either an inactive mixture or a pseudoracemic compound. The fact

FIG. 2.

of the melting points of mixtures of *d*- or *l*-salt with the *i*-salt being the same as that of any one of the salts also supports this conclusion.

Crystalline system. Prismatic. Sphenoidal Class (?).

$$a : b : c = 0.7456 : 1 : 1.1409.$$

Forms observed:  $a\{100\}$ ,  $m\{110\}$ ,  $c\{001\}$ ,  $e\{011\}$ ,  $n\{012\}$ , and  $o\{112\}$ .

The following angular measurements were made:

Angle.	Number of observations.	Limits.	Mean.	Calculated.
$m\ m''' = 110 : 1\bar{1}0$	20	73° 0' — 73° 55'	73° 25'	—
$m\ m' = 110 : \bar{1}10$	19	106 0 — 106 50	106 34	106° 35'
$a\ m = 100 : 110$	4	36 20 — 36 55	36 40	36 37
$c\ c = 001 : 011$	10	48 35 — 48 56	48 46	—
$c\ n = 001 : 012$	10	29 19 — 29 56	29 37	29 42
$e\ e' = 011 : 0\bar{1}1$	6	97 14 — 97 46	97 32	97 32
$n\ n' = 012 : 0\bar{1}2$	4	58 50 — 59 50	59 12	59 34
$c\ n = 011 : 012$	8	18 25 — 19 20	19 0	19 4
$c\ n' = 011 : 0\bar{1}2$	7	78 10 — 78 56	78 28	78 28
$m\ n = 110 : 012$	3	72 40 — 73 30	73 13	73 3
$m''\ n = 1\bar{1}0 : 012$	3	106 39 — 107 20	106 56	106 57
$c\ o = 001 : 112$	9	20 20 — 21 19	20 56	20 58
$m\ o = 110 : 112$	10	69 0 — 69 30	69 14	69 8

The author desires to express his thanks to Mr. A. Hutchinson for kindly placing at his disposal the goniometer with which the above measurements were made.

It may therefore be concluded that (1) the ammonium compounds of the type  $\text{NR}'\text{R}''\text{R}'''\text{R}''''\text{X}$  can be resolved into enantiomorphously related optically active forms, although the resolution may often be difficult owing to the feeble rotatory power of the salts and the ease with which racemisation takes place, and that (2) the existence of optical activity is independent of the existence of ordinary isomerides of the salt.

Racemisation of the active salts takes place very readily on heating or on allowing solutions in chloroform to remain in the cold; the cause of the racemisation is probably dissociation into tertiary amine and alkyl iodide, followed rapidly by recombination, as suggested by Pope and Harvey.

The expenses of this investigation have been met by a grant from the Government Grant Committee of the Royal Society, for which the author is glad to make this acknowledgment.

UNIVERSITY CHEMICAL LABORATORY,  
CAMBRIDGE.

XXIX.—*Diortho-substituted Benzoic Acids. Part V.*  
*Formation of Salts from Diortho-substituted Benzoic*  
*Acids and Organic Bases.*

By JOHN JOSEPH SUDBOROUGH and WILLIAM ROBERTS.

IN a previous communication on this subject (Lloyd and Sudborough, *Trans.*, 1899, 75, 580), it has been shown that stereochemical influences only slightly affect the reactions between substituted benzoic acids and organic bases, these influences being completely masked by the effect of the comparative strengths of the acids and bases. Since the publication of this earlier paper, Emil Fischer (*Ber.*, 1900, 33, 345, 1967) has drawn attention to the fact that diortho-substituted tertiary bases are incapable of combining with an alkyl iodide to yield quaternary ammonium compounds. As the earlier experiments were not carried out with bases of this type, we have tried to prepare salts from diortho-substituted alkylated arylamines of the type of dimethyl-

mesidine and various substituted benzoic acids, including those with two ortho-substituents. We have also attempted to combine the same acids with diethyl- $\alpha$ - and  $\beta$ -naphthylamines.

*s*-Trinitrobenzoic acid forms salts with all the bases examined; 2:4:6-tribromo-3-aminobenzoic acid also forms salts with a number of the bases, but not many have been obtained in a crystalline form. It would thus appear that the introduction of ortho-substituents into the acid and basic molecules does not prevent the formation of salts, provided that the acid is very strong and the base not too weak.

In addition, we have attempted to settle a point raised in the earlier paper (*ibid.*, p. 583), namely, the behaviour of various organic bases towards a weak diortho-substituted acid of the type of *s*-trimethylbenzoic acid. The acid forms a well-defined, crystalline salt with a strong base such as benzylamine, and also dissolves readily in 33 per cent. aqueous trimethylamine solution, but all attempts to combine it with tertiary bases such as dimethylmesidine, dimethyl- $\psi$ -cumidine, bromodimethyl-*m*-xylylidine, and diethylaniline have given negative results; in each case, the unaltered acid crystallised out from the different solvents, even when two or three times the theoretical amount of base was employed. It is clear that the loss of the function of salt formation is not due to the presence of ortho-substituents in the basic molecules, because a simple base like diethylaniline is incapable of forming a salt with this acid. In order to determine whether it is due to ortho-substituents in the acid molecule, we have endeavoured to prepare salts from the same bases and mono-substituted benzoic acids containing substituent methyl, bromo-, and nitro-groups. The fact that no salts are formed from either *m*-toluic acid and dimethylaniline, or *p*-toluic acid and dimethylaniline or  $\psi$ -cumidine indicate that the presence of ortho-substituents in the acid molecule is not necessary in order to inhibit salt formation.

In addition to the normal salts formed by the union of one molecule of acid with one of the base, we have obtained a number of acid salts formed by the union of two molecules of acid with one of the base, as, for example, the acid salts derived from  $\psi$ -cumidine and *o*-toluic acid, dimethyl- $\psi$ -cumidine and *m*-nitrobenzoic acid,  $\psi$ -cumidine and *m*-nitrobenzoic acid, dimethyl- $\psi$ -cumidine and tribromoaminobenzoic acid, and dimethyl- $\psi$ -cumidine and *o*-nitrobenzoic acid. These compounds are similar to the acid potassium and ammonium salts derived from substituted benzoic acids, which have been recently described by Farmer (*Trans.*, 1903, 83, 1440). According to this investigator, the probable constitution of these acid salts is represented by the formula  $\begin{array}{c} \text{R}-\text{CO} \\ \text{R}\cdot\text{CO}\cdot\text{O} \end{array} > \text{O} < \begin{array}{c} \text{K} \\ \text{H} \end{array}$ , and the molecule contains a quadrivalent oxygen atom. With such a formula, it is quite possible that inhibition

through stereochemical influences should occur. If ortho-substituents retard or prevent the formation of additive compounds involving the carbonyl residue of the substituted benzoic acid (compare *Trans.*, 1899, **75**, 581), it is quite possible that ortho-substituents would also prevent the conversion of the bivalent oxygen atom of the hydroxyl group into a quadrivalent oxygen. We might therefore expect that diortho-substituted benzoic acids would not give rise to acid salts. Although we have not particularly investigated this question, we have met with only one such salt derived from dimethyl- $\psi$ -cumidine and tribromoaminobenzoic acid.

The salts were usually analysed by determining the amount of acid present according to the method previously described (*loc. cit.*, 584). We have found that the majority of the salts can also be analysed by titrating their alcoholic solutions with standard baryta when phenolphthalein is used as indicator. The presence of the organic base does not interfere with the titration, and good results are obtained. For example, 20 c.c. of *N*/20 oxalic acid required 15.4 c.c. of baryta solution, and 20 c.c. of *N*/20 oxalic acid mixed with 6 drops of dimethyl- $\psi$ -cumidine also required 15.4 c.c. of the same alkali solution.

## EXPERIMENTAL.

### A. Preparation of Bases.

Dimethyl- $\psi$ -cumidine,  $C_6H_2Me_3 \cdot NMe_2$  [ $Me_3 : NMe_2 = 2 : 4 : 5 : 1$ ], was obtained by a method somewhat similar to that employed by Noelting in the preparation of dimethyl-*m*-xylidine (*Ber.*, 1891, **24**, 563); 20 grams of  $\psi$ -cumidine melting at 68°, 70 grams of methyl iodide, 47 grams of sodium carbonate, and 500 grams of water were heated in a reflux apparatus until all the iodide had disappeared; caustic potash solution was added and the base extracted with ether. The ethereal solution, when dry, gave 17 grams of a colourless oil distilling at 219°, which was characterised by the formation of its *platinichloride*.

0.3808 gave 0.1003 Pt = 26.47.

$(C_6H_2Me_3 \cdot NMe_2)_2, H_2PtCl_6$  requires 26.47 per cent.

Dimethylmesidine [ $Me_3 : NMe_2 = 2 : 4 : 6 : 1$ ], obtained in a similar manner from mesidine, was freed from secondary base by heating in a sealed tube with methyl iodide and dry magnesia at 100° (*Fischer, Ber.*, 1900, **33**, 1968).

Bromo-*m*-xylidine [ $Me_2 : NH_2 : Br = 2 : 4 : 1 : 6$ ], melting at 46–47°, was obtained by Fischer's method (*ibid.*, 1971) and transformed into the tertiary base by the method employed in the case of mesidine.

Diethyl  $\alpha$ - and  $\beta$ -naphthylamines were prepared by Morgan's

process (Trans., 1900, 77, 823). Of the acids employed, the 2:4:6-tribromo-3-aminobenzoic acid was prepared by the method already described (Trans., 1899, 75, 589), the *s*-trinitrobenzoic acid was kindly presented by the Chemische-Fabrik Griesheim, and the *s*-trimethylbenzoic acid was prepared from mesitylglyoxylic acid (Meyer, *Annalen*, 1888, 246, 139). Van Scherperzeil (*Rec. trav. chim.*, 1900, 19, 380) recommends heating the glyoxylic acid with concentrated sulphuric acid until no more carbon monoxide is evolved, but we find that in order to obtain a good yield the temperature should be carefully regulated, the best yields being obtained when the temperature is kept about 40°; above 50°, carbon dioxide begins to be evolved, and the trimethylbenzoic acid itself is destroyed. In one experiment, we obtained 2.05 grams of trimethylbenzoic acid from 2.5 grams of the glyoxylic acid (m. p. 152°). The magenta coloration produced when glyoxylic acid is dissolved in concentrated sulphuric acid is extremely characteristic.

#### B. Salts from *s*-Trinitrobenzoic Acid.

*Dimethyl-ψ-cumidine 2:4:6-Trinitrobenzoate*.—The salt,

slowly separated in the form of snow-white, small needles on mixing alcoholic solutions of the acid and base; it crystallises from benzene in small needles, dissolves in hot water, alcohol, or chloroform, but is insoluble in carbon disulphide or light petroleum. Like the salts of trinitrobenzoic acid already described, it has no definite melting point; on heating, it melts and decomposes, yielding a dark red oil; the temperature at which this occurs varies considerably with the rate of heating. When heated fairly rapidly, it begins to turn dark at 115° and melts at 120°.

0.7179 gave 0.438 trinitrobenzoic acid = 61.0.

$\text{C}_{18}\text{H}_{20}\text{O}_8\text{N}_4$  requires 61.2 per cent.

*Dimethylmesidine Trinitrobenzoate*,  $(\text{NO}_2)_3\text{C}_6\text{H}_2\cdot\text{CO}_2\cdot\text{NHMe}_2\cdot\text{C}_6\text{H}_2\text{Me}_3$ .—The salt, obtained in the form of small needles when alcoholic solutions of the two components were mixed, begins to darken at 105°, and is completely decomposed at 116—117°; it dissolves in the ordinary solvents on heating, but is decomposed by some of these, more especially water or alcohol. When boiled for a short time with alcohol, it yields crystals melting at 122°; these proved to be *s*-trinitrobenzene, as with diethyl-β-naphthylamine they furnished purplish-black needles melting at 115—116°.

0.8867 gave 0.5392 trinitrobenzoic acid = 60.8.

$\text{C}_{18}\text{H}_{20}\text{O}_8\text{N}_4$  requires 61.2 per cent.

*Bromo-m-xylylidine Trinitrobenzoate*,  $(\text{NO}_2)_3 \cdot \text{C}_6\text{H}_2 \cdot \text{CO}_2 \cdot \text{NH}_3 \cdot \text{C}_6\text{H}_2\text{Me}_2\text{Br}$ .  
 —This salt, which was prepared by mixing alcoholic solutions of the acid and base, slowly separated in yellow, prismatic crystals which begin to change colour at  $130^\circ$ , are completely decomposed at  $150^\circ$ ; it is soluble in warm alcohol.

0.7154 gave 0.3986 trinitrobenzoic acid = 55.6.

$\text{C}_{15}\text{H}_{13}\text{O}_8\text{N}_4\text{Br}$  requires 56.2 per cent.

When the alcoholic solution was boiled for a short time, it acquired a red colour, and small, red needles melting at  $104\text{--}105^\circ$  were obtained on cooling. This substance, which is the additive compound,  $\text{C}_6\text{H}_2\text{Me}_2\text{Br} \cdot \text{NH}_2, \text{C}_6\text{H}_3(\text{NO}_2)_3$ , was also obtained by mixing alcoholic solutions of bromo-*m*-xylylidine and trinitrobenzene.

0.3824 gave 0.1955 trinitrobenzene = 51.1.

$\text{C}_{14}\text{H}_{13}\text{O}_6\text{N}_4\text{Br}$  requires 51.5 per cent.

It dissolves readily in ether, benzene, chloroform, and warm alcohol.

*Bromodimethyl-m-xylylidine Trinitrobenzoate*,

$(\text{NO}_2)_3 \cdot \text{C}_6\text{H}_2 \cdot \text{CO}_2 \cdot \text{NHMe}_2 \cdot \text{C}_6\text{H}_2\text{Me}_2\text{Br}$ .

—The salt, which was obtained from alcoholic solutions, begins to change colour at  $105^\circ$ , and is completely decomposed at  $108^\circ$ .

0.6506 gave 0.3435 trinitrobenzoic acid = 52.8.

$\text{C}_{17}\text{H}_{17}\text{O}_8\text{N}_4\text{Br}$  requires 53.0 per cent.

*Diethyl- $\alpha$ -naphthylamine s-Trinitrobenzoate*.—This salt separated in the form of flat, slightly yellow plates when warm alcoholic solutions of the acid and base were mixed. The mother liquor, when kept for several days, deposited bright red needles melting at  $95^\circ$ . These consist of diethyl- $\alpha$ -naphthylamine-trinitrobenzene (Trans., 1903, 83, 1338), and if the alcoholic solution of the salt is boiled, it is completely converted into this compound.

The salt decomposes at  $117\text{--}118^\circ$  and dissolves in alcohol, benzene, or chloroform.

0.5420 gave 0.3024 trinitrobenzoic acid = 55.8.

$\text{C}_{21}\text{H}_{20}\text{O}_8\text{N}_4$  requires 56.3 per cent.

*Diethyl- $\beta$ -naphthylamine s-Trinitrobenzoate*.—This salt, which was also obtained from alcoholic solutions of the acid and base, begins to darken at  $125^\circ$  and is completely decomposed at  $132^\circ$ ; it dissolves in hot water, alcohol, benzene, and chloroform, and, like its isomeride, shows a tendency to lose carbon dioxide and to form diethyl- $\beta$ -naphthylamine-trinitrobenzene melting at  $116^\circ$  (Trans., 1903, 83, 1340). This transformation is practically quantitative when an alcoholic solution of the salt is boiled for a short time.

0.4736 gave 0.2641 trinitrobenzoic acid = 55.7.

$C_{21}H_{20}O_8N_4$  requires 56.3 per cent.

The changes which these salts undergo when their alcoholic solutions are boiled, illustrate remarkably well the difference in stability between the additive compounds of *s*-trinitrobenzene with aniline derivatives and those produced with naphthylamine derivatives.

Dimethyl- $\psi$ -cumidine and dimethylmesidine, when boiled in alcoholic solution, yield the free base and *s*-trinitrobenzene, whereas diethyl- $\alpha$ - or - $\beta$ -naphthylamine trinitrobenzoate yields the corresponding coloured additive compound of the base with *s*-trinitrobenzene.

In order to determine whether dimethyl- $\psi$ -cumidine forms a definite compound with *s*-trinitrobenzene, we have made a number of experiments with different solutions, but in all cases, even when excess of the base was employed, crystals of unaltered *s*-trinitrobenzene were deposited. A coloured compound, obtained by crystallising *s*-trinitrobenzene from the base and allowing the crystals to dry in a desiccator containing a little of the free base, separated in small, bright red needles with no definite melting point, as when warmed they readily give up the base, leaving a colourless residue. When exposed to the air, the substance readily leaves a colourless residue of *s*-trinitrobenzene.

0.5 gave 0.2831 trinitrobenzene (m. p.  $122^\circ$ ) = 56.62.

$C_{17}H_{20}O_6N_4$  requires 56.6 per cent.

An additive compound of trinitrobenzene and  $\psi$ -cumidine, obtained by mixing together alcoholic solutions of the constituents, crystallises in long, slender, purple-brown needles melting at  $115^\circ$ , and is much more stable than the compound of aniline with trinitrobenzene.

0.3036 gave 41.3 c.c. moist nitrogen at  $17^\circ$  and 765 mm.  $N = 15.9$ .

$C_{15}H_{16}O_6N_4$  requires 16.09 per cent.

#### C. *Salts from 2:4:6-Tribromo-3-aminobenzoic Acid.*

*Dimethylmesidine 2:4:6-Tribromo-3-aminobenzoate,*

—The salt was obtained by dissolving the acid in ether, adding a slight excess of dimethylmesidine, and allowing the greater part of the ether to evaporate; it crystallised from water in small needles, softening at  $147^\circ$  and melting at  $163$ — $165^\circ$ .

0.8002 gave 0.5677 tribromoaminobenzoic acid = 70.9.

$C_{18}H_{21}O_2N_2Br_3$  requires 69.6 per cent.

The salt readily dissolves in alcohol, and also to a less extent in ether, benzene, chloroform, or hot water, but is very sparingly soluble in light petroleum.

*Dimethyl-ψ-cumidine Hydrogen Tribromoaminobenzoate,*

—When the acid and base were mixed in molecular proportion, the mixture did not set to a solid mass, but remained pasty, and when the mixture was crystallised from benzene, in which it is only moderately soluble, nodular aggregates of small, colourless needles melting at  $145.5$ — $146^\circ$  were obtained. When titrated in alcoholic solution with standard baryta, using phenolphthalein as indicator,  $0.4062$  required  $17.85$  c.c. of  $N/20 \text{ Ba(OH)}_2$ .

The amount required for the normal and acid salts,

and  $2(\text{NH}_2 \cdot \text{C}_6\text{HBr}_3 \cdot \text{CO}_2\text{H}), \text{C}_6\text{H}_2\text{Me}_3 \cdot \text{NMe}_2$ , are  $15.48$  and  $17.84$  c.c. respectively.

When decomposed with dilute hydrochloric acid and extracted with ether,  $0.6024$  gave  $0.505$  tribromoaminobenzoic acid =  $83.8$  per cent.

$\text{NH}_2 \cdot \text{C}_6\text{HBr}_3 \cdot \text{CO}_2\text{H}, \text{C}_6\text{H}_2\text{Me}_3 \cdot \text{NMe}_2$  and

require  $69.6$  and  $82.1$  per cent. respectively.

The same compound, obtained in the form of glistening, well-developed prisms by dissolving molecular quantities of the acid and base in alcohol, adding water, and allowing the solvent to evaporate slowly, melted at  $146^\circ$ .

$0.3$  required  $13.24$  c.c. of  $N/20 \text{ Ba(OH)}_2$  for neutralisation;  $2$  mols. acid +  $1$  mol. base requires  $13.17$  c.c.

The melting point was not affected by crystallisation from benzene.

We have attempted to prepare the normal salt ( $1$  mol. acid +  $1$  mol. base) by dissolving a mixture of the acid with twice its weight of base in hot benzene and allowing the solution to crystallise and also by dissolving the acid ( $1$  mol.) in dry ether, and adding an ethereal solution of the base ( $4$  mols.), but the same acid salt melting at  $146^\circ$  was obtained in both cases.

Attempts to obtain salts with diethyl- $\alpha$ - and - $\beta$ -naphthylamines led to the formation of gummy, uncrystallisable masses.

*D. Salts from 2:4:6-Trimethylbenzoic Acid.*

*Benzylamine 2:4:6-trimethylbenzoate* is obtained by separately dissolving equivalent amounts of the acid and base in light petroleum and mixing the solutions; it crystallises from benzene in small, feathery, colourless needles melting at  $165^\circ$ .

$0.3052$  gave  $0.1868$  trimethylbenzoic acid =  $61.2$ .

$\text{C}_{17}\text{H}_{21}\text{O}_2\text{N}$  requires  $60.5$  per cent.

Salts could not be obtained with this acid and any of the following

bases: dimethylmesidine, dimethyl- $\psi$ -cumidine, bromodimethyl-*m*-xylylidine, diethylaniline.

### E. Salts of the Three Toluic Acids.

*Benzylamine o-toluate*, obtained from light petroleum solutions of the acid and base, crystallises from benzene in small prisms melting at 146°. It dissolves readily in water, and to a moderate extent in light petroleum.

0.4716 gave 0.2668 *o*-toluic acid = 56.5.

$C_6H_4Me \cdot CO_2 \cdot NH_3 \cdot CH_2Ph$  requires 55.9 per cent.

$\psi$ -Cumidine hydrogen *o*-toluate,  $2(C_6H_4Me \cdot CO_2H) \cdot C_6H_2Me_3 \cdot NH_2$ , produced by mixing together ethereal or light petroleum solutions of the acid and base, crystallised from water in long, snow-white, silky needles, softening somewhat at 80° and melting at 82.5°. The same compound is obtained when an excess of the base is employed.

0.5 gave 0.3315 *o*-toluic acid (m. p. 105) = 66.3.

One mol. acid + 1 mol. base requires 50.18.

Two        „        „        „        „        66.8 per cent.

0.70 gram, when dissolved in sodium carbonate and extracted with ether, gave 0.236 gram of solid base = 33.7. The acid salt requires 33.2 per cent.

0.25 gram of the salt, when dissolved in ethyl alcohol, required 24.8 c.c. of *N*/20 baryta solution for complete neutralisation, using phenolphthalein as indicator. The acid salt requires 24.6 c.c.

Salts of *o*-toluic acid with dimethylaniline, dimethyl- $\psi$ -cumidine and dimethylmesidine could not be obtained.

Definite salts could not be obtained either from *m*-toluic acid and  $\psi$ -cumidine or dimethylaniline, or from *p*-toluic acid and the same bases.

### F. Salts from the Three Nitrobenzoic Acids.

$\psi$ -Cumidine *o*-Nitrobenzoate.—This salt was obtained in the form of silky needles when ethereal or benzene solutions of the constituents were mixed; when crystallised from water, it formed long, silky, prismatic needles melting at 133—134°.

0.4137 gave 0.2260 *o*-nitrobenzoic acid = 54.6.

$C_{16}H_{18}O_4N_2$  requires 55.3 per cent.

0.3 required 20.1 c.c. of *N*/20 baryta solution for neutralisation. The normal salt requires 19.9.

*Dimethyl-ψ-cumidine hydrogen o-nitrobenzoate*,  
 $2(\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2\text{H}), \text{C}_6\text{H}_2\text{Me}_3\text{NMe}_2$ ,

obtained by mixing equal weights of the acid and base in benzene solution and crystallising from this solvent, forms small, colourless crystals melting at 124·5.

0·50 required 40·5 c.c. *N*/20 baryta solution. The acid salt requires 40·2 c.c.

*ψ-Cumidine m-nitrobenzoate* was obtained in the form of long, colourless, feathery needles melting at 129·5—130°, when the acid was mixed with twice its weight of *ψ*-cumidine and crystallised from benzene.

0·3 required 20·05 c.c. *N*/20 alkali. The normal salt requires 19·9 c.c. 0·5 requires 33·4 c.c. The normal salt requires 33·16.

The acid salt,  $2(\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2\text{H}), \text{C}_6\text{H}_2\text{Me}_3 \cdot \text{NH}_2$ , was obtained when a mixture of the acid (2 mols.) and base (1 mol.) was dissolved in benzene and allowed to cool; it crystallises from water in pale yellowish needles melting at 144°.\*

0·40 required 34·3 c.c. of *N*/20 alkali. The acid salt requires 34·12 c.c.

A mixture of the two salts was obtained when equal weights of the acid and base were crystallised together from benzene or water.

The normal salt, when boiled with water, is partially transformed into the acid salt.

*Dimethyl-ψ-cumidine hydrogen m-nitrobenzoate*, obtained when molecular quantities of the acid and base are mixed in ethereal solutions, crystallises from benzene in small, colourless prisms melting at 119·5°, dissolves readily in alcohol, ether, or chloroform, but is only sparingly soluble in carbon disulphide or light petroleum, and crystallises from hot water in colourless, flat plates.

0·3566 gave 0·2362 *m*-nitrobenzoic acid = 66·2. The acid salt requires 67·2 per cent.

0·255 required 20·77 c.c. of *N*/20 alkali. The acid salt requires 20·52 c.c.

*ψ-Cumidine p-nitrobenzoate*, obtained by mixing ethereal solutions of the acid and base, separates from water in small, feathery crystals melting at 160°.

\* The salt mentioned previously (Trans., 1899, 75, 595) as melting at 140—141° must have been the acid salt, but the specimen actually analysed must have been the normal salt melting at 129·5—130°.

0.3246 gave 0.1872 *p*-nitrobenzoic acid = 57.6.

$\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO}_2 \cdot \text{NH}_3 \cdot \text{C}_6\text{H}_2\text{Me}_3$  requires 55.3 per cent.

No definite salts could be obtained from dimethylaniline and the three nitrobenzoic acids.

#### G. Salts from the Three Bromobenzoic Acids.

$\psi$ -Cumidine *o*-bromobenzoate,  $\text{C}_6\text{H}_4\text{Br} \cdot \text{CO}_2 \cdot \text{NH}_3 \cdot \text{C}_6\text{H}_2\text{Me}_3$ , slowly separates in the form of fine needles from an ethereal solution of the acid and base; it dissolves readily in benzene, alcohol, or hot water, and crystallises from either light petroleum or hot water in colourless needles melting at 106—106.5°.

0.555 gave 0.3286 *o*-bromobenzoic acid = 59.2. The normal salt requires 59.8 per cent.

0.50 required 29.87 c.c. of *N*/20 alkali. The normal salt requires 29.76 c.c.

$\psi$ -Cumidine *m*-bromobenzoate crystallises from benzene in long, felted needles, melts at 98.5°, and is readily soluble in chloroform, alcohol, warm ether, or benzene.

0.50 required 29.7 c.c. of *N*/20 alkali. The normal salt requires 29.76 c.c.

No definite salts could be obtained from dimethylaniline and the three bromobenzoic acids, and an ethereal solution of  $\psi$ -cumidine and the *p*-bromo-acid slowly deposited crystals of the free acid melting at 251°.

### XXX.—*Studies on the Electrolytic Oxidation of Phenols.* *Part I.*

By ARTHUR GEORGE PERKIN and FREDERICK MOLLWO PERKIN.

OF the numerous substances which can be obtained by the oxidation of pyrogallol and its derivations, one of the most interesting is purpurogallin, a compound possessing well-marked tinctorial properties. Originally prepared by Gerard from pyrogallol (*Ber.*, 1869, 2, 562) by the action of potassium permanganate and sulphuric acid, it has been

subsequently obtained from the same phenol by means of a most varied series of oxidising agents. In a recent communication, certain derivatives and decomposition products of this substance were described (Trans., 1903, 83, 192), from which it appears to have the formula  $C_{11}H_8O_5$ , and to be a derivative of naphthalene, as was first indicated by Nietzki and Steinmann (*Ber.*, 1887, 20, 1277). The formation of a naphthalene compound from pyrogallol, although very remarkable, is not unique, for a somewhat similar reaction is described by Zincke and Branke (*Annalen*, 1896, 293, 120), who prepared dibromo- $\beta$ -naphthaquinonecarboxylic acid by the action of nitric acid on bromoprotocatechuic acid. During the formation of these substances, it appears likely that a certain quantity of the phenol is converted by oxidation into an open chain compound, which then condenses with the phenyl residues.

Further work on the constitution of purpurogallin is in active progress, and it appeared possible that by a study of the electrolytic oxidation of pyrogallol some intermediate or secondary product might thus be prepared, and, moreover, it was anticipated also that if the colouring matter could be produced by this method, a considerably increased yield might be obtained. The following experiments indicate without doubt that by employing certain precautions the electrolytic method is the most suitable for the production of purpurogallin, for not only can the yield be thus augmented, but an almost chemically pure product is at once isolated. On the other hand, it has not as yet been found possible to prepare any intermediate compound which would be of service in elucidating the course of the reaction.

#### EXPERIMENTAL.

In selecting a suitable electrolyte, numerous substances were examined, and although purpurogallin was obtained in all instances, it was frequently contaminated with a brownish-black impurity, which rendered the method of little service. The employment of a 15 per cent. solution of sodium sulphate has been eventually adopted, and by this means a very pure bright orange-coloured product has been obtained. Solutions of sodium and ammonium acetates do not give satisfactory results, because when they are employed a somewhat poor yield of the impure alkali salt of purpurogallin is produced.

In the earlier experiments, the anode and cathode compartments were divided by means of a porous cell, but it subsequently appeared that better results could be obtained if the anode and cathode were not separated. Satisfactory results are obtained only when the anode is made of platinum and caused to rotate rapidly during the electrolysis. When a stationary anode is employed, the colouring matter is

apt to settle on the electrode, and is thus subjected to further oxidation. A rotating anode of lead, even when previously peroxidised, was very unsatisfactory, for in this case from 10 to 16 per cent. only of very impure purpurogallin could be obtained.\*

In carrying out the oxidation, 28 grams of pyrogallol dissolved in 500 c.c. of a 15 per cent. solution of sodium sulphate were placed in a rectangular glass jar, at two opposite corners of which were fixed two thin pieces of composition piping. On to each of the pipes a copper wire was soldered, and these were connected with each other by means of a screw connection and formed the cathode. The iridio-platinum anode had a surface of 1.5 square decimetres and was rotated rapidly by means of a water turbine or electromotor. During the electrolysis, the current density was kept at 2 amperes and the *E.M.F.* was 4.3—4.5 volts. To avoid a rise in temperature, the cell was surrounded with cold water. As soon as the current commenced to flow, the solution became yellow and a yellow precipitate gradually separated. When the electrolysis had continued for 8 hours, the product was left overnight, then collected, washed with water, and dried on a porous plate.

Satisfactory results were also obtained when, instead of rotating the anode, a rapid stream of air was blown through the mixture. In this case, the cathode consisted of a perforated leaden tube placed between two anodes of platinum foil, having a total surface of 4 square decimetres. The air, which was blown through the cathode during the operation, appears to help in the oxidation of the pyrogallol. Thus 445 grams of pyrogallol dissolved in a solution of 1 kilogram of sodium sulphate ( $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ ) in six litres of water gave, after 35 hours' electrolysis, current density 9—10 amperes, *E.M.F.* 9.5—10.3 volts) 165 grams of purpurogallin or 37 per cent.

The average yield was 10.2 grams or 36.4 per cent., although on two occasions 13 grams (or 46.4 per cent.) were obtained. Nitrous acid yields only 25 per cent. of the crude product. That the substance thus obtained was practically pure is indicated by the analysis (A); the second estimation (B) was made on the product obtained with a lead anode, but this specimen was, however, first purified by crystallisation from acetic acid.

\* In the preparation of periodic acid by the electrolytic oxidation of iodic acid, with smooth platinum electrodes as anode, the yield is extremely small. But when peroxidised lead anodes are employed a very much better yield is obtained. The explanation being that the potential at which the oxygen is yielded up at the anode is higher with a lead peroxide anode than with one of polished platinum (*Ber.*, 1902, 35, 2652). In the case of pyrogallol, the probability is that when lead electrodes are used, the higher potential at which the oxygen is yielded causes the oxidation to be too vigorous.

Found (A) C = 60.03; H = 3.60. (B) C = 60.19; H = 3.60.

$C_{11}H_8O_5$  requires C = 60.00; H = 3.63 per cent.

The colouring matter was further characterised by conversion into the acetyl derivative, which was obtained in the form of yellow needles melting at 184—186°.

Found C = 58.87; H = 4.04.

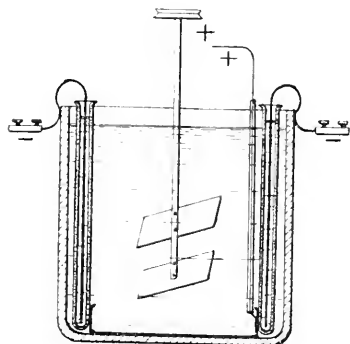

$C_{11}H_4O_5(C_2H_3O)_4$  requires C = 58.77; H = 4.12 per cent.

After one crystallisation from acetic acid, this product was found to be chemically pure.

Experiments were also tried with an alternating current, but although small quantities of purpurogallin were obtained, the method was not found satisfactory.

### *The Electrolytic Oxidation of Gallic Acid.*

It was previously shown that by the oxidation of gallic acid with potassium ferricyanide in the presence of sodium acetate a new substance, probably a purpurogallincarboxylic acid, is formed. As the yield by this method was extremely poor (3 per cent.) and the compound difficult to isolate, the electrolytic oxidation of gallic acid was studied in the hope that as in the case of pyrogallol a larger yield of a purer product would thus be obtained. Experiment showed that the purpurogallincarboxylic acid is rapidly obtained in this manner, and although the yield has up to the present been somewhat disappointing, it is evident that sufficient can be obtained by this process for a complete study of its constitution. After numerous trials, the following method was adopted.

It was found necessary to separate the anode and cathode compartments. A rectangular glass vessel was employed as before, on two sides of which were fitted two porous cells. These cells contained a piece of sheet lead, to which was soldered a stout copper wire. In order to keep the cells in position, the wire was bent over against the side of the glass jar as shown in the figure. The anodes consisted of a platinum stirrer and a stout wire bent up at each side against the bottom of the porous cells. To this wire was also welded a piece of platinum foil nearly large enough to cover the bottom of

the glass jar. The total active anode surface was about 1.75 square decimetres.

Various electrolytes were tried, but the only one which gave satisfactory results was a 15 per cent. solution of sodium or ammonium acetate acidified with acetic acid. In carrying out an electrolysis, 10—15 grams of gallic acid were dissolved in 600 c.c. of a 15 per cent. solution of ammonium or sodium acetate, 10 c.c. of glacial acetic acid were then added, and the mixture electrolysed. The cathode cells contained a similar solution. During the electrolysis, the cathode cells become too full and are apt to overflow; as the solution in these cells becomes strongly alkaline, it is necessary to remove a portion every now and then by means of a pipette in order to prevent it flowing over into the anode compartment. As soon as the current passes, the solution commences to turn brown and finally becomes almost black. After about 6 hours, the current is stopped, the electrodes and porous cells removed, the mixture left overnight, and then filtered, when a dark bronze-coloured product is obtained. This consists chiefly of the alkali salt of the acid in a somewhat crude condition. The yield varies very greatly, from 10 grams of gallic acid usually about 2 grams (or 20 per cent.) of the crude product are isolated, but we have obtained as much as 5 grams, or 50 per cent. The product of the reaction was purified as follows:

The substance ground into a thin cream with alcohol was diluted with some quantity of this solvent, a little hydrochloric acid added, and the mixture boiled for a minute or two; the solution obtained was then poured into ether, the ethereal extract washed with water, boiled with a little animal charcoal, filtered, and then evaporated to dryness. The orange-yellow, crystalline residue was collected, washed with water, then with ether, and dried.

Found C = 54.64; H = 3.52.

$C_{12}H_8O_7$  requires C = 54.54; H = 3.03 per cent.

It was found to be identical in all respects with the purpurogallin-carboxylic acid previously obtained from gallic acid by means of potassium ferricyanide.

---

# XXXI.—*The Interdependence of the Physical and Chemical Criteria in the Analysis of Butter-fat.*

By THOMAS EDWARD THORPE, C.B., F.R.S.

IN July, 1901, a Departmental Committee was appointed, at the instance of the Board of Agriculture, to inquire and report as to what regulations, if any, might with advantage be made for determining what deficiency in any of the normal constituents of butter should raise a presumption that the butter was not genuine.

To assist the Committee in arriving at a conclusion on this matter, it became necessary to obtain at first hand the values of various analytical constants of specimens of butter of known origin, and produced from milk given under varying conditions. Observation has shown that the chemical nature of butter-fat is dependent to a certain extent on the climatic influences to which the cows are exposed, on the nature and amount of the food supplied, and on the breed, period of lactation, and idiosyncrasy of the individual cow. In order to give such weight as was practicable to the effect of these factors, the samples of butter were obtained from carefully selected districts, and often from cows set apart for the purpose of the inquiry; whilst particulars of the breed, diet, stabling, and period of lactation were supplied with the samples in nearly all cases. For example, to illustrate the effects of more rigorous climatic conditions than obtain in the United Kingdom generally, farms and dairies in Caithness, Sutherland, the Orkneys, Shetlands, and the Hebrides were laid under contribution; whilst a series of samples from Hollesley Bay, Suffolk, served to exemplify the influence of exposure of the cattle to the winds of the North Sea. From the arrangements made for the collection and transmission of the butter, it is believed that all the samples can be relied on as authentic. The analyses were made at the Government Laboratory.

Altogether about 430 samples were received; of these, for special reasons, 73 samples were only examined as regards water, salt, curd, and amount of fat, with which data we are not here concerned. The analytical figures obtained for the remainder, 357 in all, included, besides the foregoing particulars, determinations of the Reichert-Wollny number of the fat, its relative density and saponification value, and the Zeiss reading at 45°. In nearly all cases, the proportions of soluble and insoluble fatty acids were also determined, together with the mean molecular weight of the insoluble acids.

Details concerning the origin of the samples are published in the

Minutes of Evidence to the Report of the Committee (Cd. 1750, Appendix xxix, 505—588).

As relatively few systematic observations appear to have been made on authentic samples of British and Irish made butter having the representative character of those now dealt with, it may be useful to put on record a summary of the results obtained.

The object of the present communication is to indicate the general relations between the analytically-important chemical and physical constants of butter-fat as disclosed by a study of the average values of these constants determined on a number of samples sufficiently large to ensure with reasonable certainty a fairly close approximation to the true values.

Before attempting to make use of the observations with a view to general deductions, it is desirable to obtain some idea of the magnitude of the error to which the several determinations are liable. Taking first the Reichert-Wollny experiments, the results were obtained by working strictly under the conditions agreed upon by myself and a Committee representing the Council of the Society of Public Analysts, who in 1900 examined the matter in conjunction with analysts of the Government Laboratory in connection with the question of butter-fat in margarine (see Abstr., 1901, ii, 77). In a large number of duplicate experiments the mean difference obtained between two determinations of the Reichert-Wollny number on the same sample of butter-fat was 0.20. So far, therefore, as what may be called fortuitous errors are concerned, the average values may be taken as known to within about  $\pm 0.1$  unit where the value is obtained from a fairly large number of samples, and probably to within  $\pm 0.2$  unit where the number is relatively small.

The relative densities of the fats were generally taken in a pycnometer of bottle form, adjusted to contain 50 grams of water at  $37.8^{\circ}$ . Duplicate weighings of the same fat with such a pycnometer rarely differ by more than 0.005 gram, corresponding with one unit in the fourth decimal place when expressed as specific gravity. In a few cases a bottle of only half the above capacity was used; the error here might be twice as great as with the larger pycnometer, or two units in the fourth decimal place. Consequently the average values may, as regards the variable errors of experiment, be looked upon as accurate to within  $\pm 0.0001$ .

A small constant error might conceivably arise thus: after the fat in the bottle has been brought to the desired temperature of  $37.8^{\circ}$  a little time is required to complete the filling and to insert the stopper. During this time, the temperature is falling, and the effect of this would be to slightly increase the weight of fat which the bottle would contain. The same tendency would, however, be found during

the adjustment of the instrument with water, and the actual error would therefore be only that arising from the difference of these effects. It would be small, and sensibly constant.

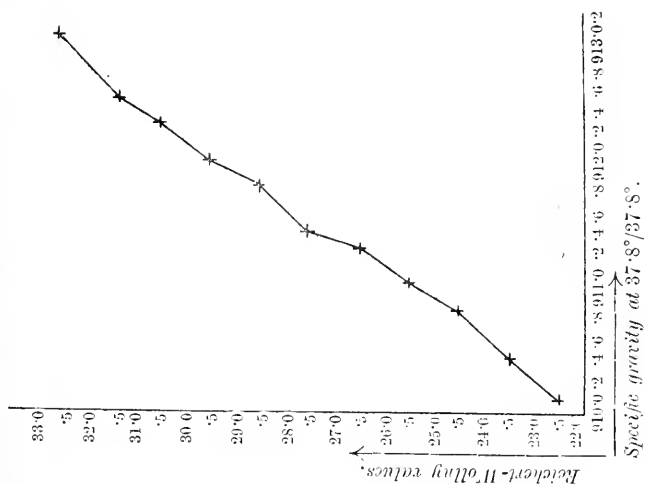

The average difference shown by duplicate determinations of the saponification value of butter-fat, deduced from a large number of experiments made by several operators, was found to be 0.065, expressed as percentage of potassium hydroxide. This corresponds to about 0.7 of a unit when calculated into "saponification-equivalents." Substantially the same difference was found in the case of the molecular weight determinations. The values may, therefore, be regarded as subject to an experimental error of about  $\pm 0.4$  of a unit. In all cases the acid and alkali used were carefully standardised, and it is not thought that any appreciable error is to be attributed to this part of the experimental work.

As regards the refractometer indications, it may be noted that there are two or three possible sources of inaccuracy in using the Zeiss butyro-refractometer. (1) Since the instrument is graduated into divisions representing whole units, the fractions of a unit have to be estimated by the eye. (2) The line of shadow is often not very sharply defined where it cuts the scale of the instrument. (3) The temperature may fluctuate slightly during the course of the experiment. Probably a single observation might be liable to a maximum error of  $\pm 0.4$  unit, and the mean of a number of experiments such as are used in the curves given below may be relied upon as accurate within about  $\pm 0.2$  of a unit.

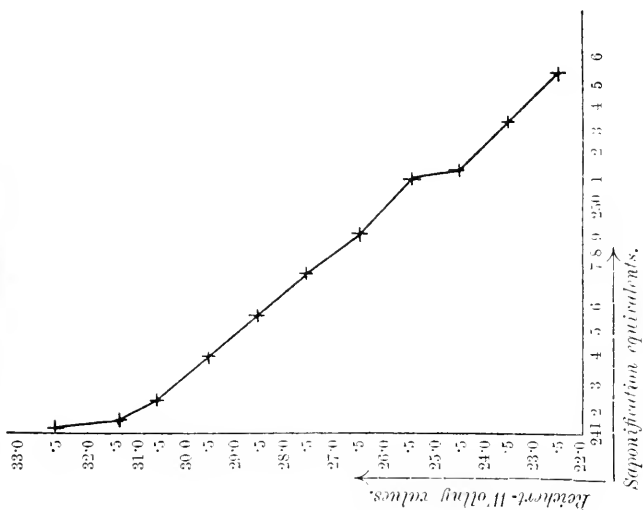

For the soluble and insoluble acids, the method adopted was substantially the modification of Hehner's process recommended by the American Association of Official Agricultural Chemists. The saponification of the fat, however, was effected in silver flasks instead of in glass. For the soluble acids, the mean difference between duplicate analyses in a large number of cases was found to be 0.12 per cent., and for the insoluble acids 0.15 per cent. So far as manipulative error is concerned the average values given in the table may therefore be taken as accurate to within about  $\pm 0.06$  and  $\pm 0.08$  per cent. in the two cases respectively.

The averages of the analytical data from which the curves given below are constructed are given on p. 254. In obtaining these figures—taking, for example, the first line—all the Reichert-Wollny values lying between 22.00 and 22.99 have been taken from the experimental results and averaged, giving the number 22.5. The corresponding values of the specific gravity, saponification-equivalent, and Zeiss number were also abstracted and averaged, giving the figures shown in the table. For the next line, the Reichert-Wollny values lying between 23.0 and 23.99 were taken; and so on for the others.

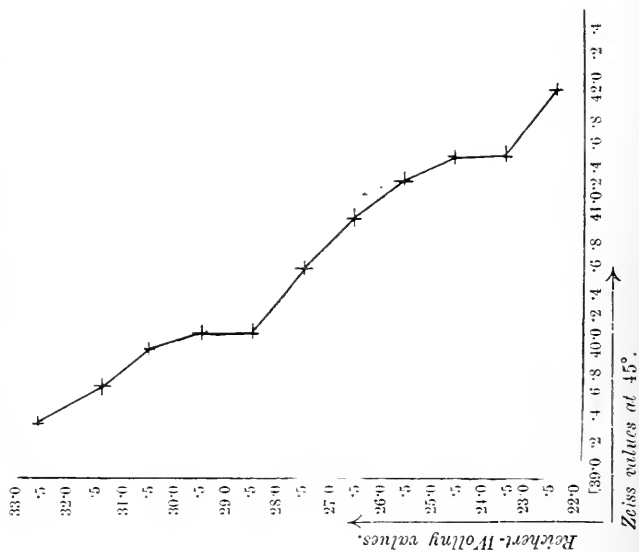

No. 1.—Variation of specific gravity with Reichert-Wollny number.

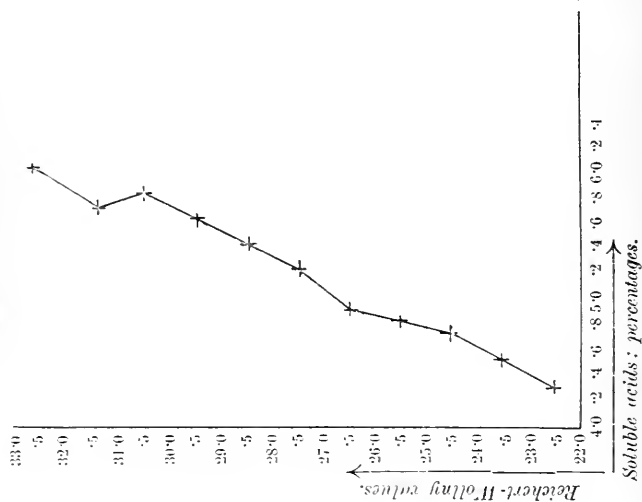

No. 2.—Variation of saponification equivalent with Reichert-Wollny number.

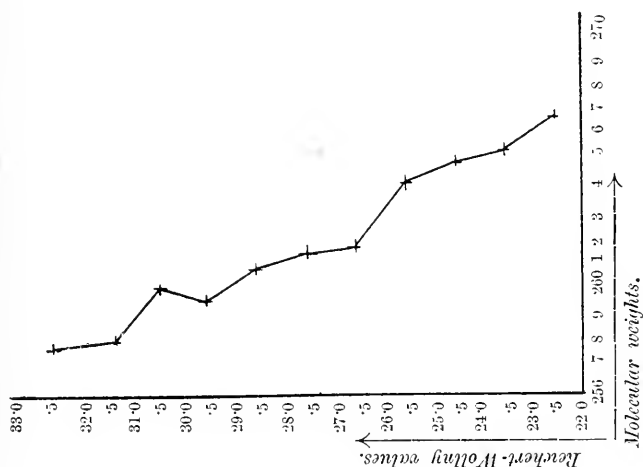

No. 3.—Variation of Zeiss value with Reichert-Wollny number.

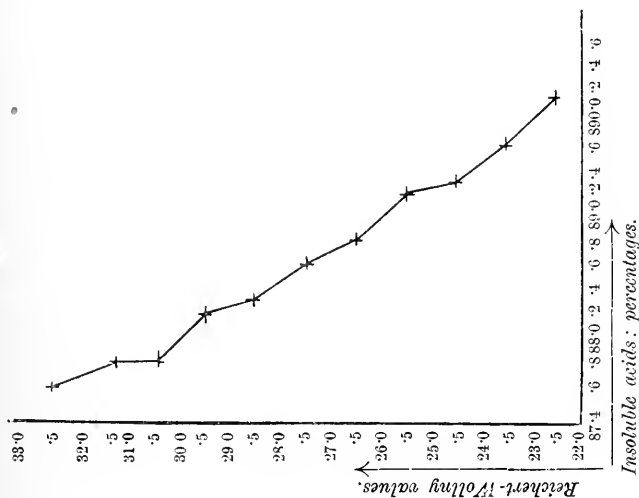

No. 4.—Variation of soluble acids with Reichert-Wollny number.

No. 6.—Variation of the mean molecular weight of the insoluble acids with the Reichert-Wollny number.

No. 5.—Variation of insoluble acids with Reichert-Wollny number.

\* Calculated as butyric acid.

Two or three samples, the data for which would fall beyond the extremities of the curves given, have been omitted on account of the number of observations being insufficient to afford trustworthy average values.

As regards the probable errors of the observations, it may be remarked that any constant error pertaining to a process will not, when the results are presented in the form of curves, affect the shape of the curve; it will only alter its position relative to the axes. Such errors are those which, for example, might arise from the thermometer of a Zeiss instrument having altered since the refractometer was standardised, or from the retention in the distilling-flask of a small constant quantity of volatile acids in determining the Reichert-Wollny figure. On the other hand, errors of manipulation and observation, the incidence of which is sometimes on one side of the truth, sometimes on the other, will, in accordance with statistical principles, be largely nullified by taking the averages of a sufficiently large number of experiments. Curves plotted, therefore, from the mean results of many observations should show with some degree of accuracy the general tendency of the relations between the several constants, and illustrate their interdependence.

A few comments may be made on these curves. It will be seen that, in a general sense, the relative density of butter-fat increases as the Reichert-Wollny number is augmented. This would, of course, follow from the well-known fact that the glycerides of low molecular weight have a greater density than the glycerides of the higher fatty acids which occur in butter. Very approximately, the increase is

directly proportional to the increase in the Reichert-Wollny values, as is shown by the curve approaching more or less closely to a straight line.

Speaking broadly, the variations of the saponification numbers are in inverse relation to those of the Reichert-Wollny values and the relative densities; but they show, as from the nature of the case might be expected, some notable departures from proportionality in the amount of variation. The aberrations are most marked towards the extremities of the curve. Here the observations are fewer in number than those from which the middle of the curve is constructed, but it is not likely that any presumable experimental error would account for the variations shown. When it is considered that the saponification-equivalents of the glycerides of the volatile fatty acids range from 100·6 for tributyrin to 212·6 for trilaurin,\* whilst those of the glycerides of the non-volatile acids vary between 240·7 for trimyristin and 296·6 for tristearin, it will be obvious that even small variations in the relative proportions of the glycerides may affect rather considerably the mean saponification-equivalent of the whole fat.

Somewhat similar remarks apply to the Zeiss numbers. These generally decrease in magnitude as the Reichert-Wollny values increase, but the rate of diminution is not regular, and this points, like the variations of the saponification-equivalent, to changes in the proportions of the individual acids which, in butter-fat, constitute the "volatile" and "non-volatile" groups respectively.

The curve showing the mean molecular weights of the insoluble acids is of some interest, from the physiological problem which it suggests. From it we infer that, as the acids of low molecular weight increase in amount, the mean molecular weight of the remaining acids decreases, and, broadly speaking, decreases proportionally. This may indicate one of several things. Remembering that the molecular weights of the insoluble acids which are believed to occur in butter are as follows: lauric (200),† myristic (228), palmitic (256), oleic (282), stearic (284),‡ and that the mean molecular weights dealt with in the table decrease from 266·9 to 257·8, it will be seen that this decrease may be due to one of the following causes. In the first place, it may be due to a diminished proportion of oleic acid. Or, the oleic acid remaining the same, the decreased molecular weight may be due to a displacement of palmitic acid by myristic and lauric acids, one or both; or, possibly, of myristic by lauric acid. Finally, if the oleic acid increases, this can

\* Or to 184·7 for tricaprin.

† Lauric acid is said to be slightly soluble in water and appreciably volatile when distilled with steam.

‡ Apparently stearic acid exists in butter to a small extent only. If this is so, it may be neglected in the present connection.

only be compensated for, and the decreased mean molecular weight explained, by an increase in the amount of lauric acid, with a simultaneous decrease in the myristic and palmitic acids. The physiological question which presents itself is whether the metabolic changes which, in the bovine organism, result in the production of an increased proportion of the lower saturated fatty acids, bring about this production at the expense of the oleic acid.

Judging from the values obtained for the iodine-absorption of a number of the specimens, it would seem that, speaking generally, a low proportion of volatile acids in butter-fat is associated with a high percentage of oleic acid, and *vice versa*. The figures are as follows :

	Reichert- Wollny number.	Iodine value.	} = Oleic acid.		Insoluble acids.	Mean molecular weight of insoluble acids.
(1) Average of 20 samples	24.2	40.0	44.4	per cent.	89.6 per cent.	264.6
(2) 30 ,,	30.8	32.4	36.0	,,	88.1 ,,	259.8

In the first series, the oleic acid constitutes 49.6 per cent. of the insoluble acids; in the second series, 40.9 per cent. This decrease in the proportion of oleic acid would diminish the mean molecular weight of the insoluble acids from 264.6 to 261.5. The actual figure obtained for the molecular weight in the second series being 259.8, it would appear that the decrease is largely, but not entirely, brought about by the diminution in the proportion of oleic acid.

Since the whole of the decrease is not accounted for by the oleic acid, it follows that the mean molecular weight of the insoluble saturated acids is lower in the second series than in the first. In fact the values, calculated from the foregoing table, are 247.4 and 244.4 respectively.

It should be mentioned that the iodine-values were determined after the fats had been kept some time, and they are not given as representing precisely the values for the fresh fat. It is well known that the oxidation changes which may take place during the keeping of butter-fat tend to affect the iodine number. Nevertheless, since the two groups cover practically the same dates and were kept side by side until examined, it may be assumed that, on the whole, they would be about equally affected, and the relative values of the averages would remain substantially unchanged.

THE GOVERNMENT LABORATORY,  
LONDON.

# XXXII.—*A Simple Thermostat for Use in Connection with the Refractometric Examination of Oils and Fats.*

By THOMAS EDWARD THORPE, C.B., F.R.S.

IN the Government Laboratory, as in other laboratories where large numbers of commercial oils and fats, and especially butter, are required to be examined, the Zeiss butyro-refractometer has proved to be of great service. As is well known, it is generally necessary in using the instrument to allow a current of water of constant temperature to flow through the apparatus for some little time before making the readings, and it was with the view of rapidly and easily obtaining this current that the little contrivance seen in the accompanying figure was devised in substitution for the special heating arrangement supplied with the instrument, which was found to be somewhat cumbrous and uncertain in action.

The temperature employed in the refractometric examination of butter-fat is  $45^{\circ}$ , and it must be understood, therefore, that the details of the arrangement as described have been adjusted in order that the circulating water shall give this temperature as indicated by the thermometer attached to the refractometer. It is, however, possible, by a slight rearrangement of the details, to obtain a considerable range of constant temperatures.

The principle of the thermostat and the method of working it will be obvious from the figure. The apparatus consists essentially of a vessel for generating steam or other appropriate vapour, containing a coil through which the current of water flows and is heated before it passes through the refractometer or other instrument, the position of which is shown in the drawing at Z, by which the observations at a given constant temperature are to be made.

In the figure (p. 258), A represents a metallic cylindrical vessel 5 cm. in diameter and 5 cm. deep, containing approximately 100 c.c. of water, &c., for generating steam, &c.

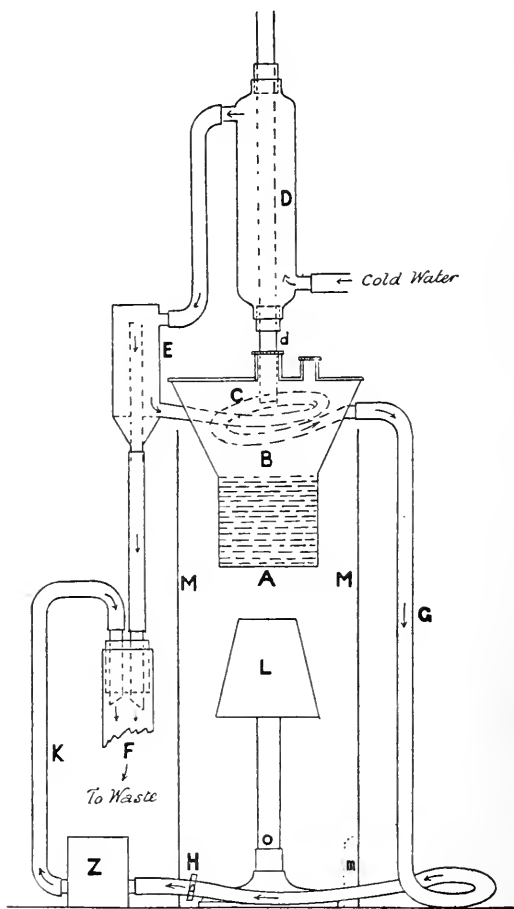

B, a conical steam-chamber, in which the coil, C, is suspended and heated by the steam from A. The diameter of cover is 10 cm.

C, a coil of copper or "compo," tubing, from 25 cm. to 30 cm. long, and having an internal diameter of about 3 mm. The current of water passing through the coil is heated before entering the instrument, Z.

D, a reflex condenser, preferably of glass, held in position by a tubulure, *d*, provided with a sliding or screw cap to prevent loss of the liquid in A.

E, an arrangement for maintaining a constant head of water at the

point of entrance to the coil, so as to reduce variations in the temperature of Z, due to fluctuations in the pressure of the current of water. It consists of an outer metal tube, through which a narrow central tube rises, and serves as an overflow when the water in the outer tube has reached the level of its upper orifice.

F, a stout glass tube, acting as a gauge or "tell-tale," to indicate whether or not the overflow and the current of water through the instrument, Z, are running properly.

G, a thick-walled caoutchouc tubing (for example, pressure-tubing), to minimise loss of heat during the passage of water from the coil to the instrument, Z.

H, a screw clamp, for regulating the rate of flow of water through the coil and through the instrument, Z. The final adjustment of the desired temperature may be made by means of the screw clamp.

K, a caoutchouc tubing, carrying away waste water from the instrument, Z, and terminating in the gauge, F, where the rate of the current can be observed.

L, Bunsen burner with cone.

M, a metallic cylinder for protecting Bunsen flame from draughts, and to reduce loss of heat due to radiation from walls of the steam generator. At the foot is a semicircular opening, *m*, for the admission of the gas tube.

This little apparatus has been in use for some years in the Government Laboratory, and has been found to answer its purpose sufficiently well. Only a few minutes are needed to bring it into action, and, under ordinary working conditions, it is readily possible to secure a steady current of water, not varying more than  $0.1^{\circ}$  or so in temperature throughout the day.

### XXXIII.—*The Action of Nitrogen Sulphide on Organic Substances. Part I.*

By FRANCIS ERNEST FRANCIS and OLIVER CHARLES MINTY DAVIS.

AN investigation of the action of nitrogen sulphide on organic substances has been undertaken in the hope that it may throw some light on the constitution of this substance.

Nitrogen sulphide is formed together with other products when ammonia acts on a solution of sulphur dichloride in carbon disulphide or benzene. According to the investigations of Fordos and Gélis (*Compt. rend.*, 1850, 31, 702), this substance has the empirical formula NS. The molecular weight, which was first given by Schenck as  $N_4S_4$ , was determined by the cryoscopic method in naphthalene, and this was confirmed by Muthmann (*Ber.*, 1896, 29, 340), who obtained the same result with the ebullioscopic method in carbon disulphide. By employing the latter method, with benzene as solvent, we have also found the same molecular complexity.

The sulphide is best prepared by passing ammonia into a 10—15 per cent. solution of sulphur dichloride in benzene. When the ordinary chloride is employed, the yield is much smaller. A rapid

current of the dry gas is passed into the solution until red fumes appear, the flask in which the operation is being conducted is then cooled, and on maintaining the current for a short time the reaction is completed. After filtering off the ammonium chloride formed, the solution, on evaporation, deposits long, orange-red prisms of nitrogen sulphide. This is a beautifully crystalline substance, and may be readily purified by recrystallisation from either boiling benzene, toluene, or carbon disulphide; our specimens always showed a perfectly constant decomposition point at  $185^{\circ}$ , although Muthmann gives  $178^{\circ}$ , and earlier determinations were even lower, these results being probably owing to contamination with free sulphur. The properties of nitrogen sulphide have been fully described, but it may be of interest to state that Prof. Muthmann informed us that it was unwise to keep more than a few grams of the substance in one vessel, since it is apt to explode spontaneously with considerable violence. Although dealing with moderately large quantities, we have never observed this change, and are inclined to believe that the sulphide is rather more stable than is usually supposed.

The first group of organic substances investigated were the aromatic aldehydes. With benzaldehyde, a violent reaction takes place near the boiling point of this liquid; sulphur dioxide and water are evolved, and considerable amounts of triphenylcyanidine (cyaphenin),

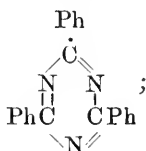

are formed. The reaction proceeds more slowly at lower temperatures, and at  $100^{\circ}$  was complete in about 30 hours. In each case, the main product is cyaphenin, and a much smaller quantity of a less fusible, crystalline substance, which was only isolated with difficulty. This product appears to be  $\alpha\beta\mu$ -triphenylglyoxaline or lophin,  $\text{C}_3\text{N}_2\text{H}(\text{C}_6\text{H}_5)_3$ ; it is probably formed by the reduction of cyaphenin by sulphur dioxide; this view of its formation is strengthened by the fact that small quantities of ammonium sulphate were detected among the products of the reaction. This interesting reaction does not seem to be dependent on the intermediate formation of benzonitrile, since nitrogen sulphide does not yield cyaphenin when treated with this substance. Benzylideneaniline, in a similar way, yields cyaphenin, and we are at present investigating the other products of this reaction. With *p*-tolaldehyde and nitrogen sulphide, the action is very similar, and the corresponding tritolycyanidine is easily obtained.

G. Glock (*Ber.*, 1888, 21, 2652) described the preparation of a polymerised toluonitrile, which he considered was probably "kyantolin," and there is no doubt that the substance he obtained is identical with our preparation, which, judging from the method of its formation, is very probably tritolycyanidine,  $\text{C}_3\text{N}_3(\text{C}_6\text{H}_4\cdot\text{CH}_3)_3$ .

With anisaldehyde and nitrogen sulphide, the action proceeds rather

more rapidly at  $100^{\circ}$  than in previous cases, and the main product is a white, crystalline powder which is still under investigation. We only found it possible to isolate very small quantities of what appeared to be tri-*p*-methoxyphenylcyanidine,  $C_3N_3(C_6H_4 \cdot O \cdot CH_3)_3$ . Like cyanophenol, this substance, although only slightly soluble in boiling alcohol, is readily recrystallised from hot benzene; it dissolves in concentrated sulphuric acid to a deep yellow solution, and is precipitated unchanged on the addition of water. Similarly, it has been found by one of us that salicylonitrile, on heating, readily polymerises into a yellow, crystalline compound with a high melting point, this product being also soluble without decomposition in concentrated sulphuric acid giving a yellow solution. From its great stability, it is not decomposed at  $350^{\circ}$ , and from the fact that its molecular weight was found to be approximately three times that of salicylonitrile, it appears probable that this substance is tri-*o*-hydroxyphenylcyanidine,  $C_3N_3(C_6H_4 \cdot OH)_3$ . Want of material prevented us from obtaining the corresponding tri-*p*-hydroxyphenylcyanidine from the foregoing trimethyl ether and comparing its reactions with those of the *o*-derivative.

The constitution of these cyanidines or 1:3:5-triazine compounds may in all probability be represented by the formula

they are very stable substances having high melting points, and they are not decomposed by aqueous or alcoholic potassium hydroxide. The cyanidine ring is broken by reducing agents, as when the triphenyl derivative yields lophin,  $\begin{array}{c} C_6H_5 \cdot C \cdot NH \\ | \\ C_6H_5 \cdot C - N \end{array} \gg C \cdot C_6H_5$ . The complete decomposition into ammonia and benzoic acid can, however, only be effected by more powerful reducing agents, such as hydriodic acid at  $220^{\circ}$ .

We are at present pursuing the investigation of the interaction of nitrogen sulphide and aldehydes, and propose trying similar reactions with other groups of organic substances.

#### EXPERIMENTAL.

##### 1. Action of Nitrogen Sulphide on Benzaldehyde.

Two grams of nitrogen sulphide were dissolved in a small quantity of benzene and treated with 10 grams of benzaldehyde; no reaction took place on boiling for 8 hours. On distilling off the benzene and

heating with a free flame, the reaction became violent near the boiling point of the aldehyde, sulphur dioxide, water, and the excess of aldehyde distilled off, and the solid residue, after repeated crystallisation from benzene, gave about 1.3 grams of triphenylcyanidine.

The following results were obtained on analysis:

C = 81.52; H = 5.18; N = 13.61.

$C_3N_3(C_6H_5)_3$  requires C = 81.55; H = 4.85; N = 13.59 per cent.

The melting point was  $230^\circ$ , the numbers given for triphenylcyanidine by different authors being between  $231^\circ$  and  $233^\circ$ .

An attempt was made to follow quantitatively the course of the reaction, but without any very definite result. One gram of nitrogen sulphide was treated with a large excess of benzaldehyde, the operation being carried out in absence of air, and the sulphur dioxide liberated passed into a standard iodine solution. It was found that, approximately, 0.2 gram of sulphur was liberated as sulphur dioxide, and, after distilling off the unchanged aldehyde, nearly 0.12 gram was obtained from various crystallisations, the amount unaccounted for being 0.37 gram. The experiment could only, of course, be regarded as an approximation, but in attempting to account for the loss in sulphur, we were led to detect, among the residues, ammonium sulphate (in another experiment, carried out under similar conditions, this amounted to nearly 1 gram, which was equivalent to 0.24 gram of sulphur) and a substance much more soluble in absolute alcohol, and less so in benzene than triphenylcyanidine. The isolation of the latter substance in the pure state was extremely difficult, and, judging from the analysis given later, the compound we eventually obtained was not quite pure. The reaction between the aldehyde and nitrogen sulphide was then carried out on a larger scale, and the excess of aldehyde removed by distillation in steam; the aqueous solution in the distilling flask contained ammonium sulphate and a very small quantity of a substance containing nitrogen, but not sulphur; this was extracted by means of ether, recrystallised from benzene, and found to melt at  $128^\circ$ . The amount obtained was insufficient for an analysis. The residual solid, insoluble in water, was dried and treated several times with boiling alcohol; from the filtrate, small quantities of triphenylcyanidine crystallised on cooling, and on adding water it was found that the substance which separated had a much higher melting point. On repeating this process many times, a white, feathery, crystalline mass was eventually obtained, only slightly soluble in benzene, but much more so in alcohol, from which it crystallises in characteristic tufts. From its appearance, we thought it might be lophin, although its melting point was  $265$ — $267^\circ$ , whereas that substance is stated to melt at  $275^\circ$ . The following data were obtained on analysis:

C = 85.63 ; H = 5.66 ; N = 9.87.

(C<sub>6</sub>H<sub>5</sub>)<sub>2</sub>C<sub>3</sub>N<sub>2</sub>H requires C = 85.13 ; H = 5.40 ; N = 9.46 per cent.

Laurent and Brunner (*Annalen*, 1869, 151, 135) state that lophin gives a hydrochloride melting at 155°, which is soluble in alcohol but insoluble in water. In order to confirm our view that we were actually dealing with this substance, the small amount at our disposal was converted into the hydrochloride, which decomposed at 157—159°, and was soluble in alcohol but insoluble in water. In all probability then, the substance was impure lophin, formed, possibly, by the reduction of triphenylecyanidine by sulphur dioxide, this view of its formation being strengthened by the presence of ammonium sulphate in the products of the reaction. We were unable to obtain a better yield of this substance, and as many experiments gave only 0.7 gram of this product, its further investigation was consequently abandoned. The reaction between the aldehyde and nitrogen sulphide was then carried out in an inert atmosphere at 100°, and although the velocity of the reaction was thereby greatly reduced—the time required for 5 grams of nitrogen sulphide to react being about 30 hours—yet the products were very similar. The yield of triphenylecyanidine was slightly increased, the amount of free sulphur was not quite so large, and the lophin was formed in about the same proportion as in previous cases. When benzylideneaniline was employed in place of benzaldehyde, the reaction takes place much less energetically, and the products contained triphenylecyanidine and a large amount of an oil which we are at present investigating.

## 2. Action of Nitrogen Sulphide on *p*-Tolualdehyde.

On warming together *p*-tolualdehyde and nitrogen sulphide, a reaction takes place very similar to that described with benzaldehyde; the solution darkens on heating, sulphur dioxide is slowly evolved, and a crystalline substance separates, which, after washing with ether and recrystallising from boiling benzene, melts sharply at 278°; it is slightly soluble in boiling alcohol and crystallises from hot benzene in long needles. The following results were obtained on analysis:

C = 82.32 ; H = 6.20.

C<sub>3</sub>N<sub>3</sub>(C<sub>6</sub>H<sub>4</sub>·CH<sub>3</sub>)<sub>3</sub> requires C = 82.05 ; H = 5.98 per cent.

This substance appears to be identical with a polymeride of toluonitrile, termed by Gustav Glock "kyantolin" and described as crystallising in long needles melting above 260°.

3. *Action of Nitrogen Sulphide on Anisaldehyde.*

Five grams of nitrogen sulphide were heated for 20 hours with 12 grams of anisaldehyde in an inert atmosphere. The solid mass obtained at the end of that time was extracted with boiling alcohol to remove any unchanged aldehyde, and then extracted with boiling benzene. The insoluble matter constituted by far the larger bulk (about 5.6 grams); it was a white, crystalline powder, partially soluble in water, and at present it is still under investigation. The soluble matter consisted chiefly of sulphur, together with a very small quantity of a substance crystallising from benzene in white leaflets, and best separated from the sulphur by solution in acetone or concentrated sulphuric acid. This compound melts sharply at  $217^{\circ}$ , and is but slightly soluble in alcohol. On analysis, it gave the following result:  $N = 10.70$ .  $C_3N_3(C_6H_4 \cdot O \cdot CH_3)_3$  requires  $N = 10.52$  per cent.

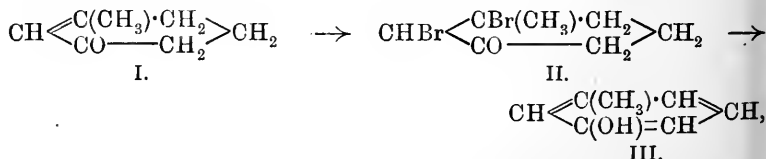

It appears to be tri-*p*-methoxycyanidine, which is soluble in concentrated sulphuric acid forming a deep yellow solution and is precipitated unchanged on the addition of water. As previously mentioned, tri-*o*-hydroxycyanidine is a yellow, crystalline substance also soluble in sulphuric acid to a yellow solution.

# XXXIV.—*Aromatic Compounds obtained from the Hydroaromatic Series. Part I. The Action of Bromine on 3:5-Dichloro-1:1-dimethyl- $\Delta^{2:4}$ -dihydrobenzene.*

By ARTHUR WILLIAM CROSSLEY.

MANY instances have been recorded of the conversion of hydroaromatic into aromatic substances under the influence of such reagents as bromine or nitric acid. For example, 1-keto-3-methyl- $\Delta^2$ -tetrahydrobenzene (I) readily absorbs two atoms of bromine to form an unstable product (II) which loses two molecules of hydrogen bromide yielding *m*-cresol (III) (Knoevenagel, *Ber.*, 1893, 26, 1951):

and with nitric acid, 1:3-dimethyldihydrobenzene gives mono-, di-, and tri-nitroxylenes (Wallach, *Annalen*, 1890, 258, 319).\*

This direct conversion of hydroaromatic into aromatic substances has often been of fundamental importance as a method for determining the constitution of a hydroaromatic compound when, by its transformation into an aromatic derivative of known constitution, the relative positions of its substituting groups have been ascertained. But the method is not always valid, for instances are known in which an alkyl group wanders during the conversion (Baeyer and Villiger, *Ber.*, 1898, 31, 2068).

Recently it has been shown that 3:5-dichloro- $\Delta^{2:4}$ -dihydrobenzene under the influence of excess of phosphorus pentachloride or bromine is converted into *m*-dichlorobenzene (Trans., 1903, 83, 495) and that 3:5-dichloro-1:1-dimethyl- $\Delta^{2:4}$ -dihydrobenzene, when acted on with excess of phosphorus pentachloride, is converted into 3:5-dichloro-*o*-xylene (Trans., 1902, 81, 1536):

also when phosphorus pentabromide acts on dimethyldihydroresorcin brominated *o*-xlenols are produced (Trans., 1903, 83, 116).

In the two latter cases, the reaction is complicated by the fact that, as the original substance contains the *gem*-dimethyl group, the migration of one of these methyl groups becomes an essential step in the production of the aromatic compound.

As a quantity of 3:5-dichloro-*o*-xylene was wanted for another research, and as the action of bromine on dichlorodihydrobenzene had resulted in the formation of *m*-dichlorobenzene as the main, if not the sole product, it was thought advisable to try the action of bromine on 3:5-dichloro-1:1-dimethyl- $\Delta^{2:4}$ -dihydrobenzene (Trans., 1902, 81, 827). From the desired point of view, the reaction is disappointing, inasmuch as only a very small quantity of 3:5-dichloro-*o*-xylene is formed, but it has afforded an interesting example of the passage from hydroaromatic to aromatic substances, and as it is, on account of the symmetry of the molecule, one of the simplest cases in which the wandering of an alkyl group can take place, it has been worked out, so as to gain an insight into the course of such reactions. Moreover, as the dimethyldihydroresorcin, which forms the starting point of the investigation, is readily obtained from aliphatic substances (ethyl

\* The following are references to a number of typical examples of reactions involving the conversion of hydroaromatic into aromatic substances: Schweitzer, *J. pr. Chem.*, 1841, 24, 257; Wallach, *Annalen*, 1877, 187, 159; Baeyer, *Ber.*, 1892, 25, 1037; Knoevenagel, *Ber.*, 1894, 27, 2347; Einhorn and Willstätter, *Annalen*, 1894, 280, 88; Zelinsky, *Ber.*, 1895, 28, 782, and 1901, 34, 2803; Baeyer and Villiger, *Ber.*, 1898, 31, 1401, 2067; Klages, *Ber.*, 1899, 32, 1516; Crossley and Le Sueur, Trans., 1902, 81, 831, 1533, and 1903, 83, 116; Crossley and Haas, Trans., 1903, 83, 495.

malonate and mesityl oxide, Trans., 1899, '75, 772), the subject becomes of interest as helping to connect together the aliphatic and aromatic series.

The main products of an aromatic nature obtained when bromine acts on dichlorodimethyldihydrobenzene are the two theoretically possible dichlorobromo-*o*-xylenes containing the chlorine atoms in the 3:5-position, and no substance has been encountered in which an alkyl group has wandered into any but an ortho-position.

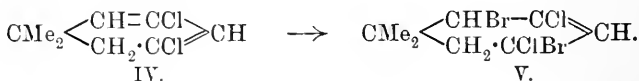

The reaction is largely influenced by the condition of experiment, entirely different results being obtained according as to whether one or two molecules of bromine are employed.

When dichlorodimethyldihydrobenzene, dissolved in a small amount of chloroform, is treated with bromine, so long as this reagent is used up a quantity is absorbed corresponding almost exactly with two molecular proportions, and during the later stages of the reaction volumes of hydrogen bromide are evolved. The product consists mainly of a viscid, syrupy liquid, which, on distillation, or preferably when left in a vacuum over potassium hydroxide, gives 3:5-dichloro-4-bromo-*o*-xylene (see page 275); and to a smaller extent of a beautifully crystalline solid having the formula  $C_8H_9Cl_2Br_3$ . This substance is evidently a *dichlorotribromodimethyltetrahydrobenzene*, but the exact position of the halogen atoms cannot be readily ascertained.

It has been shown (Trans., 1902, 81, 823) that when 1:1-dimethyl- $\Delta^{2:4}$ -dihydrobenzene is treated with bromine or hydrogen bromide, only one molecule of either reagent is absorbed, in the latter case giving rise to 5-bromo-1:1-dimethyl- $\Delta^3$ -tetrahydrobenzene,

and presumably, therefore, the first action of bromine on dichlorodimethyldihydrobenzene would consist in the direct addition of two atoms of bromine in a similar way, giving rise to a *dichlorodibromodimethyltetrahydrobenzene* (V), having the following constitution:

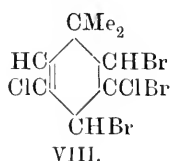

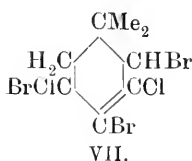

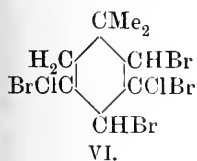

Notwithstanding the fact that the product contains a double linking, the net result of the second phase of the reaction is the replacement of hydrogen by bromine in this compound.

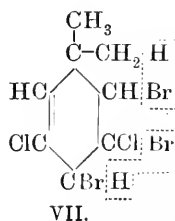

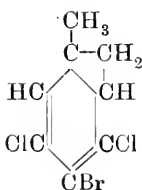

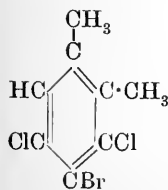

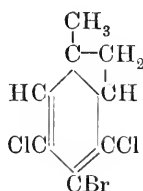

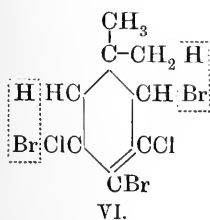

It is a well-known fact that substances containing two double linkings in the position indicated in formula IV,  $\cdot C:C:C:C \cdot$ , do add on bromine at the terminal carbon atoms with the formation of a new double bond between the central carbon atoms,  $\cdot C:C:C:C \cdot$ , and that this new bond often does not perform the ordinarily accepted func-

tions of an unsaturated linking by taking up a further molecule of bromine to give a saturated substance. Such appears to be the case with the compound under discussion, for in order to obtain a derivative having the formula  $C_8H_9Cl_2Br_3$  from the unsaturated compound (V), one hydrogen must be replaced by bromine.

In discussing the position of this bromine atom, it must be borne in mind that dichlorotribromodimethyltetrahydrobenzene,  $C_8H_9Cl_2Br_3$ , on heating, loses two molecules of hydrogen bromide giving a dichlorobromo-*o*-xylene,  $CMe \leq \begin{smallmatrix} CMe:CCl \\ CH-CCl \end{smallmatrix} \geq CBr$ , the constitution of which has been definitely ascertained by synthesis (see page 277). It would appear from this fact that the bromine atom must become attached to the carbon atom between the two chlorine atoms, and this is explained by supposing that either substitution takes place, or more probably that bromine is first added on at the double linking, giving an unstable substance having the formula VI, which immediately loses hydrogen bromide. This loss may take place in several ways :

giving rise to substances with a double linking in different positions; but, as will be seen from the context, only two of these possibilities need be considered, namely, those involving the configurations VII and VIII, and from which the production of the above dichlorobromoxylene can be readily accounted for in the manner indicated by the following formulæ :

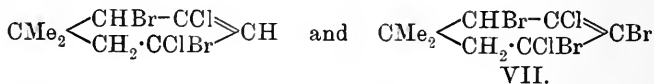

Now when dichlorotribromodimethyltetrahydrobenzene is oxidised with potassium permanganate, the sole products are bromoform and dimethylmalonic acid (thus definitely proving the presence of the *gem*-dimethyl group), the yield of the latter substance being 71 per cent. of that theoretically obtainable. It has been observed during the oxidation of many hydroaromatic substances containing halogen, that although they may be originally broken down at a double linking, the oxidation does not become completed until all those carbon atoms to which halogen atoms are attached in the original substance are either eliminated from the oxidation product or form part of a terminal carboxyl group; in other words, an acid obtained as an oxidation product is always free from halogen. For example, 5-bromo-1:1-dimethyl- $\Delta^3$ -tetrahydrobenzene (Trans., 1902, 81, 824) gives on oxidation  $\beta\beta$ -dimethylglutaric acid and not bromodimethyladipic acid:

Bearing this in mind, the formula which would best represent dichlorotribromodimethyltetrahydrobenzene would be VIII, for from a substance with formula VII dimethylsuccinic acid should result; but unfortunately the latter structure cannot be altogether excluded on these grounds.

The first product of the action of one molecule of bromine on dichlorodimethyldihydrobenzene is, for the foregoing reasons, supposed to have the following constitution:  $\text{CMe}_2 \begin{array}{c} \text{CHBr} - \text{CCl} \\ \text{CH}_2 \cdot \text{CClBr} \end{array} \text{CH}$ . This dichlorodibromodimethyltetrahydrobenzene is a liquid which cannot be purified, as on distillation either in air or in a vacuum it decomposes, evolving hydrogen bromide. In order to obtain some clue as to its constitution, the raw material in aqueous suspension was oxidised with potassium permanganate, when it became necessary to heat the mixture to the temperature of boiling water. The main product was dimethylmalonic acid, no trace of dimethylsuccinic acid being obtained, but the latter acid was produced in small quantities by carrying out the oxidation in cold acetone solution.

From a comparison of the formulæ of dichlorodibromo- and dichlorotribromodimethyltetrahydrobenzene, VII, it would appear that the substances represented by the formulæ

should give the same oxidation products, but the reactions are not strictly comparable on account of the greater stability of the latter

substance, which is not oxidised by potassium permanganate in the cold. This greater stability may be due simply to the presence of an additional halogen atom, or it may possibly point to the double linking being in a different position.

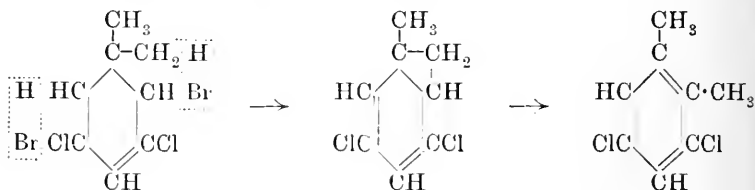

On referring to the oxidation of dichlorodimethyldihydrobenzene,  $\text{CMe}_2 \begin{smallmatrix} \text{CH}=\text{CCl} \\ \text{CH}_2 \cdot \text{CCl} \end{smallmatrix} \text{CH}$ , with potassium permanganate (Trans., 1902, 81, 829), it is seen that, when carried out at  $100^\circ$ , a mixture of dimethylmalonic and dimethylsuccinic acids is obtained, whereas if allowed to take place in the cold only the latter acid is formed. This proves fairly conclusively that if *as*-dimethylsuccinic acid can result as an oxidation product, the amount obtainable may be considerably lessened by carrying out the oxidation at a high temperature, since *as*-dimethylsuccinic acid is further oxidised to dimethylmalonic acid in similar cases when heat is employed.

If, therefore, dichlorotribromodimethyltetrahydrobenzene be represented by formula VII, it might be expected that some trace of *as*-dimethylsuccinic acid would have been obtained, which, however, was not the case; so that formula VIII seems the more probable, although this point is not quite definitely established.

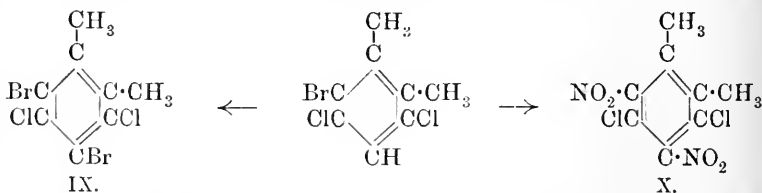

When dichlorotribromodimethyltetrahydrobenzene is heated with ordinary concentrated nitric acid, a somewhat unexpected reaction takes place, resulting in the formation of 3:5-dichloro-4:6-dibromo-*o*-xylene,  $\text{CH}_3 \cdot \text{C} \begin{smallmatrix} \text{C}(\text{CH}_3) \cdot \text{CCl} \\ \text{CBr}=\text{CCl} \end{smallmatrix} \text{CBr}$ , a substance which has also been synthetically prepared by the direct bromination of pure 3:5-dichloro-*o*-xylene. Its production in the above case is accounted for by supposing that, under the influence of heat, dichlorotribromodimethyltetrahydrobenzene first loses two molecules of hydrogen bromide forming 3:5-dichloro-4-bromo-*o*-xylene, which is then further brominated by the bromine liberated from the interaction of the concentrated nitric acid and hydrogen bromide.

As already mentioned, the product of the action of one molecule of bromine on dichlorodimethyldihydrobenzene is supposed to be dichlorodibromodimethyltetrahydrobenzene,  $\text{CMe}_2 \begin{smallmatrix} \text{CHBr}-\text{CCl} \\ \text{CH}_2 \cdot \text{CClBr} \end{smallmatrix} \text{CH}$ , but owing to the instability of this substance there does not seem to be any method of proving this supposition. As, however, it gives *as*-dimethylsuccinic acid on oxidation, it must contain the grouping  $\text{CMe}_2 \begin{smallmatrix} \text{C}- \\ \text{CH}_2 \cdot \text{C} \end{smallmatrix}$ . When heated, it evolves hydrogen bromide and gives as the two main products, 3:5-dichloro-*o*-xylene and 3:5-dichloro-6-bromo-*o*-xylene,  $\text{MeC} \begin{smallmatrix} \text{CMe} \cdot \text{CCl} \\ \text{CBr}=\text{CCl} \end{smallmatrix} \text{CH}$ .

The production of the former compound is readily explained by the loss of two molecules of hydrogen bromide:

but at the present time no reasonable explanation can be offered for the formation of 3:5-dichloro-6-bromo-*o*-xylene, as in the case of the isomeric substance obtained by heating dichlorotribromodimethyltetrahydrobenzene. The reaction, which is more involved, is by no means quantitative, only 17—20 grams of the dichlorobromoxylene being obtained from the product of the action of bromine on 50 grams of dichlorodimethyldihydrobenzene. There can, however, be no doubt about the constitution of this substance, for in the first place it is shown to be a derivative of 3:5-dichloro-*o*-xylene, because on treatment with bromine it is quantitatively converted into 3:5-dichloro-4:6-dibromo-*o*-xylene (IX), identical with the substance produced by the direct bromination of pure 3:5-dichloro-*o*-xylene; and, further,

when treated with fuming nitric acid, it yields 3:5-dichloro-4:6-dinitro-*o*-xylene (X), identical with the compound obtained by the direct nitration of pure 3:5-dichloro-*o*-xylene.

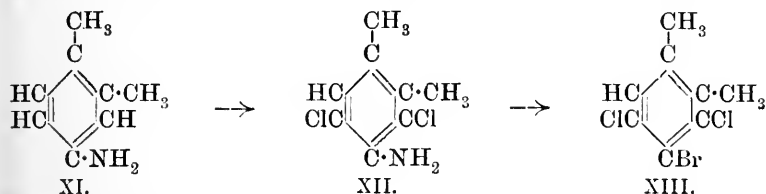

The only additional point to be decided is the position of the bromine atom, which is proved to be attached to the carbon atom 6 in the following manner.

There are but two possible forms of dichlorobromo-*o*-xylenes containing the chlorine atoms in the 3:5-position, and both these possibilities,

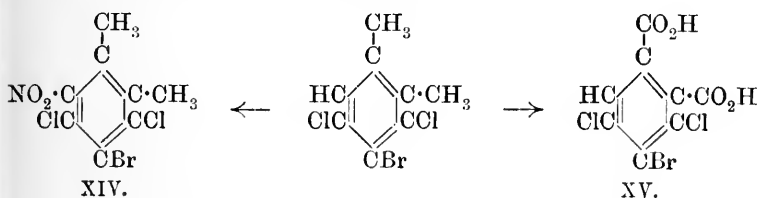

have been encountered in the course of this investigation. The best method for deciding between these seemed to consist in synthesis, and 4-*o*-xylidene (XI) was used as the starting point. This base, the constitution of which has been definitely established by the work of

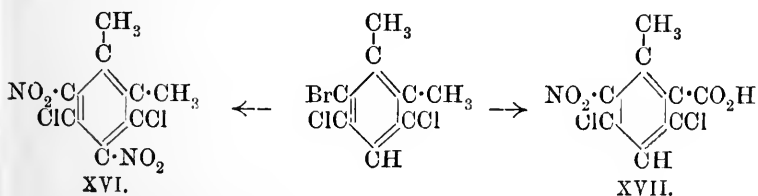

Jacobson (*Ber.*, 1884, 17, 159), when successively acetylated and treated with chlorine in glacial acetic acid solution, yields a dichloro-acetoxylidide, in which the chlorine atoms occupy the ortho-positions relatively to the amino-group. The corresponding dichloro-base, XII,

when diazotised in presence of cuprous bromide and hydrogen bromide, yields 3 : 5-dichloro-4-bromo-*o*-xylene (XIII), melting at 100°, and possessing all the characteristic properties and reactions of the compound obtained by the action of heat on dichlorotribromodimethyltetrahydrobenzene, thus proving that the substance obtained by heating dichlorodibromodimethyltetrahydrobenzene has the constitution of 3 : 5-dichloro-6-bromo-*o*-xylene. Both dichlorobromo xylenes give, on further bromination, one and the same dichlorodibromo-*o*-xylene, but in their behaviour towards nitric acid they differ markedly. When occupying position 4, the bromine atom is stable towards this reagent, but in position 6 it is readily replaced by a nitro-group. Thus, 3 : 5-dichloro-4-bromo-*o*-xylene gives, with fuming nitric acid, 3 : 5-dichloro-4-bromo-6-nitro-*o*-xylene (XIV), and, on oxidation with dilute nitric acid under pressure, is converted into 3 : 5-dichloro-4-bromo-*o*-phthalic acid (XV) :

whereas 3 : 5-dichloro-6-bromo-*o*-xylene gives, under similar conditions, respectively 3 : 5-dichloro-4 : 6-dinitro-*o*-xylene (XVI) and 3 : 5-dichloro-6-nitrotoluic acid (XVII).

## EXPERIMENTAL.

*Interaction of 3:5-Dichloro-1:1-dimethyl- $\Delta^4$ -dihydrobenzene with Two Molecules of Bromine.*

One hundred grams of freshly prepared dichlorodimethyldihydrobenzene (1 mol.) (Trans., 1902, 81, 826) were dissolved in 100 grams of dry chloroform, and 190 grams of bromine (2 mols.) added as rapidly as the comparative violence of the earlier stages of the reaction permitted. At first, the bromine was rapidly absorbed without the evolution of much hydrogen bromide, but subsequently, torrents of the gas were given off, and a quantity of a solid substance separated. The chloroform was then evaporated on the water-bath as quickly as possible\*, and the whole when left became semi-solid. It was filtered at the pump (Filtrate = A) and the solid residue (50 grams) purified by crystallisation from alcohol.

0.1388 gave 0.1176  $\text{CO}_2$  and 0.0368  $\text{H}_2\text{O}$ . C = 23.10; H = 2.94.

0.1442 „ 0.1220  $\text{CO}_2$  „ 0.0360  $\text{H}_2\text{O}$ . C = 23.07; H = 2.77.

0.1034 „ 0.2112 Ag haloids and 0.1340 Ag. Cl = 17.00; Br = 57.65.

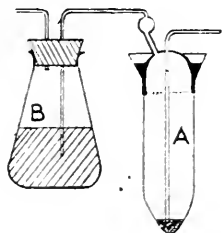

$\text{C}_8\text{H}_9\text{Cl}_2\text{Br}_3$  requires C = 23.07; H = 2.16; Cl = 17.07; Br = 57.69 per cent.

The high results obtained for the hydrogen are doubtless due to the fact that at its melting point this substance rapidly evolves hydrogen bromide, a small amount of which might find its way into the calcium chloride tube.

3:5-Dichloro-2:4:5-tribromo-1:1-dimethyl- $\Delta^5$ -tetrahydrobenzene,

is readily soluble in the cold in chloroform, benzene, or acetone, and in light petroleum or alcohol on warming; it crystallises from the latter solvent in stout, prismatic needles melting with evolution of gas at  $118^\circ$ .

*Action of Heat on Dichlorotribromodimethyl-tetrahydrobenzene.*—The action of heat on this compound was investigated in the apparatus given in the accompanying sketch, when it was found that the reaction is almost a quantitative one corresponding with the loss of two molecules of hydrogen bromide.

A weighed quantity of the substance was placed in the tube, A, which was heated at  $120$ — $125^\circ$  in a sulphuric

\* If the heating on the water-bath is continued for long, decomposition takes place, thus causing a considerable decrease in the amount of solid product.

acid bath and through which a slow current of dry air was drawn, thus causing the evolved hydrogen bromide to pass into the aqueous solution of silver nitrate contained in the flask, *B*. When no more gas was given off from the molten substance, the contents of *B* were filtered, dried, and weighed.

0.5138 gave 0.4466 AgBr.  $\text{HBr} = 37.45$ .

$\text{C}_8\text{H}_9\text{Cl}_2\text{Br}_3$ , when losing  $2\text{HBr}$ , requires  $\text{HBr} = 38.94$  per cent.

The residue in *A* solidified on cooling, and was proved by the following facts to be identical with the 3:5-dichloro-4-bromo-*o*-xylene described on p. 275; it crystallised from alcohol in masses of felt-like needles melting at  $99-100^\circ$ .

0.1148 gave 0.2140 Ag haloids. Halogen = 59.26.

$\text{C}_8\text{H}_7\text{Cl}_2\text{Br}$  requires Ag haloids = 187.0. Halogen = 59.44 per cent.

Moreover, on treatment with bromine in the presence of iron, it gave 3:5-dichloro-4:6-dibromo-*o*-xylene melting at  $233^\circ$  (see page 284), and fuming nitric acid converted it into 3:5-dichloro-4-bromo-6-nitro-*o*-xylene melting at  $176^\circ$  (see page 275).

*Action of Nitric Acid on Dichlorotribromodimethyltetrahydrobenzene.*

Five grams of the tetrahydrobenzene derivative and 40 c.c. of nitric acid (sp. gr. 1.42) were placed in a flask with a ground-glass stopper attached to a condenser. No reaction took place in the cold, so the mixture was heated on a water-bath, when the solution soon became coloured and quantities of nitrous fumes and bromine were evolved. The solid was quickly converted into an oil, which gradually resolidified in flakes. After heating for ten minutes, the contents of the flask were poured into water, filtered, spread on porous plate, and the residue (2.5 grams) crystallised from ethyl acetate. The needles so obtained melted at  $233^\circ$ , and the melting point was not altered on mixing with the 3:5-dichloro-4:6-dibromo-*o*-xylene described on page 284; and that these two substances are identical is conclusively proved by the following analytical figures:

0.1566 gave 0.1670  $\text{CO}_2$  and 0.0268  $\text{H}_2\text{O}$ .  $\text{C} = 29.08$ ;  $\text{H} = 1.89$ .

0.2006 „ 0.4012 Ag haloids and 0.2617 Ag.  $\text{Cl} = 21.65$ ;  $\text{Br} = 47.94$ .  
 $\text{C}_8\text{H}_6\text{Cl}_2\text{Br}_2$  requires  $\text{C} = 28.83$ ;  $\text{H} = 1.80$ ;  $\text{Cl} = 21.32$ ;  $\text{Br} = 48.05$  per cent.

The ethyl acetate mother liquors contained a small quantity of a more fusible solid; this substance and the small oily residue obtained on evaporating the aqueous filtrate from the raw material were not further investigated.

*Oxidation of Dichlorotribromodimethyltetrahydrobenzene.*—Twenty

grams of the substance were suspended in 500 c.c. of water and heated on the water-bath in a flask attached to a reverse condenser, and 60 grams of finely powdered potassium permanganate added in small portions at a time. After heating for ten hours, practically all the permanganate had been used up and the whole was distilled in steam, when a small amount of bromoform passed over. The residue was filtered from manganese dioxide, the filtrate evaporated to a small bulk, acidified, and extracted ten times with ether. The ethereal solution, on evaporation, left a residue weighing 4.5 grams, whereas the amount calculated for the production of dimethylmalonic acid is 6.3 grams. This residue rapidly solidified and melted at 187—188°; after one crystallisation from water, it melted at 190° with evolution of gas.

0.1412 gave 0.2346  $\text{CO}_2$  and 0.0778  $\text{H}_2\text{O}$ .  $\text{C} = 45.31$ ;  $\text{H} = 6.12$ .

$\text{C}_5\text{H}_8\text{O}_4$  requires  $\text{C} = 45.45$ ;  $\text{H} = 6.06$  per cent.

In order to prove more completely the identity of this substance with dimethylmalonic acid, the remainder was heated in a distillation flask, when carbon dioxide was evolved, and a colourless liquid with the unmistakable odour of isobutyric acid passed over, a portion of the liquid was converted into the silver salt.

0.1412 gave 0.0788 Ag.  $\text{Ag} = 55.80$ .

$\text{C}_4\text{H}_7\text{O}_2\text{Ag}$  requires  $\text{Ag} = 55.38$  per cent.

After finding that dichlorodibromodimethyltetrahydrobenzene gave dimethylsuccinic acid on oxidation with potassium permanganate in acetone solution (see page 283), the oxidation of dichlorotribromodimethyltetrahydrobenzene was repeated, using boiling acetone as solvent, the reaction being carried out as described on page 283. The crude oxidation product melted at 189—190° with evolution of gas and formation of isobutyric acid, and therefore consisted of dimethylmalonic acid, no trace of dimethylsuccinic acid being obtained.

*Examination of the Filtrate A* (see page 272).—On distilling this liquid either in air or in a vacuum, a violent evolution of hydrogen bromide took place, and the main fraction (260—270° under 764 mm.) solidified completely on cooling to a waxy substance melting at 85—90°. Considerable difficulty was experienced in purifying this material, and it was only after repeated crystallisation from absolute alcohol that a substance melting at 98—99° was obtained.

A better method for the isolation of this substance in a pure condition consists in allowing the liquid A to remain in a vacuum over caustic potash, when it gradually solidifies to a semi-solid cake, the mother liquor being again placed in a vacuum, when more solid

separated. By repeating this process, 65 grams of a crystalline compound were obtained melting at 95—97°, and which, after recrystallisation from alcohol, melted sharply at 100°.

0.1884 gave 0.2594 CO<sub>2</sub> and 0.0470 H<sub>2</sub>O. C = 37.55; H = 2.77.

0.1083 „ 0.2004 Ag haloids and 0.1364 Ag. Cl = 27.27; Br = 31.82. C<sub>8</sub>H<sub>7</sub>Cl<sub>2</sub>Br requires C = 37.79; H = 2.75; Cl = 27.95; Br = 31.49 per cent.

3 : 5-Dichloro-4-bromo-o-xylene, CH<sub>3</sub>·C<math display="block">\begin{array}{c} \text{C}(\text{CH}\_3) : \text{CCl} \\ \text{CH} \text{---} \text{CCl} \end{array}\text{CBr}, is readily soluble in the cold in light petroleum (b. p. 80—100°), chloroform, benzene, ether, or acetone, and in glacial acetic acid or alcohol on warming. It crystallises from alcohol in long, felt-like needles (compare the properties of 4 : 5-dichloro-6-bromo-o-xylene, Claus and Kronweg, *J. pr. Chem.*, 1891, [ii], 43, 259), which, on pressing, form a waxy material melting at 100° and resolidifying at 98°. It distils without decomposition at 170—175° under 30 mm., and at 265—270° under the ordinary pressure, and is volatile in steam.

*Action of Bromine on 3 : 5-Dichloro-4-bromo-o-xylene.*—The substance was dissolved in a small quantity of chloroform, and bromine added in presence of iron filings. On warming, substitution readily took place, and the resulting solid crystallised from ethyl acetate in glistening needles melting at 233—233.5°, the melting point remaining unaltered when the substance was mixed with pure 3 : 5-dichloro-4 : 6-dibromo-o-xylene (see page 284), thus proving the identity of these two substances. The yield is quantitative.

*Action of Nitric Acid on 3 : 5-Dichloro-4-bromo-o-xylene.*—Three grams of dichlorobromoxylene were added to 40 c.c. of fuming nitric acid and warmed on the water-bath, when the solid gradually dissolved. The heating was continued for 20 minutes, when the mixture was poured into water, and the separated solid (2.6 grams) crystallised from alcohol. The crystals melted at 175—176°, and were thought to be identical with the 3 : 5-dichloro-4 : 6-dinitro-o-xylene (m. p. 175—176°), described on page 284, but a mixture of the two substances melted at 154—155°, thus proving that its components were dissimilar. After a further crystallisation of the above material, the nitrogen was determined.

0.2580 gave 10.2 c.c. moist nitrogen at 23° and 772 mm. N = 4.52.

C<sub>8</sub>H<sub>6</sub>O<sub>2</sub>NCl<sub>2</sub>Br requires N = 4.68 per cent.

3 : 5-Dichloro 4-bromo-6-nitro-o-xylene, CH<sub>3</sub>·C<math display="block">\begin{array}{c} \text{C}(\text{CH}\_3) : \text{CCl} \\ \text{C}(\text{NO}\_2) - \text{CCl} \end{array}\text{CBr}, is readily soluble in the cold in chloroform, benzene, acetone, ethyl acetate, or ether, and crystallises from dilute acetic acid or alcohol in faintly yellow, glistening needles melting at 175.5—176.5°.

*Oxidation of 3 : 5-Dichloro 4 bromo-o-xylene.*—Eight grams of the dichlorobromoxylene were heated in quantities of two grams at a time, with 15 c.c. of nitric acid (sp. gr. 1.15), in sealed tubes for 7 hours at 180—200°. The contents of the tubes, which were entirely liquid, were evaporated *in vacuo*, when 9 grams of a white solid, giving a marked fluorescein reaction, were obtained. On testing the solubilities, it was found that this substance would crystallise from xylene, and the whole was therefore boiled with this solvent, when it slowly dissolved, but on cooling only 0.9 gram separated (see page 277). The mother liquors were evaporated, and the solid residue purified by crystallisation from a mixture of benzene and light petroleum.

0.1592 gave 0.1880 CO<sub>2</sub> and 0.0084 H<sub>2</sub>O. C = 32.20 ; H = 0.58.

0.1042 „ 0.1667 Ag haloids and 0.1134 Ag. Cl = 23.50 ; Br = 27.63.  
C<sub>8</sub>H<sub>3</sub>O<sub>3</sub>Cl<sub>2</sub>Br requires C = 32.43 ; H = 0.34 ; Cl = 23.98 ; Br = 27.02  
per cent.

3 : 5-Dichloro-4-bromo-o-phthalic anhydride,  $\text{OC} \cdot \text{C} \begin{array}{l} \nearrow \text{C} = \text{CCl} \\ \searrow \text{CH} \cdot \text{CCl} \end{array} \text{CBr}$

is readily soluble in the cold in benzene, chloroform, acetone, and ethyl acetate, soluble with difficulty in alcohol and light petroleum, and crystallises from a mixture of benzene and light petroleum in radiating clusters of stumpy needles melting at 170—171°. It can be sublimed unchanged in feathery needles and gives a most marked fluorescein reaction. Its method of preparation from the corresponding acid by boiling with xylene is somewhat unusual, but presumably the temperature of boiling xylene is sufficiently high to cause the formation of anhydride, and at the same time supplies a ready means for separating the acid from the nitrogenous substance (see p. 277), which is also produced in small quantity during the oxidation.

In a second preparation, the anhydride was produced by heating the crude oxidation product with acetyl chloride, &c. The solid so obtained was found to contain nitrogen, but on submitting it to a process of sublimation, the nitrogenous substance was decomposed, whilst the sublimate, after crystallisation, melted at 169—170° and consisted of pure 3 : 5-dichloro-4-bromo-o-phthalic anhydride.

The anhydride is not acted on by cold water, but dissolves slowly in the boiling solvent, and on evaporating the solution the corresponding *acid* remains ; this substance is readily soluble in the cold in water, alcohol, and acetone, but dissolves readily in boiling chloroform or benzene ; it crystallises from water saturated with hydrogen chloride in small, flattened needles melting at 169—170° with previous diminution in bulk and partial sublimation. Unless purified in this way through the anhydride, the acid melts much lower (156—162°) with vigorous evolution of gas.

A portion of the pure acid was converted into the silver salt, which is a white, caseous precipitate.

0.2000 gave 0.0817 Ag.  $\text{Ag} = 40.85$ .

$\text{C}_8\text{HO}_4\text{Cl}_2\text{BrAg}_2$  requires  $\text{Ag} = 40.91$  per cent.

The *anil* was obtained by dissolving the anhydride in benzene and adding the calculated amount of aniline, when a precipitate was at once formed, which was filtered and dried. When heated, it melts at  $120\text{--}125^\circ$  with evolution of gas, then resolidifies, and, finally, again melts at  $180\text{--}195^\circ$ , at which temperature it was maintained until no more gas was evolved. The solid thus obtained readily dissolved in cold benzene or chloroform, but was not readily soluble in alcohol even on boiling; it crystallised from acetone or ethyl acetate in masses of glistening, silken needles melting at  $200\text{--}200.5^\circ$ .

0.2638 gave 8.6 c.c. moist nitrogen at  $14^\circ$  and 762 mm.  $\text{N} = 3.84$ .

$\text{C}_{14}\text{H}_6\text{O}_2\text{NCl}_2\text{Br}$  requires  $\text{N} = 3.77$  per cent.

It was mentioned on page 276 that on crystallising the crude oxidation product from xylene, only 0.9 gram of solid separated, which, on examination, was found to contain nitrogen.

0.1990 gave 8.6 c.c. moist nitrogen at  $18^\circ$  and 768 mm.  $\text{N} = 5.05$ .

$\text{C}_8\text{H}_3\text{O}_6\text{NCl}_2$  requires  $\text{N} = 5.00$  per cent.

This substance is in all probability 3:5-dichloro-4-nitro-o-phthalic acid, as in a halogen determination the proportion of silver in the total silver haloids showed conclusively that the substance could not contain any bromine. The acid is very readily soluble in the cold in water, alcohol, ethyl acetate, and acetone, almost insoluble in chloroform and benzene on boiling, and crystallises from xylene in clusters of flattened needles melting at  $165^\circ$  with a brisk evolution of gas.

#### *Synthesis of 3:5-Dichloro-4-bromo-o-xylene.*

The 4-o-xylylidine used in these experiments melted sharply at  $49^\circ$ , and gave an acetyl derivative crystallising from dilute alcohol in long, glistening needles melting at  $99^\circ$  (compare Jacobson, *Ber.*, 1884, 17, 161).

The acetoxylylidiide, in quantities of 5 grams, was dissolved in 10 c.c. of glacial acetic acid, the whole cooled in ice, and dry chlorine passed in until the gain in weight corresponded with the substitution of two hydrogen atoms by chlorine. A crust of white, nodular crystals then slowly separated, which was drained from excess of acetic acid and placed in water. At first, the substance became semi-liquid, part dissolving, and then the whole mass resolidified, the solid being

purified by crystallising from dilute alcohol until the melting point of the glistening scales which separated was about  $185^{\circ}$ . The yield is small, being 15—20 per cent. of the theoretical.

No attempt was made to isolate a pure acetyl derivative, and the substance melting at about  $185^{\circ}$  was directly hydrolysed by boiling for 3—4 hours with concentrated hydrochloric acid; the solid product was suspended in dilute caustic potash and distilled in steam, when an oil passed over which soon solidified. The crude material melted for the most part at  $50^{\circ}$ , but did not become clear until  $95^{\circ}$ , and was found to consist of two substances which could be easily separated by means of their different solubilities in alcohol. The whole was dissolved in the smallest possible quantity of hot absolute alcohol, when on cooling a few long, needle-shaped crystals separated, melting at  $170^{\circ}$ . The filtrate from these crystals (which were not further investigated) was diluted with water, when glistening needles separated, which melted for the most part at  $43\text{--}45^{\circ}$ , but did not become quite clear until  $85^{\circ}$ . After repeating the above process of purification, a substance was obtained melting sharply at  $44.5^{\circ}$ , and in this the chlorine was determined.

0.1028 gave 0.1560 AgCl. Cl = 37.54.

$\text{C}_8\text{H}_9\text{NCl}_2$  requires Cl = 37.37 per cent.

3 : 5-Dichloro-4-o-xylylidine,  $\text{CH}_3 \cdot \text{C} \begin{array}{c} \nwarrow \text{C}(\text{CH}_3) : \text{CCl} \\ \searrow \text{CH} \text{---} \text{CCl} \end{array} \text{C} \cdot \text{NH}_2$ , is extremely soluble in the cold in light petroleum (b. p.  $40\text{--}60^{\circ}$ ), chloroform, acetone, benzene, or ether, and crystallises from dilute alcohol in long, glistening, silken needles melting at  $44.5^{\circ}$ .

In order to replace the amino-group by bromine, the base was suspended in hydrobromic acid (sp. gr. 1.45), in which it is not at all readily soluble, a solution of freshly prepared cuprous bromide in hydrobromic acid added, and slightly more than the calculated quantity of sodium nitrite dissolved in the smallest possible amount of water dropped into the mixture, which was heated on the water-bath to a temperature of  $60\text{--}70^{\circ}$ . After one hour, the whole was distilled in steam, when a solid passed over which melted at  $95\text{--}97^{\circ}$ , and proved to be identical in every respect with the dichlorobromoxylene described on page 275. It crystallised from absolute alcohol in long, glistening, felt-like needles melting at  $100^{\circ}$ , which, on pressing together, assume a waxy consistency. When brominated in the presence of iron filings, it gave a dichlorodibromoxylene crystallising from ethyl acetate in glistening, silken needles melting at  $233^{\circ}$ , a melting point which remained unaltered on mixing with the 3 : 5-dichloro-4 : 6-dibromo-o-xylene described on page 284. Fuming nitric acid slowly dissolves the substance on warming, and on pouring the solution into water a solid separated which crystallised from alcohol in pale yellow, glistening

needles melting at 175—176°, and giving the same melting point when mixed with the dichlorobromonitroxylene described on page 275.

*Interaction of 3:5-Dichloro-1:1-dimethyl- $\Delta^2$ -<sup>4</sup>-dihydrobenzene with One Molecule of Bromine.*

Dichlorodimethyldihydrobenzene (1 molecule) was dissolved in three times its weight of dry chloroform and dry bromine (1 molecule) gradually added, the whole being cooled in ice. The bromine is readily absorbed, hardly any hydrogen bromide being evolved, and a sharp end point is noticed when one molecule of bromine has been used up. On evaporating the chloroform, a light yellow liquid remained, which, as it showed no signs of solidification even after a long time, was distilled, when torrents of hydrogen bromide were evolved, and a clear yellow, refractive liquid, boiling between 200° and 270°, passed over. On submitting the liquid to careful and repeated fractional distillation, two main fractions were obtained, boiling at 220—230° and 240—250°. All the intermediate fractions slowly deposited crystals which were found to be identical with the 3:5-dichloro-6-bromo-*o*-xylene contained in the fraction 240—250° (see page 280).

*The Fraction 220—230° contained 3:5-Dichloro-*o*-xylene* (Trans., 1902, 81, 1534).

This liquid was again fractionated, and a portion, boiling at 226°, was found to solidify on cooling and melted at 3—4°. When treated with bromine in presence of iron filings, it gave 3:5-dichloro-4:6-dibromo-*o*-xylene melting at 233° (see page 284), and on nitration gave 3:5-dichloro-4:6-dinitro-*o*-xylene melting at 175° (see page 284).

As a further proof of the presence of 3:5-dichloro-*o*-xylene, some of the liquid was oxidised with dilute nitric acid under pressure (compare Trans., 1902, 81, 1536). On opening the tube, it was found to contain a quantity of long, silken needles floating in a liquid; these were filtered (Filtrate = A), purified by crystallisation from dilute acetic acid, and the chlorine determined.

0.1088 gave 0.1544 AgCl. Cl = 35.10.

$C_8H_6O_2Cl_2$  requires Cl = 34.63 per cent.

The acid was also titrated against *N*/10 sodium hydroxide with the following result.

0.4350 required 21.94 c.c. *N*/10 solution = 0.0877 NaOH.

$C_8H_6O_2Cl_2$  requires 0.0849 NaOH.

This substance, which is evidently a *dichlorotoluic acid*, readily dissolves in the cold in potassium hydroxide, alcohol, acetone, ethyl acetate, or benzene, and is not readily soluble even on boiling in light petroleum or water; it crystallises from dilute acetic acid in long, glistening needles melting at 184—185°.

The production of this dichlorotoluic acid was never observed during the preparation of 3:5-dichloro-*o*-phthalic acid (Trans., *ibid.*). This may be accounted for by the facts that in the above oxidation rather less nitric acid was used than formerly, and that the sealed tube was not heated for so many hours. It is intended to repeat the oxidation of 3:5-dichloro-*o*-xylene in the hope of obtaining the above dichlorotoluic acid, and definitely proving its constitution.

The filtrate A (see above) was evaporated *in vacuo*, when a white solid remained which gave a very marked fluorescein reaction. The anhydride prepared from it by treatment with acetyl chloride crystallised from light petroleum in radiating clusters of glistening needles melting at 89°, the melting point remaining unaltered on mixing the compound with the anhydride of 3:5-dichloro-*o*-phthalic acid, with which the substance is evidently identical.

The *fraction* 240—250°, which solidified completely (17—20 grams from 50 grams of dichlorodimethyldihydrobenzene), was spread on porous plate and purified by crystallisation from ethyl alcohol.

0.1546 gave 0.2161 CO<sub>2</sub> and 0.0408 H<sub>2</sub>O. C = 38.12; H = 2.93.

0.1040 gave 0.1954 Ag haloids and 0.1334 Ag. Cl = 28.23; Br = 31.38. C<sub>8</sub>H<sub>7</sub>Cl<sub>2</sub>Br requires C = 37.79; H = 2.75; Cl = 27.95; Br = 31.49 per cent.

3:5-Dichloro-6-bromo-*c*-xylene,  $\text{CH}_3 \cdot \text{C} \begin{array}{c} \text{C}(\text{CH}_3) \cdot \text{CCl} \\ \text{CBr} \text{---} \text{CCl} \end{array} \text{CH}$ , is readily soluble in the cold in benzene, acetone, light petroleum, or ethyl acetate, crystallises from ethyl or methyl alcohol in long, slender, glistening needles melting at 42°, and can be distilled in air without undergoing any decomposition. It does not decolorise a chloroform solution of bromine, but in the presence of iron filings substitution takes place readily. The solid product crystallised from ethyl acetate in long, glistening needles melting at 233°, and was identical with the 3:5-dichloro-4:6-dibromo-*o*-xylene described on page 284.

*Action of Nitric Acid on 3:5-Dichloro-6-bromo-*o*-xylene.*—Two grams of the substance were gradually added to 10 c.c. of fuming nitric acid, when it readily dissolved, and the solution became warm. The whole was heated on the water-bath for 20 minutes, poured into water, the separated solid filtered, and crystallised from alcohol. It separated in pale yellow, four-sided plates melting at 174—175°, and proved to be in every way identical with the 3:5-dichloro-4:6-dinitro-*o*-xylene described on page 284.

0.2256 gave 20.0 c.c. moist nitrogen at  $19^{\circ}$  and 760 mm.  $N = 10.20$ .  
 $C_8H_6O_4N_2Cl_2$  requires  $N = 10.56$  per cent.

*Oxidation of 3:5-Dichloro-6-bromo-o-xylene.*—The substance was oxidised by heating it in quantities of 2 grams at a time with 15 c.c. of dilute nitric acid (sp. gr. 1.15) for 6 hours at  $180-190^{\circ}$ . The contents of the tube, consisting of white, needle-shaped crystals suspended in a greenish-brown liquid, were filtered (filtrate A), the solid treated with potassium hydroxide, in which a slight amount was insoluble, filtered, reprecipitated with sulphuric acid, and purified by crystallisation from water.

0.2042 gave 9.8 c.c. moist nitrogen at  $22^{\circ}$  and 770 mm.  $N = 5.51$ .  
 $C_8H_5O_4NCl_2$  requires  $N = 5.6$  per cent.

The acid was then titrated against  $N/10$  sodium hydroxide.

0.3952 required 16.2 c.c.  $N/10$  solution = 0.0648 NaOH.  
 $C_8H_5O_4NCl_2$  requires 0.0632 NaOH.

*3:5-Dichloro-6-nitrotoluic acid* is readily soluble in the cold in aqueous potassium hydroxide, alcohol, acetone, and ethyl acetate, less so in benzene or chloroform, and crystallises from water in feathery needles melting at  $187-189^{\circ}$ .

The filtrate A (see above) yielded on evaporation a solid which gave the fluorescein reaction in a marked degree, but the amount was too small for complete investigation.

As the light yellow liquid (see page 279) obtained by the action of one molecule of bromine on dichlorodimethyldihydrobenzene and presumably *dichlorodibromodimethyltetrahydrobenzene* cannot be distilled even in a vacuum without decomposition, it was submitted to oxidation with potassium permanganate in order to obtain some evidence as to its constitution.

For this purpose, 50 grams of the substance were suspended in 700 c.c. of water, 90 grams of finely-powdered potassium permanganate gradually added, and the whole heated on the water-bath in a flask attached to a reflux condenser. At first, the oxidation is vigorous, and some bromine is liberated, but it soon becomes much less active, and the permanganate is very slowly decolorised, in the above case requiring 10 hours. The contents of the flask were then filtered, when some oil passed through with the filtrate (= A), which was extracted with ether (extract = B). The residual manganese dioxide was then suspended in water and distilled in steam, when an oil passed over with the aqueous distillate, and this was extracted with ether (extract = C).

A. The filtrate was evaporated to a small bulk, acidified, and re-

peatedly extracted with ether, when 3.5 grams of a solid having a marked odour of fatty acids were obtained. On crystallisation from water, a slab of crystals separated, which melted at 190—191° with brisk evolution of gas, and consisted of dimethylmalonic acid, for on distillation, *isobutyric* acid was obtained boiling at 153—155°. A portion of this acid was converted into the silver salt.

0.1888 gave 0.1046 Ag.  $\text{Ag} = 55.40$ .

$\text{C}_4\text{H}_7\text{O}_2\text{Ag}$  requires  $\text{Ag} = 55.38$  per cent.

The mother liquors from the dimethylmalonic acid were evaporated to dryness and distilled, when a further quantity of *isobutyric* acid was obtained, and at a much higher temperature 0.5 gram of a liquid passed over which at once solidified. This solid was insoluble in cold water but dissolved on boiling, and after saturating the solution with hydrogen chloride, needle-shaped crystals separated, melting at 164° with evolution of gas. These crystals gave the fluorescein reaction in a marked degree and evidently consisted of 3:5-dichloro-*o*-phthalic acid, for on heating with acetyl chloride they were converted into an anhydride which crystallised from light petroleum in glistening, flattened needles melting at 89°; this melting point was not altered on mixing the substance with pure 3:5-dichloro-*o*-phthalic anhydride (compare *Trans.*, 1902, 81, 1536).

*B.* This extract, which weighed 9 grams, slowly deposited crystals. These were filtered and crystallised from alcohol, when the compound separated in stout needles, which melted with evolution of gas at 118° and were proved by the following facts to be identical with the dichlorotribromodimethyltetrahydrobenzene described on page 272.

0.2184 gave 0.4472 Ag haloids.  $\text{Halogen} = 74.81$ .

$\text{C}_8\text{H}_9\text{Cl}_2\text{Br}_3$  requires halogen = 74.75 per cent.

This substance, when warmed with concentrated nitric acid, yielded 3:5-dichloro-4:6-dibromo-*o*-xylene melting at 233° (see page 273). The liquid from which the above crystals had separated was distilled in air, when hydrogen bromide was evolved and two fractions were obtained boiling at 220—230° and 240—250°. The first of these fractions contained 3:5-dichloro-*o*-xylene, and the latter, on cooling, solidified almost completely to a solid which melted at 42°, and was identical with the 3:5-dichloro-6-bromo-*o*-xylene mentioned on page 280.

*C.* The oil deposited a small quantity of solid, readily soluble in the ordinary organic solvents with the exception of light petroleum and alcohol; from these solutions, the compound separated in fern-like aggregates of flattened needles melting at 143—144°. The crystals, which contained halogen, did not decolorise a chloroform solution of

bromine, and were readily oxidised by potassium permanganate on warming, but the amount was too small for a determination of their constitution.

The results of this oxidation, although appearing somewhat complicated, are easily explained. The temperature to which the mixture is heated evidently causes the partial decomposition of the original substance into hydrogen bromide, 3:5-dichloro-*o*-xylene, and 3:5-dichloro-6-bromo-*o*-xylene, from the second of which, on further oxidation, there results 3:5-dichloro-*o*-phthalic acid. Moreover, the liberated hydrogen bromide would, in contact with potassium permanganate, evolve bromine, which would act on some of the original material to give dichlorotribromodimethyltetrahydrobenzene.

The oxidation was then repeated, using acetone as solvent instead of water. Fifty grams of crude dichlorodibromodimethyltetrahydrobenzene (page 279) were dissolved in a mixture of 500 c.c. pure acetone and 100 c.c. of water, and 110 grams of finely-powdered potassium permanganate gradually added. The first stages of the oxidation were accompanied by a considerable evolution of heat, so much so that the mixture was cooled in ice-water, and later, when the oxidation became less vigorous, it was allowed to take place at the ordinary atmospheric temperature. When the permanganate had been used up, the product was filtered and the acetone evaporated, when 6 grams of an oil separated which was not further examined. After removing the oil by filtration, the filtrate was evaporated to a small bulk, acidified with sulphuric acid, extracted ten times with ether, and the ether evaporated, when a residue weighing 9 grams was obtained, which slowly solidified. The solid melted for the most part at 120–125°, but did not become clear until 150°, when a gas was evolved. This is the manner in which a mixture of dimethylmalonic and *α*-dimethylsuccinic acids behaves on heating in a capillary tube as already observed (Trans., 1902, 81, 829). The solid was therefore heated at 180° in a distillation flask until no more gas was given off, during which time a liquid distilled over which proved to be *isobutyric* acid.

The liquid residue in the distillation flask was insoluble in cold water, but dissolved on boiling, and after saturating the solution with hydrogen chloride, needle-shaped crystals separated melting at 140–141°.

0.1178 gave 0.2128 CO<sub>2</sub> and 0.0746 H<sub>2</sub>O. C = 49.26; H = 7.03.

C<sub>6</sub>H<sub>10</sub>O<sub>4</sub> requires C = 49.31; H = 6.85 per cent.

The identity of this substance with *α*-dimethylsuccinic acid was further proved by the preparation from it of an anilic acid, which

crystallised from methyl alcohol in flattened, nacreous needles melting at 186—187°.

Incidentally, it was observed that *as*-dimethylsuccinic acid gives a particularly brilliant fluorescein reaction.

*Derivatives of 3:5-Dichloro-o-xylene.*

The following derivatives were prepared from pure 3:5-dichloro-o-xylene (Trans., 1902, 81, 1533) for the purpose of comparison with substances encountered in the course of this investigation.

On adding 3:5-dichloro-o-xylene to a mixture of fuming nitric and concentrated sulphuric acids, much heat is evolved, and a solid separates almost at once. The whole was heated on the water-bath for ten minutes, poured into a large volume of water, filtered, and after purifying the residue by crystallisation from alcohol, the nitrogen was determined.

0.2550 gave 22.8 c.c. moist nitrogen at 20° and 772 mm. N = 10.39.

$\text{C}_8\text{H}_6\text{O}_4\text{N}_2\text{Cl}_2$  requires N = 10.56 per cent.

3:5-Dichloro-4:6-dinitro-o-xylene is readily soluble in the cold in chloroform, acetone, ether, benzene, or ethyl acetate, and crystallises from dilute acetic acid or alcohol in faintly yellow, glistening, four-sided crystals melting at 175—176°.

This substance is readily obtained by brominating 3:5-dichloro-o-xylene in presence of a small quantity of iron filings. It is soluble in the cold in benzene and chloroform, sparingly so in alcohol, even on boiling, and crystallises from light petroleum (b. p. 80—100°), acetone, or ethyl acetate in slender, glistening needles melting at 233—233.5°. It sublimes in stout needles without decomposition.

0.1039 gave 0.2088 mixed haloids and 0.1362 Ag. Cl = 21.65; Br = 48.12.

$\text{C}_8\text{H}_6\text{Cl}_2\text{Br}_2$  requires Cl = 21.32; Br = 48.05 per cent.

The mother liquors from the crystallisation of this derivative contained a substance of much lower melting point (100—118°), which from its appearance and properties must have consisted for the most

part of 3 : 5-dichloro-4-bromo-*o*-xylene, but although repeatedly crystallised, it was not found possible to isolate a substance of constant melting point.

The action of one molecule of bromine on 3 : 5-dichloro-*o*-xylene was also investigated, because Claus (*J. pr. Chem.*, [ii], 42, 125) attempted to prepare a dichlorobromoxylene by the action of one molecule of bromine on dichloro-*m*-xylene, but found that under these conditions one half of the substance was converted into the dichlorodibromoxylene, whilst the residue remained unchanged.

When 3 : 5-dichloro-*o*-xylene is treated with one molecule of bromine in presence of iron filings, a very small amount of unaltered material is recovered, and on submitting the solid obtained to fractional crystallisation from alcohol, it was found to consist principally of 3 : 5-dichloro-4-bromo-*o*-xylene, melting at 100° (see page 275). Some dichlorodibromoxylene (m. p. 233°) is also produced, from which it is almost impossible to separate the dichlorobromoxylene in a pure condition. Undoubtedly the latter substance is most easily obtained pure by the elimination of hydrogen bromide from dichlorotribromodimethyltetrahydrobenzene (see page 274).

3 : 5-Dichloro-4 : 6-dibromo-*o*-phthalic Acid,

This acid may be prepared by heating the above dichlorodibromoxylene in quantities of two grams at a time with 15 c.c. of dilute nitric acid (sp. gr. 1.15) in sealed tubes at a temperature of 230—240° for six hours. Experiment showed that this strength of nitric acid had little or no action on the dichlorodibromoxylene at a temperature of 190—200°, even after heating for 7 hours; with more concentrated nitric acid, considerable quantities of acids containing nitrogen were produced, and these were difficult to remove from the desired phthalic acid.

The semi-solid contents of the tubes were filtered and the residue extracted two or three times with boiling water, in which solvent any unchanged dichlorodibromoxylene is quite insoluble. On cooling the filtrate, the phthalic acid separated, and was purified by further crystallisation from water.

0.1622 gave 0.1444 CO<sub>2</sub> and 0.0126 H<sub>2</sub>O. C = 24.27; H = 0.86.

C<sub>8</sub>H<sub>2</sub>O<sub>4</sub>Cl<sub>2</sub>Br<sub>2</sub> requires C = 24.42; H = 0.51 per cent.

3 : 5-Dichloro-4 : 6-dibromo-*o*-phthalic acid is readily soluble in the cold in alcohol, acetone, and ethyl acetate, insoluble even on boiling in light petroleum or chloroform, and crystallises from water in small,

shining scales, which, on heating, sinter and partially sublime, and finally melt at  $240-241^{\circ}$  with evolution of gas. It gives a very marked fluorescein reaction, and, when heated between two watch glasses, sublimes in feathery needles, which were found to consist of the anhydride.

The *anhydride* was prepared by heating the acid with excess of acetyl chloride for one hour, evaporating the solvent, and crystallising the residue from acetic anhydride.

0.2016 gave 0.1930  $\text{CO}_2$  and 0.0014  $\text{H}_2\text{O}$ .  $\text{C} = 26.10$ ;  $\text{H} = 0.00$ .

0.1032 ,, 0.1834 mixed haloids and 0.1198 Ag.  $\text{Cl} = 19.40$ ;  
 $\text{Br} = 42.21$ .

$\text{C}_8\text{O}_3\text{Cl}_2\text{Br}_2$  requires  $\text{C} = 25.60$ ;  $\text{H} = 0.00$ ;  $\text{Cl} = 18.93$ ;  $\text{Br} = 42.67$   
per cent.

The anhydride readily dissolves in the cold in benzene and ethyl acetate, and is sparingly soluble, even on boiling, in water, alcohol, or light petroleum; it crystallises from acetic anhydride in stout, prismatic needles melting at  $248-250^{\circ}$ , and sublimes unchanged. When dissolved in benzene and treated with aniline, a white solid separates, which crystallises from alcohol in glistening, flattened needles melting with decomposition at  $266-267^{\circ}$ . This substance may be the anilic acid, although it was found to contain more than the calculated amount of nitrogen (Found,  $\text{N} = 3.6$  and  $4.0$ . Calculated 3 per cent.).

The author's thanks are due to the Research Fund Committee of the Chemical Society for a grant, which has in part defrayed the cost of this investigation.

### XXXV.—*A Microscopical Method of Determining Molecular Weights.*

By GEORGE BARGER, Scholar of King's College, Cambridge.

THIS research, a preliminary account of which has been given in the Proceedings (1903, 19, 121), originated in Professor Errera's laboratory at Brussels, where experiments were being carried out on the hereditary adaptation of fungi to strong salt solutions. The fungi were grown in hanging drops of the solutions; each drop was suspended from the lower surface of a coverslip, which was separated from the slide by a cardboard frame, the chamber thus produced being

moistened from time to time with distilled water. The experiments generally lasted a few weeks, and it was noticed that the drops of the salt solutions invariably increased in size. This phenomenon was explained by Prof. Errera in the following manner. As the vapour pressure of the salt solutions was less than that of pure water at the same temperature, and as the drop was confined in a closed space, moistened by pure water, a condensation of vapour took place on the drop. Prof. Errera then asked me to study the effect quantitatively, and for this suggestion and for the kindly interest he has taken in the work I wish to express my hearty thanks. My earliest experiments were made either with small flasks or with small crystallising dishes, which could be completely closed by ground glass plates, but as the results were only of a qualitative character, I finally determined to study the behaviour of the drops in a capillary tube, so that their change in thickness could be measured under the microscope.

#### *Description of the Method.*

A solution of known strength of the substance, the molecular weight of which is unknown, is compared with standard solutions of a substance of known molecular weight, a series of drops taken alternately from the two solutions being introduced into a capillary tube (length 6—8 cm.; bore 1.5 mm.).

After the drops have been measured, the tube is put aside for some time varying from a few minutes to a day, and then another measurement is taken. If there is a decided difference in the vapour pressure of the two solutions employed, one series of drops will be found to have increased, while those alternating with them have decreased. In that case we can decide whether the solution experimented with contains more or less molecules than the standard solution, and so arrive at two limits for the unknown molecular weight.

The theory of the determination is very simple. Each drop is placed between two others of a different solution, and can evaporate on either side into a small, closed air-chamber. This chamber is soon saturated with vapour, which can condense freely on the drops. If the vapour pressures of the two solutions are equal, the evaporation will equal the condensation, and there will be no change in volume of the drops. If, on the other hand, the vapour pressures are unequal, there will be a gradient of vapour pressure in the air spaces; some drops will therefore be in contact with an atmosphere the vapour pressure of which is greater than their own. Condensation will take place on these drops and they will increase. The others, alternating with them, will have a vapour pressure greater than that of the adjoining

air spaces ; these drops will evaporate and thus decrease. Hence there is a distillation from the drops of the one series to those of the other series, although all are at the same temperature.

By measurement, we can tell which drops increase, and hence ascertain which solution has the smaller vapour pressure. If the solvent is identical in both cases, and if the solutes are non-volatile, the solution with the smaller vapour pressure will have the greater concentration of molecules and *vice versa*, and thus the determination of the molecular weight is rendered possible.

### *Preparation of Solutions.*

The supply of the substance, the molecular weight of which is to be determined may be very limited, but good results have been obtained with as little as 30 milligrams. The substance is weighed out in a minute stoppered bottle or cylinder. A known volume of the solvent is then added from a pipette, for instance, a one c.c. pipette graduated in hundredths. It is generally easier to add enough of the solvent to dissolve the substance completely and then weigh the solution. To obtain the volume of the solution, we must know its density, but as the solution is generally dilute, we may, without great error, take its density as being equal to that of the pure solvent. The density of the solvent is easily estimated by a hydrometer.

It is best to express the concentration of the solution thus prepared by volume, and not by weight, as it is easier to make up the other (standard) solutions by volume.

The choice of the standard substance is determined by the following circumstances :

1. In the first place, it should neither be associated nor dissociated under the conditions of the experiment, that is to say, it should actually have the molecular weight deduced from its formula.

2. Secondly, the standard substance must neither combine with the solvent, nor with the other solute (for a certain amount of mixing of the two solutions is inevitable).

3. Thirdly, both the standard and the unknown substance should be very much less volatile than the solvent employed.

4. Fourthly, if the unknown substance is colourless, it is useful to employ a coloured substance as standard, for then one can always see at a glance to which solution a given drop belongs, and to what extent mixing has taken place.

Benzil and azobenzene are two good substances for work with organic liquids. They can be easily obtained pure, are freely soluble in most solvents, have normal molecular weights, and give coloured solutions.

With water, I have most frequently used cane sugar and boric acid. The latter substance has the advantage of not being attacked by moulds, so that its solutions can easily be kept unchanged; its electrolytic dissociation is so slight as to be negligible. The standard solutions are conveniently made up in 10 c.c. graduated stoppered measuring cylinders. It is then easy to obtain a solution of any desired intermediate strength by mixing two others. Sometimes it may be desirable to dilute a solution of known strength very slightly with the pure solvent. In that case, to the known volume of the solution the calculated quantity of the solvent from a one c.c. pipette graduated in hundredths can be added, this procedure being much more accurate than taking the difference between the two readings of the measuring cylinder.

With regard to choice of solvent, the method allows considerable latitude. The solvent need have neither a constant melting point nor a constant boiling point. Therefore, its purity is not an essential condition. Ether saturated with water, wet acetone (b. p. 56.7—65°) alcohol with 10 per cent. water, acetic acid with 20 per cent. water, can all be used successfully.

Boiling point determinations with acetone and pyridine, for instance, require specially purified samples of these substances, whereas by the microscopic method an approximate value of the molecular weight can easily be found in a short time. The best proof that a solvent of constant boiling point is not required is given by the experiments with light petroleum (b. p. 50—60°; see below).

Although the solvent need not be pure, it is obviously essential that all the solutions for one determination should be made up from the same sample. Very volatile solvents cannot be used, for with them it is impossible to fill tubes with any degree of accuracy. I have performed a few experiments with ether and obtained satisfactory results, but cannot recommend this solvent on account of the difficulty of manipulation. With a little care, carbon disulphide may be employed. If, on the other hand, the solvent is not sufficiently volatile, the experiment takes too long. Xylene is one of the least volatile solvents which can conveniently be used.

The *capillary tubes* are best prepared by drawing out soft glass tubing of  $\frac{1}{2}$ " bore into capillaries of 1—2 feet long, which should be cut into smaller pieces, having a smooth, regular edge, in order that the tube may be closed tightly with the finger while it is being filled. The internal diameter of the capillaries should be between 1 and 2 mm., preferably about 1.5 mm. The influence of the bore will be discussed later.

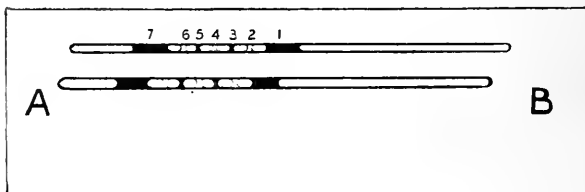

The *filling of the tubes* requires a little practice, but when this has been obtained it can be done quite rapidly. The tube is taken between

the middle finger and thumb, and its upper end, which should be rounded, is closed with the index finger. The other end is then dipped below the surface of one of the two solutions (which in the following experiments is always the standard one). By lifting the index finger very slightly, enough liquid is admitted into the tube to make a column of about 5 mm. long. The index finger is again pressed against the tube, so as to close it, and the tube is then held in a slanting position, with the open end uppermost. By again diminishing the pressure of the finger on the closed end, some air is allowed to escape, and the column of liquid slides down the tube. Its progress is regulated by the amount of slant given to the tube. When the column has travelled about 3 mm., it is stopped by closing the tube again with the finger. The tube is now once more held vertically, and its open end is made to touch the surface of the second solution, while the upper end is still closed by the index finger. This time only a minute drop enters, for the capillary forces are soon balanced by the increase in the pressure of the air inside the tube. The tube is then again held in a slanting position, and the small drop allowed to slide down a short distance, and so on.

Most organic solvents wet the glass and slide down the tube with ease, but with water, especially in narrow tubes, the drop descends very slowly or not at all. This difficulty can be overcome by previously wetting the tube with the first solution to be employed. The drops can also be sucked into the tube by heating the free end and then closing it with the finger. The air, on cooling, contracts, and the drop is forced in.

For the sake of uniformity, I always use tubes with 7 drops; when sealed, the tubes have the following appearance (natural size):

FIG. 1.

*A* is the end which has been dipped in the various solutions.

*B* is the end which is closed by the finger.

In the diagram, the drops are numbered in the order in which they have entered the tube, and the drops of the standard solution are shaded black. The first and last drops are about 5 mm. long, and are not measured, for they generally decrease by evaporation

into the air-spaces at *A* and *B*. They are also the ones most liable to become heated while sealing the tube; for this reason, they are made rather large, in order that their concentration may not so easily be changed by evaporation. The drops 2, 4, and 6 contain the substance the molecular weight of which is being determined.

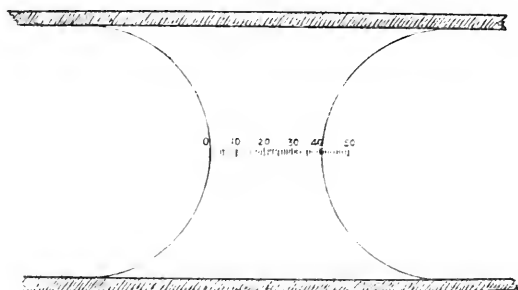

To ensure a rapid interchange of vapour with small differences of concentration, the drops should be close together—say 2 or 3 millimetres apart—but they must not be too close, or they will mix. The thickness of the drops 2—6 is limited by the size of the micrometer scale. Thicker drops can be measured with a lower objective, but then the measurements are, of course, less accurate. With a little practice, drops of the right thickness can easily be obtained. Water gives some difficulty on account of its high surface tension. If too much liquid has been sucked up, the excess can always be removed by means of filter paper. With some heavy liquids in wide tubes, the capillary rise is not great enough, in which case the end of the tube is dipped well under the surface of the liquid, and the pressure of the finger on the other end is slightly diminished until the right quantity of liquid has entered. The same procedure is sometimes necessary with very volatile solvents, the vapour of which may expand by the warmth of the hand, and so tend to drive out drops which have already entered.

When all the drops are in the tube, they are allowed to slide down until the last drop is about 1 cm. distant from the end *A*, and then this end is sealed carefully in the lower part of a small Bunsen flame, and withdrawn immediately. With volatile solvents (acetone, carbon disulphide, &c.), it is advisable to let the last drop get more than 1 cm. from the end *A* before sealing, but there is an objection to letting the drops slide so far down the tube, as will be seen later. Tubes with volatile liquids are best closed by means of soft paraffin wax, at least at the end *A*. A plug of the wax is introduced, and then, by gently warming the end of the tube, it is melted, so as to become air-tight on solidification. The end *B* may be closed by ordinary sealing, or by warming it and letting it suck up a little melted wax while cooling. The wax constitutes a slight source of error, because it attracts some of the solvent from the terminal drops, especially if the experiment lasts a long time. As these end drops are, however, especially long, no great change in their concentration need be feared. Instead of paraffin wax, fusible metal may be used, preferably d'Arcet's alloy with mercury, which melts at 45°. The difficulty here is in getting the alloy into the ends of the tube, owing to the negative capillarity of metals. It can perhaps best be accomplished by means of another thinner capillary, which is dipped into the melted alloy, and then, with some of the metal adhering, it is used to plug up the larger tube.

After the tubes have been filled, the drops are measured. For ease in handling and for purposes of identification, they are fixed to a microscope slide (3" by 1") by means of thick Canada balsam. Each slide is numbered and can take at least half a dozen tubes. The slides are placed in a glass Petri dish about  $3\frac{1}{2}$ " square, and enough water is placed in the dish to cover the tubes, so that the drops are always at the same temperature, and do not move owing to the expansion of the air between them.

Under the microscope, the drops and scale present the following appearance :

FIG. 2.

A sharp image is obtained if the microscope is focussed to the level of the centre of the tube. The menisci then become exceedingly distinct, and the distance between them (which is the minimum thickness of the drop) can be measured. The Petri dish is moved till one of the menisci almost coincides with the zero of the scale; a drop of water between the stage and the dish allows the latter to be moved small distances without jerking. The exact coincidence of the meniscus with the zero is obtained by moving the eye-piece (with the scale in it) transversely in the tube of the microscope, in which it has a little play. As we are only concerned with the *direction* of the change in the drops, not with its *magnitude*, the scale need not be standardised. The distance between the menisci can now be read off to tenths of a scale division. As the micrometer has 50 divisions, 5 numbers below 500 are obtained for each tube. I use a  $\frac{3}{4}$ " objective (Leitz, No. 3); with a lower one, larger drops can be measured on the scale, but the accuracy is correspondingly decreased. With higher objectives, the drops have to be inconveniently small, and the focussing also becomes difficult. The eye-piece should be a strong one, in order to magnify the scale as much as possible. I use a Leitz No. 4 eye-piece; a Zeiss micrometer disc is placed on its diaphragm. With a No. 3 objective, the magnification is about 65 diameters, so that a scale division is equivalent to  $17\ \mu$ , and an accuracy of  $3\ \mu$  is easily obtained.

The time during which the tubes have to be kept before a definite result is obtained varies greatly with the nature of the solvent, the difference in concentration of the solutions, &c.

The changes in the various drops of the same tube are by no means regular. Sometimes all the drops increase if the difference in concentration between them is small. The reason for this is that in filling the tube some of the solution adheres to its walls. This solution forms a dew of minute, convex drops, whereas the large drops, which are measured, have a concave surface. Now, other things being equal, the vapour pressure of a convex surface is greater than that of a concave one (Lehmann: *Molecularphysik*, vol. ii, p. 151). Hence the general tendency of the drops is to increase, and this limits the sensitiveness of the method. If the difference in concentration between the two solutions employed is not very small, the drops of one solution increase much more than those of the other solution, and often, if the tube be kept long enough, the drops which increase least will afterwards decrease.

This initial increase of all drops and subsequent decrease of some is illustrated by the following tube: azobenzene (0.19 mol.) and ethyl benzoate (0.20 mol.) in benzene:

Time.	Readings in tenths of scale divisions.				
12.15 p.m. ....	321	264	289	279	215
2.15 p.m. ....	325	272	292	297	214
5.30 p.m. ....	321	289	286	310	210

As already mentioned, solvents with very high boiling points cannot be used, because the change in the drops occurs too slowly. Theoretically, there is no good reason why tubes should not be kept for an indefinitely long time, so that even the smallest difference of vapour pressure might be demonstrated. In practice, I find, however, that when the difference between the two solutions is small, or when the solvent is insufficiently volatile, the changes in the drops are irregular.

The possibility of keeping tubes at temperatures other than the ordinary naturally suggests itself in this connection. I hoped by this means to apply the method to all high boiling solvents, but my experiments so far have not been successful. The difficulty arises from the necessity of cooling the tubes again before measuring. By cooling, the air spaces between the drops become super-saturated, and the solvent is condensed on the walls of the tube, which, being on the outside, are coldest. Hence, generally, all the drops are smaller than before they were heated.

If the tubes have not been heated too much and if they have been

cooled slowly (for instance, immersed in a large water-bath), good results may nevertheless be obtained. I have kept tubes with water or with acetic acid at a temperature of  $37^{\circ}$ , and in this way the change in the drops is more rapid than at the ordinary temperature. The temperature of the determination can therefore be varied within certain limits ; possibly this may be of use in studying the change of molecular weight with the temperature, for example, of substances which undergo association.

### *Consideration of the Probable Errors.*

The effect of the various manipulations on the accuracy of the method will now be considered. Solutions can be prepared, the concentration of which is accurately known. The only difficulty arises when the supply of the substance is very limited. Through frequent use, the concentration of a solution may gradually undergo a change, for while a tube is being filled, the bottle containing the solution is left open. If the solvent is volatile, it may evaporate ; if hygroscopic, it may attract water from the air ; in the first case, the vapour pressure of the solution will always be lowered ; in the second case, it will only be lowered with low boiling solvents (acetone, alcohol).

If accuracy is desired, it is advisable, after an approximate value has been found, to repeat the last steps in the determination with freshly prepared solutions.

The error due to increased concentration of the solution can be overcome by weighing the residue left on evaporating a small quantity of the solution. This is most easily done with volatile solvents, where it is at the same time of most importance. For the ordinary determinations in this paper, no such special precautions were taken, and the same standard solutions generally served for all the work with a given solvent. The principal object was to find a short and easy method of wide application, not necessarily a very accurate one.

The errors produced in filling the capillaries are as follows. Each drop remains for a moment at the end of the tube before it slides down and is placed between the drops of the other liquid. During this short time, it is exposed to the same influences as the solutions in an open bottle. It may evaporate and absorb moisture ; it presents a relatively large surface to the air, and so may change its vapour pressure. The time of exposure is, however, very short, and may be made approximately equal for the drops of both solutions. The two errors will then balance each other, as we are only concerned with the difference between the two solutions.

Some experiments were performed to study this source of error,

choosing acetone as solvent, because it is both volatile and hygroscopic.

Normal tube, both series of drops composed of benzil in acetone, 0.10 mole,\* and all exposed for 2—3 seconds.

3.21 p.m. ....	347	310	346	283	491
3.37 p.m. ....	351	312	345	290	490
4.3 p.m. ....	357	318	342	298	492

A similar tube, but with the 2nd, 4th, and 6th drops exposed for 10 seconds (the 1st and 7th drops were not measured).

	+	-	+	-	+
3.21 p.m. ....	349	401	366	330	388
3.37 p.m. ....	353	400	371	331	391
4.3 p.m. ....	367	392	382	326	396

It will be seen that whereas the first tube gives no clear result (theoretically, the drops ought not to change at all), the second tube shows that those drops which were exposed for 10 seconds have become distinctly more concentrated than the others.

To get an idea of the amount of concentration, two different solutions of benzil in acetone (strengths 0.09 and 0.10 mole.) were next used.

1. Normal tube, 0.10 benzil as standard (that is, drops 1, 3, 5, 7).

	-	+	-	+	-
11.59 a.m. ....	422	509	491	414	478
12.09 p.m. ....	420	510	488	416	476
12.57 p.m. ....	416	520	478	421	471

2. A similar tube with drops of 0.09 mole. exposed for 5 seconds.

	-	+	-	+	-
1.6 p.m. ....	346	392	331	394	328
1.16 p.m. ....	346	396	331	400	324
1.55 p.m. ....	342	402	330	412	336

3. Same as above, but drops of 0.09 mole. exposed for 10 seconds.

	-	+	-	+	-
11.59 a.m. ....	251	236	246	217	241
12.10 p.m. ....	250	240	250	220	246
12.57 p.m. ....	251	250	248	222	250

\* Throughout this paper the term "mole." signifies a concentration of one gram-molecule per litre.

4. Same as before, but drops of 0.09 mole. exposed for 15 seconds.

1.6 p.m. ....	249	341	222	269	165
1.16 p.m. ....	253	341	224	269	176
1.55 p.m. ....	258	349	225	275	193

From these experiments, it would appear that by an exposure of a quarter of a minute a change of something like 10 per cent. is produced in the concentration of an acetone drop, for only the last tube of the series does not clearly indicate which solution is the stronger. As this time is far in excess of the ordinary differences which occur in filling a tube, the error can only be a slight one. At the same time, it may be one of the reasons for the occasional irregular behaviour of drops in the tube. Sometimes (when the difference between the two solutions is small) there is no regular alternation of increase and decrease, so that no conclusion can be drawn. In that case, the experiment must be repeated.

We now come to the chief interference with the concentration of the drops, namely, their *mixing* with one another. Each drop, as it slides down the tube, leaves a portion of itself behind on the walls. This is shown (in a dry tube) by the decrease of the first drop. The succeeding ones travel over a part which has already been wetted, so they retain their original thickness. As each drop is composed of a different solution from its predecessor, it becomes to some extent mixed with the other solution. That this is so can be easily shown by alternately using a colourless and a coloured solution. For instance, with a potassium permanganate solution and pure water all the drops become pink or red, and the only difference between them is in the intensity of their colour. By making the drops slide up and down the tube a number of times, the mixing becomes more complete, and the difference in their colour disappears.

At first sight, this might seem to be a fatal objection to the method, but such, however, is not the case. The mixing which takes place lessens the difference in concentration between the two series of drops. It cannot, however, obliterate this difference, still less produce a difference in the opposite direction, and the method is only concerned with the *direction* of the difference, not with its *absolute magnitude*. To return to the permanganate solution and water: the drops which were originally composed of pure water will become dilute permanganate solutions; they can never be more concentrated than the other original permanganate drops. Even if an infinite amount of water were added to one drop of permanganate, the resulting mixture would never be pure water.

A difference must, therefore, always remain, and it must remain on

the same side as between the original solutions employed; if we can observe any regular changes in the drops, we shall be able to conclude which solution has the greater vapour pressure.

Although the mixing of the drops does not impair the reliability of the method, it makes it less sensitive. The rate of change depends on the difference between the concentration of the drops, and this difference is decreased by mixing. The mixing should therefore be reduced to a minimum, and it may be useful to consider what conditions will tend to make it so.

Firstly, the amount of liquid which adheres to the walls of the tube varies with the nature of the solution, and seems to depend on its viscosity as well as on its surface tension.

Secondly, the amount of mixing depends on the diameter of the tube. Suppose this diameter to be  $2r$  and the average thickness of the film of liquid which adheres to the walls of the tubes to be  $\delta$  (depending on the nature of the liquid), then, if the drop travel along the tube for a distance  $l$ , it will have lost  $2\pi r\delta l$  (supposing  $\delta$  to be small compared with  $r$ ). If the average thickness of the drop be  $d$ , its volume will be  $\pi r^2 d$ . The proportional loss will be  $\frac{2\pi r\delta l}{\pi r^2 d} = \frac{2\delta l}{rd}$ , and this will approximately represent the amount of mixing. In order to reduce this to a minimum,  $l$  should be small,  $d$  and  $r$  should be large;  $\delta$  is presumably a constant for a given liquid.

1.  $l$  should be small; this means that the drops should slide along as short a piece of the tube as possible.

The distances of each drop from the end of the tube by which it was admitted should be a minimum; the drops must, therefore, be close together, yet not so close that they come into contact and mix. The end drop must be near the entrance of the tube, yet not too close lest it becomes heated when the tube is sealed.

2. The thickness of the drop should be the greatest which can still be measured on the micrometer scale (except in the case of the first and last drops).

3. The tube should be fairly wide, yet sufficiently narrow to allow of the formation of stable drops by surface tension.

It is easy to show that the above general conditions are correct by comparing the behaviour of a coloured and a colourless solution in tubes of widely different bore. Iodine in chloroform and pure chloroform were used for this purpose. The extent of the mixing is indicated by the difference in shade of the two solutions after they have been made to slide up and down the tube a number of times. The difference between the drops sooner becomes imperceptible in the narrow capillary than in the wide one. In the same way, the influence of  $l$  and of  $d$  can be shown.

There is yet another reason why the drops should be close together; their proximity favours the rapid interchange of vapour. This may be inferred from the experiments of Stefan (*Sitzungsber. Wiener Akad.*, 1873, 68, 385) on the rate of evaporation in vertical capillaries. The rate is inversely proportional to the distance of the liquid surface in the tube to the mouth of the tube, and a similar law probably applies to the drops.

It may be asked whether the thin film of liquid which adheres to the walls of the tube does not constitute a permanent means of communication between neighbouring drops. In practice, no such interchange was ever detected (unless the drops actually touch each other). This is probably because the thin layer of liquid sticking to the side of the tube soon breaks up into a number of convex drops, which tend to disappear (as the vapour tension of a convex surface is greater than that of a concave one). Oily liquids which wet the glass with difficulty (ethylene dibromide, aniline) do not leave a uniform film adhering to the walls of the tubes, but a few relatively large drops, which makes it less convenient to work with these liquids.

The next possible source of error is in the closing of the tube. In most cases, the simplest plan is to seal it by holding the end in the lower part of a Bunsen flame. The flame should be steady and the tube should be removed from it as soon as it is completely sealed. The drops nearest the flame are liable to become slightly heated by this process, but the heating only lasts a very short time, so that no appreciable effect can be observed. With liquids such as ether and carbon disulphide and with chloroform (which seems to attack the glass), I prefer to close the tube with melted paraffin wax. In these cases, the heating effect is negligible, but a different error is introduced, because the paraffin wax attracts the organic solvent from the end drop and so gradually concentrates the latter. The end drop is, however, very large, in order that its concentration should only change slowly, whereas with volatile solvents, the change in the measured drops takes place very quickly, before the error due to the paraffin has time to make itself felt. The large size of the end drop is, of course, also useful in counteracting the error due to heating.

Occasionally the tube may turn out to be imperfectly closed; this is at once detected when the tube is measured under water by the movement of the drops and the entrance of the water. In that case, another tube had better be prepared.

In handling the tubes, they must not be jerked or dropped, for this produces sudden and irregular changes in the drops. If the tube is inconveniently long, it must not be scratched with a file, but a piece can be drawn off in a Bunsen flame.

The last error to be considered is the change in the shape of the

drops. The method presupposes that any change in the least diameter (that is, the distance measured) is accompanied by a corresponding change in the volume of the drop. Hence the curvature of the meniscus must remain the same.

This is invariably the case with nearly all organic solvents, but occasionally with water and some less volatile liquids the curvature changes, especially on one side of the drop and if the tube is not quite clean. It does not necessarily follow that the apparent change in the drops is in opposite direction to the real one, but they may become quite out of proportion. This change in the curvature of the meniscus is of rare occurrence and need only be considered with a few solvents; it can, moreover, be readily detected.

#### *Attempted Improvements and Applications of the Method.*

As was said in a previous section, the method only depends on knowing the direction of change in the drops (whether increase or decrease), not the amount of this change. Theoretically, if all the conditions were known, it should be possible to calculate the amount of this change, or, conversely, calculate at once from any observed change the difference in molecular concentration between the drops. It should, moreover, be possible to find the concentration of the unknown solution by interpolation, knowing its behaviour to two known solutions.

A good deal of time was spent in experimenting in this direction, with scarcely any result. The chief aim was to know the influence of the difference in concentration of the drops on their rate of change, the other conditions being kept constant.

To eliminate the variations in the diameter, pieces of thermometer tubing of uniform bore were used. The drops were placed at approximately equal distances from one another. All the solutions contained the same solute, and differed only in strength. The temperature was kept constant, and a special method of filling the tubes with capillary syringes was used in order to prevent mixing. The tubes were closed with wax.

Another attempt to study the change in the drops quantitatively was to use capillary tubes of about 6—10 mm. long, which were slightly constricted in the middle, so that they would, at this point, retain by capillarity a measured drop of a solution. These tubes were put horizontally into a Petri dish filled with distilled water without being sealed. In this way, mixing was excluded, as in the previous plan. These experiments did not even show a constant rate of change when all the known conditions were constant. The only

general statements which can be made about this rate of change in the drops is that it increases with the temperature, with the difference in concentration and with the proximity of the drops, and that the influence of the diameter of the tube is doubtful.

There are a few special problems which might perhaps be solved by the present method, such as the ionisation of salts in mixtures of an ionising with a non-ionising solvent. Similarly, the method may be used in studying association in mixtures of associative and a non-associative solvent (for example, alcohol and benzene). Some preliminary experiments on this are given at the end of the paper.

So far, I have mainly devoted myself to showing that the new method is reliable, widely applicable, and sufficiently accurate to be of real practical use in organic chemistry.

### *Results.*

The value of a new quantitative method can only be proved by the results obtained with it; a large number of determinations with various solvents have therefore been made.

In the experimental records, I have not only mentioned in each case the strength of the two standard solutions—the one hypertonic, the other hypotonic to the unknown solution—but the actual changes which were observed in the drops are also given. In this way, the personal factor has been eliminated.

In order to illustrate the degree of sensitiveness, and by way of showing the accuracy obtainable in the micrometer readings, some measurements are first given with different urea solutions in 90 per cent. alcohol.

The changes in the drops of the foregoing three tubes are very slight, yet they are so regular as to show the great accuracy of the measurements. The tables illustrate a further point: the drops on the right hand side, that is, those which have travelled furthest up the tube and have the greatest chance of becoming mixed, show, generally, a smaller rate of change than the other drops on the left. For this reason, I have confined myself to five measured drops. The first and the last drop in each tube, as seen in the preceding tables, do not behave in a regular manner. Therefore, the five above-mentioned drops were enclosed between two large ones which were not measured.

To economise space, in all further cases the *change* in the drops is alone recorded, not their actual measurement. For the same reason, the changes for those standard solutions which were most nearly isotonic with the unknown solution are alone given. By way of example, other concentrations of the standard solution have been included in the case of the first two determinations (glucose and mannitol in water). With these exceptions, therefore, only those tubes have been included which have the slowest rate of change. All the other tubes gave results more quickly on account of the greater difference between the two solutions contained in them.

*Water.**Glucose*, 25.02 grams per litre (0.139 mole.).

Cane sugar	0.05 mole.	18 hours	+230	-97	+71	-79	+71	+548
"	"	0.10 "	18 "	+26	-18	+25	-31	+130

"	"	0.25 "	25 mins.	-3	+2	+1	+3	+1
		18 hours	-75	+85	-81	+65	-78	-384

In the above and all subsequent tables of measurements, the first column gives the concentration of the standard solution, the second that of the time from the beginning of the experiment (where several times are given with one concentration, these times all apply to the same tube). The next column gives the changes observed during that time in five drops. The figures denote tenths of a micrometer scale division. As has already been said in the description of the method, the first, third, and fifth of these drops contain the substance the molecular weight of which is being determined (glucose in this case). The other two are composed of the standard solution, and in addition the whole series of five are enclosed between two large drops of the standard solution which are not measured. In the last column is shown the change between the aggregate thickness of the three glucose drops and that of the two cane sugar drops (in a period of about 20 hours). These figures show at once that the glucose solution is somewhere between 0.13 and 0.14 mole. They also show that the rate of change in the drops is greatly influenced by the difference between their concentrations.

Assuming the molecular weight of cane sugar to be 342, we have now for glucose  $M$  between  $\frac{25.02}{0.14}$  and  $\frac{25.02}{0.13}$ .

$M$  between 179—192. Mean 186;  $C_6H_{12}O_6$  requires 180.

*Mannitol*, 15·69 grams per litre (0·0862 mole.).

Cane sugar	0·064 mole.	24 hours	+5	-7	+4	-7	+10	+33
"	"	0·072 "	24 "	+4	-4	+3	-2	+3
"	"	48 "	+7	-5	+5	-5	+10	+16

$\alpha$ -Naphthol	0.17 mole.	90 mins.	+4	0	+8	-4	+5
„	0.19 „	110 „	-8	+20	-17	+31	-19

Molecular weight = 128—143 ;  $C_8H_9ON$  requires 135.

*Diphenylamine*, 30.42 grams per litre (0.18 mole.).

$\alpha$ -Naphthol	0.17 mole.	60 mins.	+11	-7	+13	-9	+8
„	0.19 „	125 „	0	+7	-7	+6	+1

Molecular weight = 160—178 ;  $C_{12}H_{11}N$  requires 169.

The error in the preceding ten determinations in no case exceeds 5 per cent., but a greater deviation from the theoretical value was found with the following substances: hippuric acid, diphenyl, dinitrobenzene, and urea. These all gave values which were more than 10 per cent. too high as compared with  $\alpha$ -naphthol in absolute alcohol.

It was repeatedly found that the molecular weight of urea was too high as compared with other substances. Urea is therefore not a good standard. This is further illustrated by the first of the following three determinations, all of which were carried out in 90 per cent. of methylated spirit.

*Urea as Standard ; 90 per cent. Alcohol.**Phenyl Salicylate*, 38.52 grams per litre (0.18 mole.).

Urea 0.18 mole.	20 hours	0	-6	+12	-10	+18
„ 0.19 „	2 „	-2	+2	0	0	-3
„ 0.20 „	2 „	-2	+6	-1	+5	-7

The change with 0.19 mole. is not very decisive. The phenyl salicylate solution gives values between 0.18 and 0.20 mole. (probably between 0.18 and 0.19). Taking the values 0.18 and 0.20, we get :

Molecular weight = 193—214 ;  $C_{13}H_{10}O_3$  requires 213.

*Phenyl Salicylate as Standard ; 90 per cent. Alcohol.**Azobenzene*, 29.12 grams per litre (0.16 mole.).

Phenyl salicylate 0.15 mole.	130 mins.	+8	-3	+21	+2	+5
„ 0.16 „	90 „	-13	+23	-13	+7	-27

Molecular weight of azobenzene = 182—194 ;  $C_{12}H_{10}N_2$  requires 182.

*Benzil*, 23.10 grams per litre (0.11 mole.).

Phenyl salicylate 0.115 mole.	70 mins.	+20	-19	+18	-40	-1
„ 0.12 „	120 „	-6	+7	-10	+6	-5

Molecular weight of benzil = 193—201 ;  $C_{14}H_{10}O_2$  requires 210.

*Acetone.*

The acetone used for all the experiments contained water and boiled between 56.7° and 65°. Various substances were used as standard.

*With Phenyl Salicylate as Standard.**Salicylic Acid*, 27.40 grams per litre.

Phenyl salicylate 0.18 mole.	35 mins.	+12	-10	+15	-26	+31
„ 0.19 „	20 „	-7	+7	-10	+12	-1

Molecular weight = 124—131, mean 127 ;  $C_7H_6O_3$  requires 138.

*Picric Acid*, 45.80 grams per litre.

Phenyl salicylate 0.20 mole.	11 mins.	+11	-7	+8	-11	+17
„ 0.21 „	48 „	-3	0	-6	+5	-14

Molecular weight = 217—229, mean 223 ;  $C_6H_3O_7N_3$  requires 229.

*Benzil*, 42.00 grams per litre.

Phenyl salicylate	0.20 mole.	22 mins.	+54	-76	+93	-71	+75
,,	0.21	,, 15	-8	+71	-67	+88	-47

Molecular weight = 200—210, mean 205 ;  $C_{14}H_{10}O_2$  requires 210.

*Phenol*, 18.8 grams per litre.

Phenyl salicylate	0.17 mole.	40 mins.	+6	0	+6	-2	+6
,,	0.18	,, 30	-8	+24	-22	+29	-14

Molecular weight = 103—111, mean 107 ;  $C_6H_6O$  requires 94.

*With Salicylic Acid as Standard.*

*Phenol*, 18.8 grams per litre.

Salicylic acid	0.16 mole.	20 mins.	+48	-12	+3	-2	+11
,,	0.17	,, 20	-21	+75	-48	+27	-21

Molecular weight = 111—119, mean 115 ;  $C_6H_6O$  requires 94.

The two values for phenol are a good deal too high. This is because the vapour pressure of phenol is not negligible at the ordinary temperature. To further illustrate this point, I made some determinations with aniline as standard. Although two substances having approximately the same boiling point need not have nearly the same vapour pressure at the ordinary temperature, yet the boiling point gives a general indication as to the volatility of the substance.

*With Aniline as Standard.*

*Phenol*, 18.8 grams per litre.

Aniline	0.19 mole.	80 mins.	+22	-3	+16	-19	0
,,	0.20	,, 120	-4	+14	+1	+5	-14

Molecular weight = 94—99, mean 97 ;  $C_6H_6O$  requires 94.

*Nitrobenzene*, 24.6 grams per litre.

Aniline	0.19 mole.	25 mins.	+2	-5	+16	-15	+2
,,	0.20	,, 25	-13	+1	-13	+17	-21

Molecular weight = 117—123, mean 120 ;  $C_6H_5O_2N$  requires 123.

*Ethyl Benzoate*, 30.00 grams per litre.

Aniline 0.19 mole.	50 mins.	+30	-2	+7	-11	+10
„ 0.20 „	20 „	-5	0	-5	+2	-5

Molecular weight = 143—150, mean 146;  $C_9H_{10}O_2$  requires 150.

The last three determinations give good results. The boiling points of phenol, nitrobenzene, and ethyl benzoate are close to that of aniline. With the same standard, the molecular weight of a considerably less volatile substance is found to be too low.

*Phenyl Salicylate*, 38.52 grams per litre (0.18 mole.).

Aniline 0.21 mole.	60 mins.	0	-30	+70	-92	+175
„ 0.22 „	—	-6	+12	-7	+2	-11

Molecular weight = 175—182, mean 178;  $C_{13}H_{10}O_3$  requires 214.

In the same way, the molecular weights of salicylic acid and of catechol are found to be more than 10 per cent. too low when these substances are compared with aniline. Conversely, for camphor and phenetole, which are more volatile, values are found which are a good deal too high.

As a last example of a determination in acetone solution, I give that of a new substance kindly given me by Dr. Ruhemann (Trans., 1903, 84, 1133).

*Dimethoxybisketocoumaran*.

Owing to the small quantity available (0.04 gram) the process was slightly modified. The strength of the solution of the substance was determined after it had been rendered isotonic with a solution of benzil.

1.0415 grams of the solution left a residue of 0.0315 gram of the substance. The density of the acetone was 0.794; hence the volume of this solution was 1.312 c.c. and the solution contained 24.01 grams per litre.

The following readings were obtained :

With benzil, 0.0775 mole.	23 mins.	+9	-7	+31	-19	+19
„ 0.080 „	30 „	0	+4	0	+4	-3
„ 0.0825 „	13 „	-4	+13	-3	+7	-8

The solution of the new substance was therefore between 0.0775 and 0.080 mole.

Taking 0.0775 as the value, we get  $M = \frac{24.01}{0.0775} = 309$ .  $C_{18}H_{14}O_6$  requires 326.

*Acetic Acid.*

Glacial acetic acid was used, with benzil as standard substance.

*Acetanilide*, 18.90 grams per litre (0.14 mole.).

Benzil	0.135 mole.	23 hours	+45	-68	+95	-105	+160
„	0.145 „	23 „	-10	+36	-20	+12	-89

Molecular weight = 130—138, mean 134;  $C_8H_9ON$  requires 135.

*Triphenylmethane*, 34.16 grams per litre (0.14 mole.).

Benzil	0.135 mole.	45 hours	0	-9	+2	-3	+5
„	0.145 „	21 „	-58	+30	-30	+29	-31

Molecular weight = 236—253, mean 245;  $C_{19}H_{16}$  requires 244.

*Picric Acid*, 27.48 grams per litre (0.12 mole.).

Benzil	0.115 mole.	19 hours	+10	-4	+23	-6	+7
„	0.12 „	19 „	-16	+21	-31	+37	-10

Molecular weight = 229—239, mean 234;  $C_6H_3O_7N_3$  requires 229.

*Diphenyl*, 21.56 grams per litre (0.14 mole.).

Benzil	0.10 mole.	17 hours	+10	-4	+23	-6	+7
„	0.11 „	21 „	-16	+21	-31	+37	-10

Molecular weight = 196—216, mean 206;  $C_{12}H_{10}$  requires 154.

The last of these determinations was repeated, but the same high value was found, this inaccuracy differing markedly from the exact results obtained in the three preceding examples.

The following is an example of a determination in a mixed solvent namely, 80 per cent. acetic acid, 20 per cent. water:

*Acetanilide*, 29.83 grams per litre.

Urea	0.20 mole.	17 hours	+6	+1	+12	-3	+5
„	0.208 „	17 „	-4	+24	-6	+8	-1

Molecular weight = 143—147, mean 145;  $C_8H_9ON$  requires 135.

*Benzene.*

In all the experiments except the last, azobenzene was used as standard substance; in this case, it was benzil.

*Benzil*, 42·00 grams per litre (0·20 mole.).

Azobenzene	0·19 mole.	4 hours	+ 4	- 9	- 2	- 6	+ 7
„	0·21 „	30 mins.	- 13	+ 5	- 8	+ 11	- 3

Molecular weight = 200—221;  $C_{14}H_{10}O_2$  requires 210.

*Diphenyl*, 30·80 grams per litre (0·20 mole.).

Azobenzene	0·19 mole.	100 mins.	+ 7	- 2	+ 5	+ 3	+ 10
„	0·20 „	18 hours	- 32	+ 11	- 20	- 2	- 13

Molecular weight = 154—162, mean 158;  $C_{12}H_{10}$  requires 154.

*Triphenylmethane*, 48·80 grams per litre (0·20 mole.).

Azobenzene	0·20 mole.	30 mins.	+ 4	- 10	0	0	+ 3
„	0·215 „	3 hours	- 2	+ 9	- 8	+ 4	- 2

Molecular weight = 227—244, mean 235;  $C_{19}H_{16}$  requires 244.

*Diphenylamine*, 33·80 grams per litre (0·20 mole.).

Azobenzene	0·19 mole.	100 mins.	+ 3	0	+ 4	+ 1	+ 4
„	0·21 „	100 „	- 1	+ 6	- 4	+ 3	0

(With 0·20 mole., no definite result could be obtained.)

Molecular weight = 161—177;  $C_{12}H_{11}N$  requires 169.

*$\alpha$ -Nitronaphthalene*, 34·60 grams per litre (0·20 mole.).

Azobenzene	0·18 mole.	75 mins.	+ 9	- 7	+ 1	- 3	+ 1
„	0·20 „	5 hours	- 10	- 2	- 13	+ 8	- 12

(With 0·19 mole., no definite result could be obtained.)

Molecular weight = 173—192, mean 183;  $C_{10}H_7O_2N$  requires 173.

*m-Dinitrobenzene*, 32·26 grams per litre (0·192 mole.).

Azobenzene	0·18 mole.	75 mins.	+ 7	0	- 2	- 4	+ 6
„	0·19 „	2 hours	+ 1	0	- 21	+ 3	- 4

Molecular weight = 170—179, mean 175;  $C_6H_4O_4N_2$  requires 168.

*Ethyl Benzoate*, 30·00 grams per litre (0·20 mole.).

Azobenzene	0·18 mole.	70 mins.	+ 16	0	+ 5	- 2	+ 7
„	0·19 „	5 hours	0	+ 25	- 3	+ 31	- 5

Molecular weight = 158—167, mean 162;  $C_9H_{10}O_2$  requires 150.

Ethyl benzoate is slightly volatile; phenetole is still more so, and accordingly gives a higher molecular weight.

*Phenetole*, 23.42 grams per litre (0.192 mole.).

Azobenzene	0.16 mole.	40 mins.	+12	-1	+5	+1	+12
„	0.17 „	150 „	-9	+16	-1	+40	-14

Molecular weight = 138—146, mean 142;  $C_8H_{10}O$  requires 122.

*Triphenylguanidine*, 28.70 grams per litre (0.10 mole.).

Azobenzene	0.09 mole.	65 mins.	+53	-2	+8	-8	+1
„	0.10 „	130 „	-7	+9	-1	+6	-3

Molecular weight = 287—319, mean 303;  $C_{19}H_{17}N_3$  requires 287.

The following acids show association in benzene solution :

*Benzoic Acid*, 24.40 grams per litre (0.20 mole.).

Azobenzene	0.10 mole.	85 mins.	+6	-3	+3	-1	+2
„	0.11 „	70 „	0	+6	-4	+1	0

Molecular weight = 222—244, mean 233;  $C_7H_6O_2$  requires 122.

*Cinnamic Acid*, 29.60 grams per litre (0.20 mole.).

Azobenzene	0.17 mole.	45 mins.	-31	+27	-22	+20	-27
------------	------------	----------	-----	-----	-----	-----	-----

The change in the drops is a large one in a small time.

The molecular weight is considerably above 174;  $C_9H_8O_2$  requires 148.

*Azobenzene*, 20.02 grams per litre (0.11 mole.).

Benzil	0.10 mole.	4 hours	+12	-44	+18	+5	+17
„	0.12 „	4 „	-15	+13	+2	+22	-1

Molecular weight of azobenzene = 167—200;  $C_{12}H_{10}N_2$  requires 182.

### *Chloroform.*

With chloroform, there was often some difficulty in sealing the tubes; the glass was attacked, and did not fall together very easily. Hence paraffin wax was always used to close the capillaries.

*Phenyl Salicylate as Standard.*

*Benzil*, 42.00 grams per litre (0.20 mole.).

Phenyl salicylate	0.19 mole.	2 hours	+16	-19	+30	-23	+52
„	0.21 „	2 „	-11	+4	-8	+4	-2

Molecular weight = 200—220;  $C_7H_{10}O_2$  requires 210.

*m*-Dinitrobenzene, 33·60 grams per litre (0·20 mole.).

Phenyl salicylate	0·21 mole.	2 hours	+19	-6	+3	-6	+14
„	0·22 „	3 „	-4	+3	-7	+18	-21

Molecular weight = 153—160 ;  $C_6H_4O_4N_2$  requires 168.

*Benzil as Standard.*

*Triphenylmethane*, 24·40 grams per litre (0·10 mole.).

Benzil	0·095 mole.	2 hours	+19	-6	+3	-6	+14
„	0·105 „	3 „	-4	+3	-7	+18	-21

Molecular weight = 232—256 ;  $C_{19}H_{16}$  requires 244.

*Diphenyl*, 15·40 grams per litre (0·10 mole.).

Benzil	0·095 mole.	1 hour	+4	-8	+1	-6	+2
„	0·105 „	1 „	-6	+2	-4	+4	-1

Molecular weight = 146—162 ;  $C_{12}H_{10}$  requires 154.

*Diphenylamine*, 16·90 grams per litre (0·10 mole.).

Benzil	0·09 mole.	10 mins.	+7	+1	+7	+2	+7
„	0·095 „	2 hours	-5	+3	-1	+3	-3

Molecular weight = 178—188 ;  $C_{12}H_{11}N$  requires 169.

*m*-Dinitrobenzene, 16·80 grams per litre (0·10 mole.).

Benzil	0·09 mole.	2 hours	+31	-22	+16	0	+37
„	0·095 „	3 „	-2	+14	-3	+11	-1

Molecular weight = 177—187 ;  $C_6H_4O_4N_2$  requires 168.

*Phenyl Salicylate*, 21·40 grams per litre (0·10 mole.).

Benzil	0·09 mole.	40 mins.	+3	-2	+6	-3	+8
„	0·095 „	2 hours	-8	+5	-1	+6	-5

Molecular weight = 225—238 ;  $C_{13}H_{10}O_3$  requires 214.

$\alpha$ -Nitronaphthalene, 17·30 grams per litre (0·10 mole.).

Benzil	0·09 mole.	90 mins.	+15	-1	+3	0	+6
„	0·10 „	—	-12	+9	-5	+6	-7
„	0·095 „	(gave no distinct result)					

Molecular weight = 173—192 ;  $C_{10}H_7O_2N$  requires 173.

*Caffeine* (anhydrous, dried at  $110^{\circ}$ ), 19.4 grams per litre (0.10 mole.).

Benzil	0.10	mole.	3 hours	+10	-9	+4	-6	+10
„	0.105	„	1 hour	-8	+4	-2	+6	-7

Molecular weight = 185—194;  $C_8H_{10}O_2N_4$  requires 194.

*Caffeine* (with water of crystallisation), 21.2 grams per litre (0.10 mole.).

Benzil	0.105	mole.	2 hours	+6	-4	+28	-12	+28
„	0.11	„	2 „	-3	+4	-1	+2	-1

Molecular weight = 193—202;  $C_8H_{10}O_2N_4 \cdot H_2O$  requires 212.

*Cocaine* (crystalline, dried at  $110^{\circ}$ ), 30.3 grams per litre (0.10 mole.).

Benzil	0.105	mole.	50 mins.	+2	-22	+13	-17	+17
„	0.11	„	—	-6	+9	-6	+5	-10

Molecular weight = 275—289;  $C_{17}H_{21}O_4N$  requires 303.

*Piperine* (air-dried crystals), 28.5 grams per litre (0.10 mole.).

Benzil	0.105	mole.	45 mins.	+14	-8	+16	-2	+2
„	0.11	„	100 „	-2	+10	-5	+4	-4

Molecular weight = 259—271;  $C_{17}H_{19}O_3N$  requires 285.

*Quinine* (precipitated, dried at  $120^{\circ}$ ), 32.4 grams per litre (0.10 mole.).

Benzil	0.09	mole.	50 mins.	+5	-3	+6	-5	+20
„	0.095	„	2 hours	-24	+27	-20	+30	-22

Molecular weight = 341—360;  $C_{20}H_{24}O_2N_2$  requires 324.

### *Phenylbenzylmethylethylammonium Iodide.*

For a specimen of this salt, I am indebted to Mr. H. O. Jones (Trans., 1903, 83, 1419). Two determinations were made.

#### *I. Triphenylmethane as Standard.*

0.0487 gram of the iodide was dissolved in 2 c.c. of chloroform, this being equivalent to 24.35 grams per litre.

Afterwards 2.358 grams of the solution left 0.0370 gram of salt, dried at  $70^{\circ}$ . Density of chloroform = 1.502.

This gives a concentration of  $\frac{37 \times 1.502}{2.358} = 23.6$  grams per litre. Mean concentration = 23.9 grams per litre.

Triphenylmethane	0.07 mole.	30 mins.	+22	-11	+20	-22	+42
„	0.075 „	70 „	+4	+4	+2	+5	+9
„	0.08 „	30 „	-5	+4	-3	+3	-3

Taking the concentration to be 0.075 mole. :  $M = \frac{23.9}{0.075} = 319$ .

## II. Azobenzene as Standard.

0.2008 gram of salt in 8 c.c. = 25.1 grams per litre.

Azobenzene	0.07 mole.	35 mins.	+15	-10	+4	0	+3
„	0.075 „	23 „	-3	+2	-1	0	-5

Mean = 0.725 mole.

$$M = \frac{25.1}{0.0725} = 346 ; \text{C}_{16}\text{H}_{20}\text{NI requires } 353.$$

*α-Phenylbenzylmethylallylammonium Iodide*.—This salt, for a sample of which I am indebted to Mr. H. O. Jones, is of special interest because Wedekind, its discoverer, has recently found that by the ebullioscopic method its molecular weight is one-third of the normal value (*Zeit. physikal. Chem.*, 1903, 46, 235).

## Triphenylmethane as Standard.

0.2771 gram of salt in 4.70 c.c. = 59.0 grams per litre (0.162 mole. theoretically).

Triphenylmethane	0.17 mole.	—	-16	+13	-8	+9	-6
„	0.15 „	70 min.	-1	+9	-3	+3	-4

This was within a few hours of making up the iodide solution. The molecular weight of the salt is greater than the normal value. Next morning, the determination was continued :

Triphenylmethane	0.15 mole.	20 mins.	+6	-1	+3	-2	+5
„	0.17 „	15 „	-1	+4	-1	+5	-5
„	0.155 „	1 hour	+10	-4	+3	-5	+15

Taking the numbers 0.155 and 0.17 (intermediate concentrations giving uncertain results), it was found that the values for the molecular weight ranged between 335 and 381 (mean 358);  $\text{C}_{17}\text{H}_{20}\text{NI}$  requires 365.

A second determination was made.

0.5450 gram of salt in 7.60 c.c. of chloroform = 71.71 grams per litre (0.196 mole.).

Within 2 hours of making up this solution :

Triphenylmethane	0.150 mole.	—	+8	-2	+14	-28	+26
„	0.165 „	35 mins.	-23	+20	-23	+9	-12

Molecular weight = 435—478, mean 457.

The salt is therefore associated, as in the previous determination. The new solution (71.71 grams per litre) was now directly compared with the old one (59.0 grams per litre), which had been made some days previously.

The old solution as standard	7 mins.	-8	+9	-5	+10	-11
------------------------------	---------	----	----	----	-----	-----

The new solution contains, therefore, less molecules. Two days later this had changed :

The old solution as standard	95 mins.	+10	-5	+5	-6	+34
------------------------------	----------	-----	----	----	----	-----

The molecular weight in the new solution had diminished. The following numbers were obtained :

Triphenylmethane	0.21 mole.	7 mins.	-8	0	-2	+7	-2
„	0.238 „	15 „	+18	-1	+2	-1	+21

Molecular weight between 301 and 341, mean 321.

The effect of heat was next tried. The second iodide solution was divided into two parts, one of which was kept overnight at the ordinary temperature, the other at 37°, both in tightly stoppered bottles in the dark. The determinations were made on the following day, the solution which had not been heated being taken as standard :

30 mins.	+22	-16	+17	-9	+15
----------	-----	-----	-----	----	-----

The molecular concentration of the solution has been, therefore, considerably increased by heating. This explains the fall in the molecular weight observed by Wedekind in employing the ebullioscopic method.

#### *Carbon Disulphide.*

Triphenylmethane was used as standard. The other substances were used in solutions of 0.20 mole.

*Azobenzene*, 36.4 grams per litre.

Standard	0.19 mole.	15 mins.	+13	-14	+14	-17	+6
„	0.20 „	100 „	-26	-2	-28	+5	-2

Molecular weight = 182—192, mean 187 ;  $C_{12}H_{10}N_2$  requires 182.

*Diphenyl*, 30·8 grams per litre.

Standard	0·20 mole.	35 mins.	+3	+1	+4	0	+8
„	0·21 „	45 „	-7	+3	-12	0	-32

Molecular weight = 147—154, mean 150;  $C_{12}H_{10}$  requires 154.

*Phenyl Salicylate*, 42·8 grams per litre.

Standard	0·18 mole.	50 mins.	+2	-7	-4	-8	+1
„	0·19 „	—	-15	-11	-19	+6	-30

Molecular weight = 225—238, mean 232;  $C_{13}H_{10}O_3$  requires 214.

*$\alpha$ -Nitronaphthalene*, 34·6 grams per litre.

Standard	0·18 mole.	—	+5	-1	0	+4	+10
„	0·19 „	15 mins.	-18	-2	-30	+7	-16

Molecular weight = 172—192, mean 182;  $C_{10}H_7O_2N$  requires 173.

*Ethyl Benzoate*, 30·0 grams per litre.

Standard	0·19 mole.	25 mins.	+2	-7	0	-12	+2
„	0·20 „	35 „	-14	+17	-6	-1	-7

Molecular weight = 150—158, mean 154;  $C_9H_{10}O_2$  requires 150.

*Phenetole*, 24·4 grams per litre.

Standard	0·18 mole.	15 mins.	+9	-3	+5	-1	+3
„	0·19 „	35 „	-16	+1	-1	+17	0

Molecular weight = 128—136, mean 132;  $C_8H_{10}O$  requires 122.

The behaviour of the last two substances is interesting, since ethyl benzoate is very slightly volatile, and phenetole rather more so. In benzene, for instance, solutions of 0·20 mole. behave as if they were respectively between 0·18 and 0·19 mole. and between 0·16 and 0·17 mole. Carbon disulphide is much more volatile than benzene, so ethyl benzoate and phenetole approach more nearly to the theoretical values. As the latter substance is the more volatile of the two, it gives a greater difference from the theory than the former.

*Benzoic Acid*, 24·4 grams per litre.

Standard	0·10 mole.	30 mins.	+45	-77	+60	-40	+37
„	0·11 „	—	-8	+9	-4	+8	0

Molecular weight = 222—244, mean 233;  $C_7H_6O_2$  requires 122.

*Phenol*, 18.4 grams per litre.

Standard 0.10 mole.	—	+5	+1	+5	+1	+4
„ 0.11 „	12 mins.	-1	+5	-1	+1	-2

Molecular weight = 167—184, mean 180;  $C_6H_6O$  requires 94.

It will be seen that, while ethyl benzoate and phenetole give normal values, the substances with which they are closely connected, namely, benzoic acid and phenol, have almost double the normal molecular weight. This association was to be expected in a non-hydroxylic solvent like carbon disulphide. When the hydrogen of the hydroxyl is replaced by ethyl, the association disappears.

*Sulphur*.

The determination of the molecular weight of sulphur in carbon disulphide gave the following numbers:

Triphenylmethane, 0.14 mole.	14 mins.	+4	-8	+6	-20	+5
„ 0.15 „	35 „	-1	+18	0	+5	-2

After these results had been obtained, the strengths of the standard solutions were checked. Of the solution called 0.15 mole., 5 c.c. left on evaporation 0.2030 gram of triphenylmethane. Its concentration had, therefore, changed during the determination to 0.166 mole., and the other solution, obtained from it by dilution, was in reality 0.155 mole. The mean = 0.160 mole. may be taken to represent the strength of the sulphur solution.

Of this, 1.70 c.c. left on evaporation 0.0738 gram of sulphur, that is, 43.4 grams per litre.

1.00 c.c. left on evaporation 0.0432 grams of sulphur, that is, 43.2 grams per litre.

Mean, 43.3 grams per litre. 0.160 gram-molecules = 43.3.

Molecular weight of sulphur = 270 =  $S_8 - S_9$ .

This is in close agreement with the value previously obtained by E. Beckmann (*Zeit. physikal. Chem.*, 1890, 5, 8) who finds as an average  $S_8 = 256$ .

*Light Petroleum*.

A fraction boiling between 50° and 60° was obtained from ordinary light petroleum by distilling once with a Young's still-head. All the substances were tried at a concentration of 0.10 mole., on account of the sparing solubility of certain of them. Azobenzene was used as standard in all cases.

*Triphenylmethane*, 24·4 grams per litre.

Azobenzene	0·10 mole.	40 mins.	+5	-1	+1	-6	+3
„	0·108 „	25 „	+1	+9	+1	+11	-6

Molecular weight = 226—244, mean 235 ;  $C_{19}H_{16}$  requires 244.

*Diphenyl*, 15·4 grams per litre.

Azobenzene	0·09 mole.	14 mins.	+8	+1	+4	0	+5
„	0·10 „	150 „	-10	+14	-21	+30	+3

Molecular weight = 154—169, mean 162 ;  $C_{12}H_{10}$  requires 154.

*Diphenylamine*, 16·9 grams per litre.

*Ethyl Benzoate*, 15.0 grams per litre.

Azobenzene	0.08 mole.	85 mins.	+29	0	+20	0	+30
,,	0.09	,,	—	-1	+10	-4	+20
							-2

Molecular weight = 167—187, mean 177;  $C_9H_{10}O_2$  requires 150.

As might have been expected, ethyl benzoate gives a result most nearly approaching to the real value, because it is the least volatile of this series. As petroleum is a non-hydroxylic solvent, phenols, acids, &c., are associated in it, and give high values for their molecular weights. This is shown by the following examples:

*Thymol*, 15.0 grams per litre.

Azobenzene	0.07 mole.	30 mins.	+4	-6	+1	-10	-3
,,	0.08	,,	35	,,	-1	+12	-13

,,	0.22 ,	5 ,	-4	+8	-4	+5	0

Molecular weight = 131—136, mean 134 ;  $C_{10}H_8O$  requires 144.

Judging from the comparatively small errors in the values for cinnamic and salicylic acids and for  $\alpha$ -naphthol, the association in pyridine does not seem very marked, which is in accordance with the results obtained by Ross Innes (Trans., 1901, 79, 261).

Abnormal results were obtained for the following : *m*-dinitrobenzene, phenyl salicylate, diphenyl (more than 10 per cent. too high), picric acid, succinic acid, thiocarbanilide (more than 10 per cent. too low).

With azobenzene as standard, the error for *m*-dinitrobenzene and for diphenyl was 5—10 per cent.

*Ether.*

The ether was previously saturated with water to avoid the effect of atmospheric moisture. The tubes were sealed with paraffin wax.

*Diphenyl*, 30.8 gram per litre (0.20 mole.).

Benzil	0.18 mole.	4 mins.	+8	-3	+4	-2	0
„	0.22 „	5 „	0	+5	+1	+8	-2

Molecular weight of diphenyl = 140—171;  $C_{12}H_{10}$  requires 154.

*Quinol*, 22.0 grams per litre (0.20 mole.).

Benzil	0.18 mole.	4 mins.	+5	-3	+2	-2	+26
„	0.22 „	4 „	-10	+1	-3	+5	-4

Molecular weight of quinol = 100—122;  $C_6H_6O_2$  requires 110.

*Xylene.*

*Triphenylmethane*, 51.24 grams per litre (0.21 mole.).

Benzil	0.17 mole.	55 mins.	+15	-6	+1	-3	+1
„	0.223 „	—	-24	+12	-9	+10	-4

Molecular weight of triphenylmethane = 230—301, mean, 265;  $C_{19}H_{16}$  requires 244.

*Association in Mixtures of an Associative and a Non-associative Solvent.*

As the microscopic method is particularly suited for work with mixed solvents, it seems desirable to study with its help the problems of association. The results of some preliminary experiments are here communicated, and although no special attention was paid to accuracy, the values show the general nature of the association in mixtures.

The object in view was to determine the molecular weight of acids, phenols, &c., in mixtures of varying composition of two solvents, the boiling points of which are not very remote, and in one of which the substance has a normal molecular weight, whereas it is associated in the other.

Such pairs of solvents are: ether and carbon disulphide, methyl alcohol and chloroform, ethyl alcohol and benzene, &c. Determinations were carried out with the second and third pairs, using cinnamic and benzoic acids respectively as solutes. In both cases, the concentration

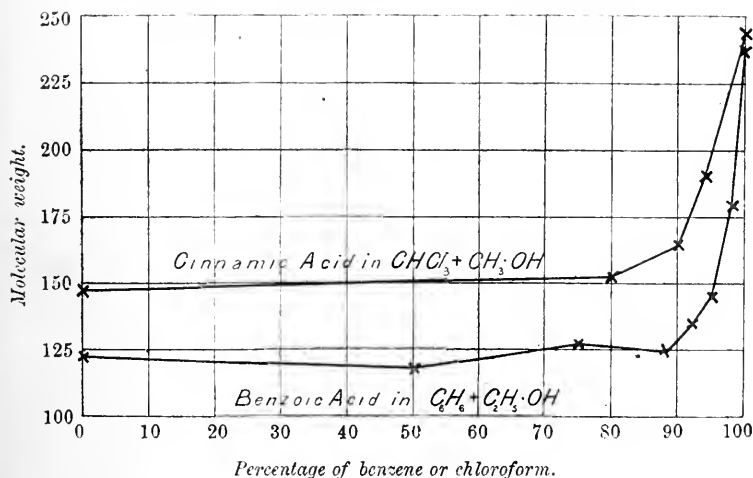

was 0.20 mole., the standard substance was benzil, and the temperature was  $16^{\circ}$ .

Mixtures were made containing the two solvents in known proportion by volume, and with each mixture the cinnamic (or benzoic) acid solution was prepared, together with the necessary benzil solutions.

The molecular weight of cinnamic acid in 100 per cent. methyl alcohol has not been determined, but in ethyl alcohol it was found to be 148.

The values for benzoic acid may be slightly vitiated by its relatively considerable vapour pressure at the ordinary temperature. With the molecular weights as ordinates and the percentage of benzene or chloroform as abscissæ, two curves have been plotted which clearly show that a small proportion of alcohol is sufficient to do away with the association. Should this observation prove to be general, it may be of considerable practical importance in those cases where one is restricted to associative solvents because the substance is not sufficiently soluble in the others. A small percentage of a non-associative solvent would not materially affect the solubility, yet it would reduce the molecular weight to its normal value.

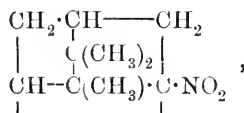

THE WELLCOME PHYSIOLOGICAL RESEARCH LABORATORIES,  
HERNE HILL, S.E.

# XXXVI.—*Studies in the Camphane Series. Part XIII.* *Action of Nitrogen Peroxide on 1-Nitrocamphene*

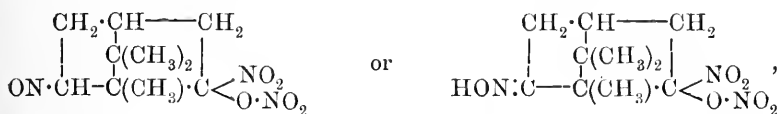

By MARTIN ONSLOW FORSTER and FRANCES MARY GORE MICKLETHWAIT.

IN connection with the study of *isonitrosocamphor*, it seemed probable that an examination of structural isomerides would furnish useful information, and we have therefore attempted to prepare a substance of this class from 1-nitrocamphene, the compound obtained by the action of silver nitrate on 1-bromo-1-nitrocamphane dissolved in alcohol (Forster, *Trans.*, 1901, 79, 644).

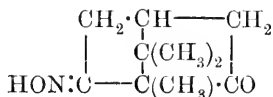

The behaviour of 1-hydroxycamphene towards bromine, which converts it into  $\beta$ -bromocamphor (*Trans.*, 1902, 81, 264), renders it probable that the constitution of 1-nitrocamphene is expressed by the formula

and the fact that this compound readily yields additive derivatives with bromine, hydrogen bromide, and hydrogen iodide led us to hope that nitrogen peroxide would give rise to the nitrosate,

from which on hydrolysis, followed by elimination of nitrous acid, an *isonitrosocamphor* having the constitution

should be formed.

On submitting 1-nitrocamphene to the action of nitrogen peroxide, we obtained a compound having the composition  $\text{C}_{10}\text{H}_{15}\text{O}_6\text{N}_3$ , and therefore containing the elements of  $\text{N}_2\text{O}_4$  in addition to those of the original material. The substance, however, although empirically the nitrosate of 1-nitrocamphene, is not a genuine member of this class, because alcoholic ammonia and piperidine, instead of transforming it into a nitrolamine and a piperidide respectively, convert it into a substance,  $\text{C}_{10}\text{H}_{14}\text{O}_4\text{N}_2$ , identical with the product arising from the limited action of alcoholic potash. Moreover, the high melting point

and sparing solubility of this nitrosate suggest a bimolecular character, but we have no evidence that it belongs to the class of dioxime peroxides. Furthermore, the treatment to which it has been subjected has failed to provide us with the structural isomeride of isonitrosocamphor.

Circumstances having compelled us to interrupt the investigation, and costliness in time and material precluding the likelihood of its being resumed, we confine ourselves to recording the changes which have been observed, without speculating on the constitution of the substances obtained.

*Action of Nitrogen Peroxide on 1-Nitrocamphene.*

The nitrocamphene required for the investigation was prepared by the method already described (Trans., 1901, 79, 646), and on repeating this process 20 or 30 times it was found that when alcoholic silver nitrate acts on 1-bromo-1-nitrocamphane, a certain amount of the silver salt leaves the solution in combination with nitrocamphene. After evaporating off the greater portion of the alcoholic filtrate from the silver bromide, the liquid yielded colourless crystals when left for several hours. This product, when suspended in boiling water, gave a solution of silver nitrate from which highly purified nitrocamphene was obtained by distillation in steam. The circumstances controlling the formation of the substance, however, could not be determined; it was isolated on several occasions, but in more frequent cases the crystalline deposit consisted of the compound of silver nitrate with silver bromide.

The nitrogen peroxide was prepared by heating dry lead nitrate, and was passed into solutions containing 10 grams of nitrocamphene in 50 c.c. of chloroform. The liquid gradually became pale brown, and a rise of temperature occurred; when a considerable amount of gas had been absorbed, the colour became greenish-brown, and at 50° lustrous crystals appeared, and increased rapidly. The passage of the gas was then interrupted, and, after an interval of 12 hours, the intensely green, or bluish-green liquid was filtered. The conditions of this experiment have been considerably varied from time to time with the object of improving the yield, but although the operation has been repeated more than 50 times, we have not succeeded in obtaining the nitrosate in quantities exceeding 24 per cent.

The crude substance is usually stained with blue, which is retained with some persistence. By recrystallisation from boiling alcohol, 100 c.c. of which are required by 1 gram, the substance is obtained in lustrous, snow-white, flattened needles which melt and completely decompose at 217°. The greatest difficulty has been experienced in

obtaining concordant results in the combustion of this compound, owing to the readiness with which nitrous gases are eliminated on heating; whilst the determinations of nitrogen have served to distinguish between the nitrosate and the nitrosite, we cannot claim to have established conclusively the empirical formula  $C_{10}H_{15}O_6N_3$  in preference to  $C_{20}H_{28}O_{12}N_6$ .

0.2262 gave 0.3670  $CO_2$  and 0.1222  $H_2O$ .  $C = 44.25$ ;  $H = 6.05$ .

0.2003 „ 0.3280  $CO_2$  „ 0.1070  $H_2O$ .  $C = 44.67$ ;  $H = 5.98$ .

0.2043 „ 27.4 c.c. nitrogen at  $17^\circ$  and 766 mm.  $N = 15.69$ .

0.1803 „ 23.4 c.c. „ at  $16^\circ$  „ 782 mm.  $N = 15.58$ .

$C_{10}H_{15}O_6N_3$  requires  $C = 43.95$ ;  $H = 5.50$ ;  $N = 15.38$  per cent.

$C_{20}H_{28}O_{12}N_6$  „  $C = 44.11$ ;  $H = 5.01$ ;  $N = 15.44$  „

$C_{10}H_{15}O_5N_3$  „  $C = 46.69$ ;  $H = 5.84$ ;  $N = 16.34$  „

One gram of the nitrosate requires nearly 600 c.c. of cold alcohol to dissolve it, and the compound is very sparingly soluble in all organic media; we have not been able, therefore, to determine its molecular weight, but this behaviour, and a comparison of the temperature at which it decomposes with the melting points of the derivatives herein described, and of 1-nitrocamphene ( $56^\circ$ ), indicate the bimolecular expression,  $C_{20}H_{30}O_{12}N_6$ .

The substance is insoluble in boiling aqueous potassium hydroxide and in hot concentrated hydrochloric acid; it dissolves in fused phenol, and develops an intense green coloration when the solution is warmed gently with concentrated sulphuric acid, but the colour disappears on dilution and is not regenerated by alkalis. In fuming nitric acid, it dissolves slowly, without rise of temperature, and is precipitated unchanged on dilution; concentrated sulphuric acid dissolves it less readily, but on warming gently a clear, deep brown solution is formed, from which gas is slowly evolved.

#### *Action of Piperidine on the Nitrosate.*

Ten grams of the nitrosate were covered with 8 grams of piperidine, when the liquid became hot and the crystals dissolved. Having completed the action by heating for a short time on the water-bath, the viscous product was poured into water, yielding a crystalline solid weighing 6 grams. On recrystallising the substance twice from hot absolute alcohol, it was obtained in transparent, flattened prisms melting at  $123^\circ$ .

0.1988 gave 0.3857  $CO_2$  and 0.1136  $H_2O$ .  $C = 52.90$ ;  $H = 6.39$ .

0.1875 „ 0.3640  $CO_2$  „ 0.1064  $H_2O$ .  $C = 52.94$ ;  $H = 6.35$ .

0.2470 „ 26.8 c.c. nitrogen at  $16^\circ$  and 756 mm.  $N = 12.59$ .

$C_{10}H_{14}O_4N_2$  requires  $C = 53.10$ ;  $H = 6.19$ ;  $N = 12.39$  per cent.

These results show that the product is not a piperidide, but is produced by elimination of the elements of nitrous acid from the foregoing substance. It is insoluble in hot dilute sulphuric acid and in a 10 per cent. solution of potassium hydroxide; it gives no coloration with ferric chloride, is indifferent towards fuming nitric acid, and does not give Liebermann's reaction. Phosphorus pentachloride has no action on it. Boiling petroleum dissolves it very sparingly, and although only moderately soluble in cold alcohol, it dissolves readily in the heated liquid.

A solution containing 0.5920 gram in 25 c.c. of chloroform at  $21^{\circ}$  gave  $\alpha_D - 7^{\circ}32'$  in a 2-dcm. tube, whence  $[\alpha]_D - 159.0^{\circ}$ .

The transformation of the nitrosate into the compound  $C_{10}H_{14}O_4N_2$  can be effected also by the action of alcoholic ammonia, and, under certain conditions, by alcoholic potash. When the former agent is employed, and heated with the nitrosate under a reflux apparatus, the crystals become completely dissolved in about 15 minutes, and the smell of ammonia is then scarcely perceptible; on cooling the liquid, an oil separates and rapidly solidifies. If alcoholic potash is used, it is necessary to limit the quantity of alkali, because the product undergoes further decomposition if an excess is employed.

Ten grams of the nitrosate were suspended in 25 c.c. of hot absolute alcohol and treated with 5 grams of potassium hydroxide in the minimum of water. After five minutes on the water-bath, a clear, yellow solution was produced, from which a crystalline precipitate separated on cooling. This was identical with the product obtained by the action of piperidine, and, on evaporating the alcohol from the filtrate, a residue was obtained which dissolved very readily in water; this solution set free iodine from potassium iodide, and yielded a dark green oil when acidified.

Evidence of the elimination of nitrous acid was obtained also in using piperidine. The filtrate from the solid substance precipitated by water was neutralised with dilute sulphuric acid, which precipitated a sticky, blue material; on filtering the liquid, adding alkali, extracting with ether, and evaporating the solvent, an oil was obtained which gave Liebermann's reaction very intensely, and most probably consisted of nitrosopiperidine.

#### *Complete Hydrolysis of the Nitrosate.*

Although the compound  $C_{10}H_{14}O_4N_2$  is obtainable from the nitrosate by the action alike of piperidine, alcoholic ammonia, and alcoholic potash, this fact is only true of the last named when the action is restricted, for if excess of the agent is employed the product is a

potassium derivative which forms a dark brown solution in water and yields a green oil on acidification.

This compound can be separated also as a by-product in the preparation of the nitrosate, for if the chloroform filtrate from that substance is shaken with 10 per cent. potassium hydroxide, the latter becomes brown, and furnishes the green oil on treatment with acid.

Owing to the unstable character of the liquid, we have not been able to determine its composition, but crystalline derivatives have been obtained from it, and are described below. The ethereal solution, when dried with calcium chloride and evaporated, yields a bright green varnish, which turns brown spontaneously and evolves a gas without colour or odour; if a freshly prepared specimen is heated in boiling water, it decomposes suddenly, emitting clouds of brown fumes with considerable violence, and becoming converted into a charred mass. If an attempt is made to distil the green oil in steam the colour changes to brown, but nothing volatile is produced; the brown product, unlike the green substance from which it is obtained, is insoluble in sodium carbonate, but dissolves in caustic alkali. It has not been found possible to obtain crystalline derivatives of the green oil by the action of phenyl isocyanate or of benzoyl chloride. Concentrated hydrochloric acid does not eliminate hydroxylamine, and reduction with sodium amalgam has failed to give a definite product; oxidation with potassium permanganate takes place very readily in the alkaline solution, and appears to decompose the substance completely.

#### *Action of Potassium Ferricyanide on the Green Oil.*

Twenty grams of the nitrosate were suspended in 150 c.c. of absolute alcohol and heated on the water-bath during two hours with 14 grams of caustic potash dissolved in the minimum quantity of water; the alcohol was then evaporated and the residue taken up with water, in which it dissolved completely. To this liquid, which was pale brown, 500 c.c. of a 25 per cent. solution of potassium ferricyanide were added, when a dark brown colour was developed in the liquid, the temperature of which rose to about 40°, whilst slight effervescence occurred. After an interval of 12 hours, dilute sulphuric acid was added until a greenish-blue coloration was produced; the viscous, brown oil which separated was removed and washed several times, when it became solid and was purified by reprecipitation from the solution in sodium carbonate, followed by crystallisation of the dried substance (about 14 grams) from light petroleum.

The same substance has been obtained from nitrocamphene in the following manner. One hundred grams, after treatment with nitrogen

peroxide in the manner described, having furnished 24.2 grams of the nitrosate, the chloroform filtrate was extracted with 300 c.c. of 30 per cent. potassium hydroxide solution, which became dark brown. This liquid was treated with 1200 c.c. of a 25 per cent. solution of potassium ferricyanide, and the mixture, which had evolved gas and risen in temperature, was acidified with dilute sulphuric acid after an interval of 3 hours; the brown oil quickly hardened and was redissolved in sodium carbonate, filtered from a little insoluble tarry matter, and reprecipitated. The pale brown solid obtained in this manner weighed 51.5 grams.

As in the case of the nitrosate, we have encountered difficulties in analysing this substance, which has, we believe, the empirical formula  $C_{10}H_{14}O_5N_2$ .

0.1786 gave 0.3275  $CO_2$  and 0.1067  $H_2O$ .  $C = 50.01$ ;  $H = 6.64$ .

0.1954 „ 19.8 c.c. nitrogen at  $20^\circ$  and 763 mm.  $N = 11.63$ .

$C_{10}H_{14}O_5N_2$  requires  $C = 49.59$ ;  $H = 5.78$ ;  $N = 11.57$  per cent.

It dissolves readily in organic media excepting light petroleum, 1000 c.c. of a boiling concentrated solution in the latter depositing 4.2 grams in the form of snow-white needles melting at  $85-86^\circ$ . It dissolves readily in sodium carbonate forming a pale yellow liquid, and the solution in 2 per cent. sodium hydroxide yields an intense purple-blue precipitate with ferrous sulphate. The alcoholic solution develops with ethereal ferric chloride a red coloration which is not very intense, and on adding copper acetate dissolved in alcohol the deep bluish-green colour of the copper salt changes to grass-green, but no separation of crystals takes place.

The compound does not decolorise bromine dissolved in chloroform, but hydrogen bromide is evolved on boiling the solution. The solution in phenol develops a green coloration when warmed with concentrated sulphuric acid, changing to a very deep bluish-green; on dilution, the colour becomes pink and then changes to intense blue on adding alkali. Fuming nitric acid dissolves the substance without any rise of temperature taking place, and phosphorus pentachloride, nitrous acid, potassium permanganate, benzoyl chloride, alcoholic potash, and boiling acetyl chloride are also without action.

The substance is not affected by hot concentrated hydrochloric acid, and after heating it during 2 hours with alcohol and hydrochloric acid in a sealed tube at  $100^\circ$ , it crystallised from the liquid, and the filtrate did not reduce Fehling's solution even when boiled. Dry hydrogen chloride was passed into a solution of the compound in methyl alcohol during 2 hours without producing a trace of a methyl derivative.

By dissolving it in excess of standardised sodium hydroxide and

titrating with sulphuric acid in presence of phenolphthalein, concordant results have been obtained without difficulty.

0.0861 gram dissolved in 10 c.c. of sodium hydroxide solution (containing 3.926 grams per litre) required 5.7 c.c. of sulphuric acid (containing 4.92 grams per litre), whence 242 grams require 46.0 grams NaOH.

0.1063 gram dissolved in 12 c.c. of sodium hydroxide solution required 6.7 c.c. of sulphuric acid, whence 242 grams require 46.0 grams NaOH.

The *ammonium* derivative separated when the substance was treated with concentrated ammonia, forming colourless needles which became yellow at about  $115^{\circ}$  and decomposed violently at  $136^{\circ}$ ; after remaining during 2 days in the desiccator, the substance did not change colour until heated at about  $140^{\circ}$ ; it decomposed at  $155^{\circ}$ .

0.2045 gave 27.8 c.c. nitrogen at  $18^{\circ}$  and 767 mm.  $N = 15.86$ .

$C_{10}H_{17}O_5N_3$  requires  $N = 16.21$  per cent.

The *copper* derivative crystallised in blue needles on adding copper sulphate to the ammoniacal solution, becoming olive-green after 2 days in the desiccator.

0.2152 gave 0.0208 CuO.  $Cu = 7.72$ .

$(C_{10}H_{13}O_5N_2)_2Cu$ ,  $C_{10}H_{14}O_5N_2$  requires  $Cu = 8.08$  per cent.

The *silver* derivative formed a pale yellow, granular precipitate on adding silver nitrate (1 mol.) to a neutral solution of the ammonium derivative.

0.1326 gave 0.0404 Ag.  $Ag = 30.46$ .

$C_{10}H_{13}O_5N_2Ag$  requires  $Ag = 30.96$  per cent.

It darkens rapidly on exposure to light, and dissolves in hot water.

It will be recognised that the behaviour of the substance  $C_{10}H_{14}O_5N_2$  is remarkable, because, although its production by the action of potassium ferricyanide on an oximino-compound would suggest its classification as a secondary nitro-derivative, nevertheless, the acidity which characterises it is more pronounced than that of many carboxylic acids; if it belonged to the latter class, the indifference towards hydrogen chloride of a solution in methyl alcohol would be explained if the group were attached to tertiary carbon. The compound, however, although optically active to a slight extent only, exhibits definite mutarotation, and we think that this fact, in conjunction with the experiments still to be described, is evidence in support of the view that it is a secondary nitro-derivative.

A solution containing 1.1925 grams in 25 c.c. of chloroform at  $20^{\circ}$  was prepared in a darkened room, and transferred to the 2-dcm. tube

without more than a minute's interval after dissolution; the reading observed was  $21'$ , which fell to  $10'$  while confirmatory observations were being made. In half an hour, the solution gave  $\alpha_D -39'$ , remaining constant at  $\alpha_D -1^\circ 8'$ , which was reached on the eleventh day. Thus, the initial and final specific rotatory powers are  $[\alpha]_D +3.6^\circ$  and  $[\alpha]_D -11.9^\circ$  respectively.

*Action of Potassium Hypobromite.*—Ten grams were dissolved in aqueous potassium hydroxide and treated with potassium hypobromite prepared by adding 20 grams of bromine to an ice-cold, concentrated solution of caustic potash. A snow-white precipitate was formed immediately, and this was filtered, washed, and crystallised from hot alcohol, which deposited 13 grams; on recrystallisation, it was obtained in colourless needles melting at  $157^\circ$ .

0.3314 gave  $0.4543 \text{ CO}_2$  and  $0.1106 \text{ H}_2\text{O}$ .  $\text{C} = 37.39$ ;  $\text{H} = 3.73$ .

0.2336 „  $0.1367 \text{ AgBr}$ .  $\text{Br} = 24.90$ .

$\text{C}_{10}\text{H}_{13}\text{O}_5\text{N}_2\text{Br}$  requires  $\text{C} = 37.38$ ;  $\text{H} = 4.05$ ;  $\text{Br} = 24.92$  per cent.

A solution containing 1.2415 grams in 25 c.c. of chloroform at  $20^\circ$  gave  $\alpha_D -6^\circ 45'$  in a 2-dcm. tube, whence  $[\alpha]_D -68.0^\circ$ .

The substance dissolves sparingly in boiling light petroleum, from which it separates in minute needles, and is moderately soluble in benzene, alcohol, ethyl acetate, or glacial acetic acid, crystallising from the first named in well-formed, six-sided prisms; acetone and chloroform dissolve it freely. The Liebermann reaction is very intense in all its stages. When the bromo-derivative is heated with alcoholic potash, the compound  $\text{C}_{10}\text{H}_{14}\text{O}_5\text{N}_2$  is regenerated.

*Action of Hydroxylamine.*—Ten grams of the substance were dissolved in 250 c.c. of absolute alcohol, and treated first with 20 grams of hydroxylamine hydrochloride and then with 18.7 grams of potassium hydroxide, both dissolved in water; after 2 hours on the water-bath, the liquid was evaporated and filtered from the solid (1.2 grams) which separated on cooling. The filtrate was faintly alkaline and yielded a colourless precipitate (6.1 grams) on acidification. Both products were then crystallised from hot water, which deposited the former in lustrous, orange leaflets melting at  $184^\circ$ .

0.1709 gave 19.4 c.c. nitrogen at  $20^\circ$  and 749 mm.  $\text{N} = 12.80$ .

$\text{C}_{10}\text{H}_{14}\text{O}_4\text{N}_2$  requires  $\text{N} = 12.39$  per cent.

The substance is moderately soluble in alcohol, from which it crystallises in thin, striated prisms. It dissolves in 2 per cent. sodium hydroxide, but gives no coloration with ferrous sulphate, and does not reduce Fehling's solution, although ammoniacal silver nitrate is reduced immediately on boiling. The alcoholic solution develops an intense purple coloration with ethereal ferric chloride, and, when

treated with copper acetate in alcohol, destroys the colour of the first few drops and quickly yields a sage-green precipitate. It does not give Liebermann's reaction.

The second product dissolves more readily in sodium carbonate than the foregoing substance, and crystallises from boiling water in colourless, transparent pyramids melting at  $161^{\circ}$ , the solution being acid to litmus.

0.3924 gave 26.4 c.c. nitrogen at  $19^{\circ}$  and 748 mm.  $N = 7.61$ .

$C_{10}H_{15}O_3N$  requires  $N = 7.10$  per cent.

This compound gives no coloration with ethereal ferric chloride, and reduces ammoniacal silver nitrate very slightly on continued boiling. It does not give Liebermann's reaction, and gives no characteristic precipitate in 2 per cent. sodium hydroxide with ferrous sulphate or with potassium hypobromite. It is practically insoluble in light petroleum, dissolves very sparingly in chloroform and carbon bisulphide, and is only moderately soluble in hot alcohol or acetone. It neither decolorises dissolved bromine nor yields hydrogen bromide when warmed with the halogen, but the sodium carbonate solution reduces potassium permanganate freely.

*Reduction with Sodium Amalgam.*—By this treatment, the compound  $C_{10}H_{14}O_5N_2$  is converted into a deep red substance, and hydroxylamine is eliminated.

Ten grams were dissolved in 50 c.c. of 10 per cent. sodium hydroxide and shaken with 360 grams of 2 per cent. sodium amalgam, which was added in quantities of 40 grams at intervals of half an hour, the liquid being kept cool and diluted occasionally with a few c.c. of water. With the first addition of amalgam, a turbidity appeared, followed by a pink coloration, which rapidly deepened to an intense dark red tint; meanwhile, an ammoniacal odour became noticeable. When all the reducing agent had been used, a few c.c. of sodium carbonate were added, so that the product being soluble in both acids and alkalis, the next step, acidification, can be interrupted when effervescence begins. A vermilion precipitate was thus obtained, and the filtrate reduced cold Fehling's solution immediately.

The substance could not be recrystallised, but a specimen reprecipitated from a filtered solution in 10 per cent. potassium hydroxide was analysed.

0.1991 gave 15.2 c.c. nitrogen at  $17^{\circ}$  and 772 mm.  $N = 9.00$ .

$C_{10}H_{15}ON$  requires  $N = 8.48$  per cent.

$C_{20}H_{30}ON_2$  „  $N = 8.92$  „

It is insoluble in light petroleum, but dissolves very freely in cold alcohol and in boiling water, forming red solutions which have no

action on ammoniacal silver nitrate and Fehling's solution respectively. The solution in dilute sulphuric acid has the colour of potassium permanganate, and the wine-red liquid produced by dissolving the substance in 2 per cent. sodium hydroxide yields a dark brown precipitate with ferrous sulphate. An alcoholic solution gives no distinctive coloration with ethereal ferric chloride, but develops a magnificent purple with potassium hydroxide.

*Action of Potassium Hypobromite on the Green Oil.*

Ten grams of the nitrosate were suspended in 75 c.c. of absolute alcohol and heated on the water-bath during 2 hours with 7 grams of caustic potash dissolved in the minimum quantity of water; the residue obtained on evaporation having been dissolved in ice-cold water, a freshly prepared solution of potassium hypobromite containing 30 grams of bromine was added. A heavy, yellow oil was precipitated, hardening immediately on treatment with cold water, and weighing 15 grams.

This compound has been obtained also by treating with excess of potassium hypobromite the brown alkaline liquid formed on shaking with aqueous potash the green chloroform filtrate from the nitrosate; 16 grams were thus produced from 25 grams of nitrocamphene.

The substance prepared by these methods dissolves in boiling light petroleum, and crystallises in stellate aggregates of lustrous, pale brown prisms melting at 78°.

0.3201 gave 0.3040 CO<sub>2</sub> and 0.0885 H<sub>2</sub>O. C = 25.90; H = 3.09.

0.4382 „ 22.6 c.c. nitrogen at 20° and 763 mm. N = 5.93.

0.2542 „ 0.2971 AgBr. Br = 49.73.

C<sub>10</sub>H<sub>11</sub>O<sub>5</sub>N<sub>2</sub>Br<sub>3</sub> requires C = 25.05; H = 2.30; N = 5.84; Br = 50.10 per cent.

It is readily soluble in cold chloroform and ethyl acetate, and less freely in alcohol and acetic acid. A solution containing 1.2882 grams in 25 c.c. of chloroform at 20° gives  $\alpha_D^{26}$  in a 2-dcm. tube, whence  $[\alpha]_D + 4.2^\circ$ . Although it undergoes reduction in alcoholic solution with zinc dust, aluminium amalgam, and with potassium hydroxide, in no case has a crystalline product been obtained. The tribromo-derivative gives Liebermann's reaction with great intensity in all its stages.

*Methylaminocamphene, C<sub>10</sub>H<sub>15</sub>·NH·CH<sub>3</sub>.*

At one time it seemed possible that the object we had in view might be attained by the use of derivatives of aminocamphene, and experiments were made with benzoylaminocamphene and methyl-

aminocamphene, but without success. The latter substance was obtained by the process devised for the preparation of methylbornylamine (Trans., 1899, 75, 936); this consists in converting the benzylidene derivative of the primary base into the methiodide, and heating this with moist ethyl acetate, which hydrolyses it to benzaldehyde and the hydriodide of the methylated base.

Six grams of benzylideneaminocamphene (Trans., 1901, 79, 650) were heated in a sealed tube with 22 grams of methyl iodide at  $100^{\circ}$  during 2 hours, the product being treated with ether and filtered. The yellow crystals weighed 7 grams and had a faint odour of benzaldehyde.

0.1309 gave 0.0828 AgI.  $I = 34.19$ .

0.2188 „ 0.1418 AgI.  $I = 34.21$ .

$C_{10}H_{15} \cdot N \cdot CH \cdot C_6H_5, CH_3I$  requires  $I = 33.34$  per cent.

Twenty-eight grams of this material were heated with 200 c.c. of undried ethyl acetate during 1 hour; 21 grams of methylaminocamphene hydriodide were obtained and recrystallised from hot water.

0.2040 gave 0.1632 AgI.  $I = 43.23$ .

$C_{11}H_{20}NI$  requires  $I = 43.34$  per cent.

On decomposing the salt with caustic alkali, methylaminocamphene was obtained as a colourless oil which boils at  $202-203^{\circ}$  under 756 mm. pressure, and has sp. gr. 0.9171 at  $22^{\circ}$ . A solution containing 0.5447 gram in 25 c.c. of absolute alcohol gave  $\alpha_D 1^{\circ}17'$  in a 2-dcm. tube, whence  $[\alpha]_D + 28.7^{\circ}$ .

The *platinichloride* melts and decomposes at  $214^{\circ}$ .

0.1322 gave 0.0349 Pt.  $Pt = 26.39$ .

0.2893 „ 0.0763 Pt.  $Pt = 26.37$ .

$(C_{11}H_{19}N)_2, H_2PtCl_6$  requires  $Pt = 26.27$  per cent.

The salt dissolves readily in alcohol, from which it crystallises in minute needles.

XXXVII.—*The So-called "Hydrocellulose."*

By ARTHUR LANDAUER STERN, D.Sc.

It is well known that all kinds of cellulose, when exposed to the action of certain reagents, lose their tenacity and become friable. This fact has hitherto been explained as being the result of the hydration of the cellulose, leading to the formation of hydrocellulose. All the evidence concerning this change appears to be contained in the work of A. Girard (*Compt. rend.*, 1875, **81**, 1105—1108; 1879, **88**, 1322—1324; and *Ann. Chim. Phys.*, 1881, [v], **24**, 337—384), who prepared hydrocellulose by several different methods, and having determined its empirical composition found this to agree fairly well with the formula  $C_{12}H_{22}O_{11}$ . The results of certain experiments carried out by the author in the course of another investigation threw doubt on the accuracy of Girard's observations, and consequently some of his experiments were repeated.

Girard prepared hydrocellulose by treating cellulose with cold sulphuric acid (sp. gr. 1.45), by the action of cold moist hydrogen chloride on air-dried cellulose, and by heating cellulose with dilute acids. The attempts made to prepare hydrocellulose by the first two of these methods proved unsuccessful, but the action of boiling 5 per cent. sulphuric acid on flax or cotton cellulose soon destroyed the tenacity of the fibres and converted the substance into a friable mass.

As the change of  $2C_6H_{10}O_5$  into  $C_{12}H_{22}O_{11}$  is accompanied by an increase in weight of 5.6 per cent., it should be possible to detect this by quantitative experiments. Girard, however, states that under the most favourable conditions the weight of hydrocellulose obtained is less than the weight of the original cellulose, and he explains this discrepancy by assuming that *d*-glucose is simultaneously produced, but adduces no evidence in support of this assumption beyond the fact that, after the reaction, the acid solution reduces Fehling's solution.

Experiments made to determine the relation between the weight of the cellulose taken and (*A*) the weight of the hydrocellulose and (*B*) the weight and nature of the other products of the reaction, gave the following results.

A. (1) Flax cellulose, boiled for  $2\frac{1}{4}$  hours in 5 per cent. sulphuric acid, lost 2.1 per cent., and was reduced to a powder.

(2) Cotton cellulose, boiled for 1 hour with 5 per cent. sulphuric acid, similarly lost 3.9 per cent.

(3) Cotton cellulose, immersed in sulphuric acid (sp. gr. 1.45) for 16 hours at 26°, lost 3.3 per cent.; the fibres were rendered brittle, but were not converted into a powder.

The following experiments show that this loss in weight is not a peculiar concomitant of the conversion of cellulose into hydrocellulose, but also occurs when hydrocellulose itself is submitted to the further action of the acid. The flax cellulose, which had been converted into hydrocellulose in the manner indicated by boiling with 5 per cent. sulphuric acid for 2½ hours, was again submitted to the same process, when a further loss of 1.9 per cent. was observed, and the treatment being again repeated on the hydrocellulose remaining, there was an additional loss of 2.0 per cent.

*B.* About 380 grams of purified cotton cellulose, covered with 5 per cent. sulphuric acid, were digested at 100° for 4 hours; the soluble matter was then filtered off and the "hydrocellulose" produced thoroughly washed with water. The sulphuric acid was removed from the solution by neutralisation with baryta, the precipitated barium sulphate filtered off, and the filtrate evaporated to a syrup *in vacuo*. This residue was treated with methyl alcohol, in which the greater portion dissolved. The total soluble products of the hydrolysis weighed 6.4 grams, or 1.8 per cent. of the cellulose employed.

The syrup, which was uncrystallisable, had an optical activity of +37° and a cupric reducing power  $K = 90$  (*d*-glucose having  $K = 100$ ). A portion of the syrup, when treated with phenylhydrazine acetate in the usual way, yielded a golden-yellow osazone closely resembling glucosazone, which crystallised in needles and melted at 208°. Another portion, to which a small quantity of yeast had been added, lost 60 per cent. of its optical activity in a few days; the optical activity of the matter fermented was  $[\alpha]_D = 48^\circ$ , and its  $K = 107$ . All these facts indicate that one of the soluble products of the hydrolysis is *d*-glucose; the amount obtained is, however, insufficient to explain Girard's theory that the deficiency in the yield of hydrocellulose which is always found may be explained by the conversion of this deficiency into *d*-glucose.

The production of *d*-glucose in the conversion of ordinary cellulose into hydrocellulose is not, however, a peculiar characteristic of this change, as it is also formed when hydrocellulose is further acted on by hot dilute sulphuric acid. The hydrocellulose obtained in the last transformation was treated for a further period of 4 hours with 5 per cent. sulphuric acid at 100°. The soluble products of the transformation, when separated in the same way, amounted to 5.3 grams, or 1.5 per cent. of the weight of hydrocellulose taken. A methyl-alcoholic solution of the syrupy product deposited crystals which had the following properties :  $c = 7.517$  ;  $D = 3.972$  ;  $[\alpha]_D = 36.9^\circ$  ;

and, after recrystallisation, gave the following data:  $c = 2.582$ ;  $D = 3.916$ ;  $[\alpha]_D = 45.9^\circ$ ;  $K = 95.2$ .\*

A solution of the recrystallised product, when fermented with a small quantity of yeast, lost 58 per cent. of its optical activity in a few days, and another portion yielded a yellow, crystalline osazone resembling glucosazone and melting at  $208^\circ$ .

The hydrocellulose residue of this reaction, when again treated in the same way, yielded 4.0 grams of soluble products, the methyl-alcoholic solution of which deposited crystals having the following properties:  $c = 4.778$ ;  $D = 3.926$ ;  $[\alpha]_D = 47.3^\circ$ ;  $K = 97.5$ . A portion put to ferment with yeast lost 61 per cent. of its optical activity in a few days, and another portion yielded a yellow, crystalline osazone melting at  $210^\circ$ .

The hydrocellulose residue now remaining was again treated as before and 2.5 grams of soluble products were obtained, the methyl-alcoholic syrup of which gave crystals having the following properties;  $c = 4.195$ ;  $D = 3.893$ ;  $[\alpha]_D = 45.6^\circ$ ;  $K = 97.8$ . A portion of this substance, when fermented with yeast for 10 days, a longer time than the previous fermentations, lost 97.8 per cent. of its optical activity, and another portion gave a yellow, crystalline osazone melting at  $204^\circ$ .

*Analysis of Hydrocellulose.*—Girard's results, which vary between 41.8 and 42.1 per cent. of carbon and 6.3—6.7 per cent. of hydrogen, although not very satisfactory, yet agree moderately well with the empirical formula  $C_{12}H_{22}O_{11}$ , which requires 42.1 per cent. of carbon and 6.4 per cent. of hydrogen.

The celluloses employed in the present experiments were burnt before and after having been exposed to the action of acids as described above and yielded the following results:

	Flax cellulose.	Flax cellulose after the action of sulphuric acid. Sp. gr. 1.45, not friable.	Flax cellulose reduced to powder by the action of 5 per cent. sulphuric acid for two hours at $100^\circ$ .	Flax cellulose after being treated with 5 per cent. sulphuric acid for 7 hours at $100^\circ$ .	Cotton cellulose.	Cotton cellulose reduced to powder by the action of 5 per cent. sulphuric acid at $100^\circ$ .	Cotton cellulose after the action of sulphuric acid. Sp. gr. 1.45 at $26^\circ$ , very brittle.	Theory for $C_6H_{10}O_5$ .
Carbon .....	44.28	44.39	44.44	44.27	44.45	44.38	44.31	44.42
Hydrogen ...	6.28	6.28	6.26	6.24	6.32	6.27	6.29	6.22

\*  $c$  = Concentration in grams per 100 c.c.  $D$  = Divisor; a factor obtained by dividing the specific gravity minus 1, by  $c$  and multiplying the result by 1000.  $K$  = Cupric reducing power compared with that of *d*-glucose as 100.

These figures agree very closely with the formula  $C_6H_{10}O_5$ .

It appeared at first difficult to understand how Girard came to obtain his analytical figures, but this investigator's account of his experiments will render this quite clear. He states that hydrocellulose is easily oxidised on exposure to warm air; at  $80^\circ$ , it becomes coloured, and at  $100^\circ$  this change takes place very rapidly. In several of the author's experiments, it was found that, after the action of the acid, the cellulose, when washed in the usual way, was blackened on drying at  $100^\circ$ , but in every case in which this took place, sulphuric acid was detected in the filtrate obtained by extracting the blackened mass with hot water. On the other hand, all the preparations of which the analyses are given above were dried in a current of dry air at  $100^\circ$ ; in no case was the slightest colour produced, and the preparations did not contain sulphuric acid. As Girard's preparations became coloured when exposed to a temperature of  $100^\circ$ , it is evident that they must have contained free acid, and as, on account of this, he only dried them at  $35-40^\circ$ , it is extremely probable that they also contained water, and hence the low numbers obtained for the carbon and the high values for the hydrogen are explained. One of the author's specimens prepared by the action of sulphuric acid (sp. gr. 1.45) at  $25^\circ$  gave only 44.05 as the percentage of carbon, but in washing this specimen free from acid, a little ammonia had been added to one of the wash waters, and although it was thought that the cellulose had been properly washed, yet when another portion of the specimen was extracted with hot water, sulphuric acid was found in the filtrate, showing that a small amount of sulphate had been contained in the specimen burnt, thus accounting for the low percentage of carbon.

It is evident from a consideration of these results that when cellulose is exposed to the action of hot dilute acids there is no formation of hydrocellulose; the cellulose is partly hydrolysed with the production of soluble products, one of which is in all probability *d*-glucose. The cellulose residue, after exposure to the action of hot dilute acid for some hours, does not differ in elementary composition from the original cellulose, but has been converted into a fine powder. A microscopic examination of the disintegrated cellulose at different stages of the reaction, shows that the disintegration is due to the fact that certain portions of the fibre are more easily attacked than others, and when these portions of the fibres are converted into soluble products the whole fibre falls to pieces. Although this change is most marked in the first stage of the reaction, yet each successive digestion results in the production of a finer product, until that obtained in the above-described experiments, after treatment for 16 hours, was so fine as to be most difficult to filter.

The slowness of the action and the consequent long period of time

during which it was necessary to allow the hydrolysis to proceed in order to obtain a sufficient amount of soluble products, rendered it impossible to decide whether *d*-glucose was the only product of the hydrolysis or whether, as seems probable from Fenton's experiments, there are other soluble products (Trans., 1 98, 73, 554; 1899, 75, 423; 1901, 79, 361 and 807; and Proc., 1901, 17, 166). Lævulose, for example, would be destroyed in the foregoing experiments, owing to the protracted action of the hot acids.

---

### XXXVIII.—*Intramolecular Rearrangement in Derivatives of the Aromatic Aminoketones.*

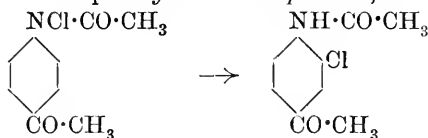

By FREDERICK DANIEL CHATTAWAY.

THE acylchloroamino-derivatives of the aromatic ketones readily undergo the intramolecular rearrangement characteristic of aromatic chloroamides, in which the halogen radicle leaves the nitrogen and changes place with a hydrogen atom occupying an ortho- or para-position in the ring. The presence of the ketonic group does not, apparently, influence the rearrangement. As, however, the final transformation whereby both vacant positions are filled only takes place at a somewhat high temperature, the ketonic group becomes involved under the influence of the catalyst employed, uncrystallisable tarry substances are produced, and the yield of the disubstituted aminoketone is small.

By these intramolecular changes, a number of substituted amino-ketones have been prepared, which are not easily obtained by direct substitution, this reaction as a rule only yielding a tarry product from which no pure substance can be isolated.

The mode in which these substituted ketones are produced fixes their constitution, as in such transformations the halogen is known always to take up the para- in preference to the ortho-position, whilst the meta-position with respect to the amino-group is never assumed.

*Transformation of Acetyl-p-chloroaminoacetophenone into 3-Chloro-p-acetylaminoacetophenone,*

This transformation slowly takes place when a solution of the chloroamide in chloroform containing about 5 per cent. of acetic acid is allowed to remain at the ordinary temperature, light being excluded; the change is complete in about 14 days. On evaporating off the chloroform, a red solid is left from which 3-chloro-p-acetylaminoacetophenone can be obtained by repeated crystallisation from alcohol. This substance crystallises in slender, colourless prisms (m. p. 163°).

0.3635 yielded 0.2520 AgCl. Cl = 17.17.

$\text{C}_{10}\text{H}_{10}\text{O}_2\text{NCl}$  requires Cl = 16.75 per cent.

*3-Chloro-p-acetylchloroaminoacetophenone,*

was prepared by adding a solution of 3-chloro-4-acetylaminoacetophenone dissolved in alcohol to an ice-cold solution of potassium hypochlorite containing an excess of potassium hydrogen carbonate; it was extracted by chloroform, and, to complete the action, the solution was repeatedly shaken with fresh hypochlorous acid. The compound crystallises from petroleum (b. p. 60–80°) in clusters of colourless, transparent plates (m. p. 56°).

0.1746 liberated I = 13.8 c.c. N/10 I. Cl (as NCl) = 14.01.

$\text{C}_{10}\text{H}_9\text{O}_2\text{NCl}_2$  requires Cl (as NCl) = 14.41 per cent.

When dissolved in glacial acetic acid and heated, it undergoes transformation, but the quantity of the crystalline dichloro-transformation product which could be isolated from the tarry product of the action was so small that it was not further studied.

*3-Chloro-p-aminoacetophenone,*  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NH}_2$ , was prepared by hydrolysing the acetyl derivative by heating it for four hours with a mixture of alcohol and concentrated hydrochloric acid and decomposing the hydrochloride of the base with caustic potash. It crystallises from a mixture of chloroform and petroleum in short, four-sided, colourless prisms (m. p. 92°).

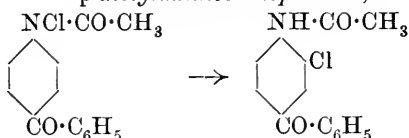

0.1959 yielded 0.1668 AgCl. Cl = 21.05.

$\text{C}_8\text{H}_8\text{ONCl}$  requires Cl = 20.91 per cent.

3-Chloro-p-benzoylaminoacetophenone,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4\text{Cl} \cdot \text{NH} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ , crystallises from alcohol in slender, colourless needles (m. p.  $132^\circ$ ).

3-Chloro-p-propionylaminoacetophenone,  
 $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4\text{Cl} \cdot \text{NH} \cdot \text{CO} \cdot \text{C}_2\text{H}_5$ ,  
 crystallises from a mixture of chloroform and petroleum in groups of slender, colourless needles (m. p.  $115^\circ$ ).

*Transformation of Acetyl-p-chloroaminobenzophenone into 3-Chloro-p-acetylaminobenzophenone,*

This transformation takes place slowly under similar conditions to those which bring about the transformation of the acetophenone derivative. When the chloroamide dissolved in chloroform containing 5 per cent. glacial acetic acid was allowed to remain at the ordinary temperature and screened from light, it became completely transformed in about 14 days. On evaporating off the chloroform, a viscid, oily substance was left, which, however, solidified to a nearly colourless mass on warming for a short time with a solution of potassium hydrogen carbonate. When repeatedly crystallised from alcohol, the pure 3-chloro-4-acetylaminobenzophenone,  $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NH} \cdot \text{CO} \cdot \text{CH}_3$ , was obtained in colourless, rhombic plates (m. p.  $99.5^\circ$ ).

0.2440 gave 0.1265 AgCl. Cl = 12.82.

$\text{C}_{15}\text{H}_{12}\text{O}_2\text{NCl}$  requires Cl = 12.96 per cent.

3-Chloro-p-acetylchloroaminobenzophenone,

crystallises from a mixture of chloroform and petroleum (b. p.  $60-80^\circ$ ) in transparent, colourless plates (m. p.  $102^\circ$ ).

0.3760 liberated I = 24.5 c.c.  $N/10$  I. Cl (as NCl) = 11.55.

$\text{C}_{15}\text{H}_{11}\text{O}_2\text{NCl}_2$  requires Cl (as NCl) = 11.51 per cent.

3-Chloro-p-aminobenzophenone,  $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NH}_2$ , was obtained by heating the acetyl derivative for three hours on a water-bath with alcoholic hydrochloric acid and decomposing the hydrochloride of the base with caustic potash; it crystallises from a mixture of chloroform and petroleum in small, slender, colourless prisms (m. p.  $140^\circ$ ).

0.1942 gave 0.1209 AgCl. Cl = 15.39.

$\text{C}_{13}\text{H}_{10}\text{ONCl}$  requires Cl = 15.31 per cent.

3-Chloro-p-benzoylaminoacetophenone,  $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3\text{Cl} \cdot \text{NH} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ ,

is sparingly soluble in alcohol, from which it crystallises in colourless, flattened prisms (m. p. 126°).

*3-Chloro-p-benzoylchloroaminobenzophenone,*

crystallises from light petroleum in short, colourless, flattened prisms with domed ends (m. p. 123°).

0.1404 liberated I = 7.5 c.c. *N*/10 I. Cl (as NCl) = 9.46.

$\text{C}_{20}\text{H}_{13}\text{O}_2\text{NCl}_2$  requires Cl (as NCl) = 9.58 per cent.

*3-Chloro-p-propionylaminobenzophenone,*

crystallises from alcohol or a mixture of chloroform and petroleum in slender, colourless needles (m. p. 107.5°).

*3-Chloro-p-propionylchloroaminobenzophenone,*

crystallises from a mixture of chloroform and petroleum in colourless plates (m. p. 114°).

0.2790 liberated I = 17.4 c.c. *N*/10 I. Cl (as NCl) = 11.05.

$\text{C}_{16}\text{H}_{13}\text{O}_2\text{NCl}_2$  requires Cl (as NCl) = 11.01 per cent.

*Transformation of Acetyl-o-chloroaminobenzophenone into 5-Chloro-o-acetylaminobenzophenone,*

This compound does not become transformed nearly so readily as the corresponding para-derivative, and remains apparently unchanged in chloroform solution containing 5 per cent. of acetic acid for a period sufficient for the complete transformation of the latter.

This transformation can, however, be effected, accompanied by some decomposition and the formation of tarry products, by dissolving the chloroamide in glacial acetic acid containing about 0.5 per cent. of hydrogen chloride and heating the solution in a sealed tube in a water-bath for a few hours. On pouring the product into water and washing with a dilute solution of potassium hydrogen carbonate in order to remove the acid, a pale brown, tarry mass is obtained. On dissolving this in a little alcohol, the transformation product slowly separates in colourless needles.

The behaviour of all similar derivatives leaves no doubt that the chlorine passes almost exclusively into the para-position with regard to the acetylamino-group.

5-Chloro-o-acetylaminobenzophenone,  $C_6H_5 \cdot CO \cdot C_6H_3Cl \cdot NH \cdot CO \cdot CH_3$ , crystallises from alcohol in slender, colourless prisms (m. p. 117°).

0.2103 yielded 0.1104 AgCl.  $Cl = 12.98$ .

$C_{15}H_{12}O_2NCl$  requires  $Cl = 12.96$  per cent.

5-Chloro-o-acetylchloroaminobenzophenone,

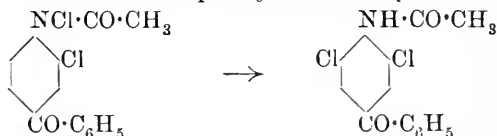

crystallises from a mixture of chloroform and petroleum in clusters of colourless plates (m. p. 107°).

0.2599 liberated  $I = 16.8$  c.c.  $N/10$  I.  $Cl$  (as  $NCl$ ) = 11.46.

$C_{15}H_{11}O_2NCl_2$  requires  $Cl$  (as  $NCl$ ) = 11.51 per cent.

5-Chloro-o-aminobenzophenone,  $C_6H_5 \cdot CO \cdot C_6H_3Cl \cdot NH_2$ .—The acetyl derivative of this base is hydrolysed only with difficulty, and requires prolonged boiling with excess of alcoholic hydrochloric acid. 5-Chloro-2-aminobenzophenone is readily soluble in chloroform or alcohol, sparingly so in petroleum; it crystallises from a mixture of chloroform and light petroleum in slender, yellow needles (m. p. 100°).

*Transformation of 3-Chloro-p-acetylchloroaminobenzophenone into 3:5-Dichloro-p-acetylaminobenzophenone,*

The transformation of the acylchloroaminobenzophenones is exactly analogous to that of the acylchloroamino-derivatives of the similarly constituted chloroanilines. The transformation of acetyl-p-chloroaminobenzophenone is effected more readily than that of acetyl-o-chloroaminobenzophenone, and the transformation of the latter more readily than that of 3-chloro-p-acetylchloroaminobenzophenone. Even when dissolved in glacial acetic acid containing a little hydrogen chloride and heated at 100° for several hours, this compound undergoes no appreciable amount of transformation.

Intramolecular rearrangement, however, occurs when the solution is heated for some hours at 130–140°; after eight hours at this temperature, the chloroamide was found to have completely disappeared. On diluting the product and adding a slight excess of potassium hydrogen carbonate to neutralise the acid, a pale yellow, viscid mass was obtained which was readily soluble in warm alcohol, the solution slowly depositing needle-shaped crystals of the transformation product. The yield, however, is small, a considerable quantity of a tarry substance being formed,

3 : 5-Dichloro-p-acetylaminobenzophenone,

crystallises from alcohol in colourless, needle-shaped crystals (m. p. 185°).

0.1626 gave 0.1509 AgCl.  $\text{Cl} = 22.94$ .

$\text{C}_{15}\text{H}_{11}\text{O}_2\text{NCl}_2$  requires  $\text{Cl} = 23.02$  per cent.

The constitution of the compound follows from its mode of preparation, as the chlorine atoms can only enter the ortho-positions with respect to the acetyl-amino-group.

3 : 5-Dichloro-p-acetylchloroaminobenzophenone,

crystallises from a mixture of chloroform and petroleum in groups of transparent, colourless plates (m. p. 118°).

0.1019 liberated  $\text{I} = 5.9$  c.c.  $\text{N}/10$  I.  $\text{Cl}$  (as  $\text{NCl}$ ) = 10.26.

$\text{C}_{15}\text{H}_{10}\text{O}_2\text{NCl}_3$  requires  $\text{Cl}$  (as  $\text{NCl}$ ) = 10.35 per cent.

3 : 5-Dichloro-p-aminobenzophenone,  $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{NH}_2$ , prepared by hydrolysing the acetyl compound by boiling with alcoholic hydrochloric acid, crystallises from alcohol in short, colourless prisms (m. p. 137°).

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE,  
LONDON, E.C.

### XXXIX.—The Separation of $\beta$ -Crotonic Acid from $\alpha$ -Crotonic Acid.

By ROBERT SELBY MORRELL and ALBERT ERNEST BELLARS.

THE separation of  $\beta$ -crotonic acid from  $\alpha$ -crotonic acid is effected, according to Michael and Schulthess (*J. pr. Chem.*, 1892, [ii], 46, 245), by means of the different solubilities of the sodium salts in alcohol. One part of sodium  $\alpha$ -crotonate dissolves in 340 parts of alcohol (98—99 per cent.) at 15°, whilst at the same temperature, one part of sodium  $\beta$ -crotonate requires 12.7 parts of alcohol of the same strength; the more soluble  $\beta$ -crotonate is then decomposed by hydrochloric acid, and the free acid purified by distillation *in vacuo*.  $\beta$ -Crotonic acid, obtained by Michael's method or by the method described by Fittig and Kochs (*Annalen*, 1892, 268, 15), is stated by J. Wislicenus (*Chem. Centr.*, 1897, ii, 259) to contain  $\alpha$ -crotonic acid, in spite of Michael's acid giving no precipitate in alcoholic precipitate on neutralisation

with alcoholic sodium hydroxide. The pure acid has been obtained (J. Wislicenus, *loc. cit.*) by transforming liquid  $\beta$ -crotonic acid, dissolved in alcohol, into its sodium salt, and by removing the sodium  $\alpha$ -crotonate by concentrating the solution and precipitating the last traces of the salt by the addition of an equal volume of ether; the sodium  $\beta$ -crotonate left in solution is decomposed by hydrochloric acid, and the acid, which is purified by recrystallisation from pentane, crystallises in needles or prisms melting at  $15.45-15.5^{\circ}$ ; the yield must be small, and the method of preparation seems tedious.

In a paper by one of us (Morrell and Hanson, *Trans.*, 1904, 85, 197), the optically active constituents of  $\alpha\beta$ -dihydroxybutyric acid, prepared from  $\alpha$ -crotonic acid, were described, and it was stated that the optically active constituents of a second  $\alpha\beta$ -dihydroxybutyric acid were under investigation.

The oxidation of "*isocrotonic*" acid, supplied by Kahlbaum, gave an acid the brucine and quinine salts of which were virtually identical with those of symmetrical  $\alpha\beta$ -dihydroxybutyric acid, so that it was necessary to devise a method of separation of the two isomeric acids, and to prepare salts of  $\beta$ -crotonic acid, which are less soluble than the corresponding  $\alpha$ -crotonates. The brucine salts of the two acids were found to have different solubilities, and the  $\beta$ -acid yielded the less soluble salt, but unfortunately these salts are very soluble in all ordinary solvents. The quinine salts, however, are sparingly soluble in water, and the salt of the  $\beta$ -acid is much less soluble than that of the  $\alpha$ -acid; it is therefore quite easy to separate the two salts by crystallisation from water, and the quinine  $\beta$ -crotonate can be recrystallised from that solvent without undergoing any change in melting point. From the quinine salt, the barium  $\beta$ -crotonate has been prepared, and this has given the pure acid by treatment with dilute sulphuric acid in the presence of pure ether. The melting point agrees with that given by Wislicenus, namely,  $15^{\circ}$ . Determinations of the density, molecular weight, and molecular refraction have been made. The molecular weight in glacial acetic acid solution corresponds with the formula  $C_4H_6O_2$ , and there seems no justification for the double formula proposed by Wislicenus (*Chem. Centr.*, 1897, ii, 259).

Michael and Schulthess (*loc. cit.*) state that the purity of  $\beta$ -crotonic acid can be shown by neutralising its alcoholic solution with 10 per cent. caustic soda solution; sodium  $\beta$ -crotonate is very soluble in alcohol, and, under the experimental conditions, no precipitate ought to be formed on neutralisation. We have tested the  $\beta$ -crotonic acid prepared from the quinine salt, following Michael's directions, and have found that no insoluble sodium crotonate was formed; moreover, the determination of the solubility of sodium  $\beta$ -crotonate gave values agreeing with those obtained by Michael.

## EXPERIMENTAL.

*Brucine  $\alpha$ -Crotonate.*—This salt, which was prepared by neutralising a boiling aqueous solution of  $\alpha$ -crotonic acid with brucine, is exceedingly soluble in water, alcohol, or benzene; 5 grams dissolve in 7 c.c. of hot benzene, and the salt slowly crystallises out in hexagonal prisms, which soften at  $90^\circ$  and melt at  $125^\circ$ .

*Quinine  $\alpha$ -Crotonate.*—This salt crystallises from a hot aqueous solution in aggregates of slender needles, which melt at  $136^\circ$  without decomposition; a solubility determination at  $17^\circ$  showed that 0.3203 gram was dissolved in 13.7 grams of solution, hence the solubility of the salt in water at  $17^\circ$  is 2.4.

*"isocrotonic" Acid.*—The acid was obtained from Kahlbaum, who stated that it was prepared by heating  $\beta$ -hydroxybutyric acid, and freed from  $\alpha$ -crotonic acid, as far as possible, by distillation *in vacuo* and by freezing out the last traces of the  $\alpha$ -isomeride at  $-20^\circ$ . Several analyses of the acid were made, but the percentages of carbon were invariably found to be too low (compare Michael and Schulthess, *loc. cit.*).

0.1845 gave 0.3732  $\text{CO}_2$  and 0.1145  $\text{H}_2\text{O}$ . C = 55.16; H = 6.89.

0.1950 ,, 0.3920  $\text{CO}_2$  ,, 0.1243  $\text{H}_2\text{O}$ . C = 54.82; H = 7.08.

$\text{C}_4\text{H}_6\text{O}_2$  requires C = 55.8; H = 6.97 per cent.

On distilling 100 grams of "*isocrotonic*" acid, about 40 grams boiled at  $87^\circ$  under 15—30 mm. pressure; the residue in the distilling flask became solid at the ordinary temperature, and the distillate was no purer than the original acid.

0.1773 gave 0.3515  $\text{CO}_2$  and 0.1190  $\text{H}_2\text{O}$ . C = 54.06; H = 7.45.

The analysis showed that it was not possible to purify the acid by further distillation. The liquid  $\beta$ -crotonic acid passed slowly into  $\alpha$ -crotonic acid and solidified completely.

*Brucine  $\beta$ -Crotonate.*—This salt is very soluble in water, alcohol, or benzene; from the last solvent, it crystallises out in prismatic needles, which melt between  $98^\circ$  and  $100^\circ$  without decomposition.

*Quinine  $\beta$ -Crotonate.*—The salt was prepared from the crude  $\beta$ -crotonic acid, and also from the acid which had been freshly distilled; the first crop of crystals melted at  $147^\circ$ , and on recrystallisation from water the fraction which separated first melted at  $156$ — $158^\circ$ , the melting point being unchanged on repeated crystallisation from this solvent. The mother liquors, from the crystallisation of the fraction melting at  $147^\circ$ , gave crystals which melted at  $134$ — $136^\circ$ . It would seem as if the two quinine salts crystallised together in about

equal quantities, and, on recrystallisation, separated into a less soluble form melting at 156—158° and a more soluble form melting at 134—136°.

$\beta$ -Crotonic acid, which had been distilled *in vacuo* at 87°, gave a quinine salt which melted at 147°. Seventy grams of the quinine salt (m. p. 147°), obtained from 30 grams of redistilled  $\beta$ -crotonic acid, gave, on recrystallisation, 60 grams of salt melting at 156°. The mother liquors were found to contain the quinine  $\alpha$ -crotonate (m. p. 132°). There is no evidence that quinine  $\beta$ -crotonate changes into the  $\alpha$ -salt on crystallisation from water. The quinine  $\beta$ -crotonate crystallises in prismatic needles; an air-dried specimen of the crystals, on heating at 105°, does not lose in weight. A determination of the solubility of the salt gave the following numbers: 13.5930 grams of a saturated aqueous solution at 17° contained 0.1410 gram of the salt, hence its solubility in water at 17° is 1.04.

0.3045 gave 18 c.c. moist nitrogen at 16° and 757 mm.  $N = 6.97$ .

0.1858 „ 0.4805  $CO_2$  and 0.1212  $H_2O$ .  $C = 70.5$ ;  $H = 7.24$ .

$C_{20}H_{24}O_2N_2 \cdot C_4H_6O_2$  requires  $C = 70.24$ ;  $H = 7.31$ ;  $N = 6.83$  per cent.

*Barium  $\beta$ -Crotonate.*—The quinine  $\beta$ -crotonate (m. p. 157°) was dissolved in hot water and decomposed by a slight excess of baryta water. The quinine was filtered off and a current of carbon dioxide passed through the filtrate in order to remove excess of baryta. The clear liquid was concentrated to a small bulk *in vacuo* at 50° and poured into alcohol; the barium salt was precipitated in large, lustrous, rhomboid plates, which contained a molecule of water of crystallisation.

0.9925 (air-dried) lost, at 110°, 0.0562  $H_2O$ .  $H_2O = 5.64$ .

0.2255 (dried at 110°) gave 0.1723  $BaSO_4$ .  $Ba = 44.85$ .

$(C_4H_5O_2)_2Ba \cdot H_2O$  requires  $H_2O = 5.53$ .  $(C_4H_5O_2)_2Ba$  requires  $Ba = 44.62$  per cent.

### *$\beta$ -Crotonic Acid.*

The barium  $\beta$ -crotonate was covered with pure ether and a little water added; the calculated quantity of 10 per cent. sulphuric acid was added drop by drop, the mixture being thoroughly shaken; the barium sulphate was removed by filtration and the clear ethereal solution of  $\beta$ -crotonic acid was concentrated *in vacuo* at the ordinary temperature. On cooling, the liquid acid solidifies immediately in long needles melting at 15°. Wislicenus gives the melting point of the acid as 15.5°; the melting point with the thermometer in the solid is 14—15°.

0.1856 gave 0.3765  $\text{CO}_2$  and 0.1161  $\text{H}_2\text{O}$ .  $\text{C} = 55.32$ ;  $\text{H} = 6.94$ .

0.1895 „ 0.3845  $\text{CO}_2$  „ 0.1180  $\text{H}_2\text{O}$ .  $\text{C} = 55.33$ ;  $\text{H} = 6.91$ .

$\text{C}_4\text{H}_6\text{O}_2$  requires  $\text{C} = 55.8$ ;  $\text{H} = 6.97$  per cent.

A molecular weight determination in glacial acetic acid gave the following numbers:

0.3903 in 16.7390 glacial acetic acid gave  $\Delta t = 1.062^\circ$ .  $\text{M. W.} = 85.6$ .

$\text{C}_4\text{H}_6\text{O}_2$  requires  $\text{M. W.} = 86$  per cent.

The density of the acid was found to be  $D_4^{25} = 1.0342$ ; Wislicenus (*loc. cit.*) obtained  $D_4^{15} = 1.0312$ .

Mr. Gold, of St. John's College, was kind enough to determine the refractive index of the acid for sodium light:  $\mu_D^{15} = 1.4483$ , molecular refraction = 37.27. The molecular refraction for  $\alpha$ -crotonic acid is 36.94 (Kannonikoff, *J. pr. Chem.*, 1885, [ii], 31, 347).

In order to test the purity of the  $\beta$ -crotonic acid obtained from the quinine salt, the following experiments were performed:

(a) 0.5 gram of the acid was dissolved in 7.5 c.c. of absolute alcohol and neutralised by a 10 per cent. absolute alcoholic solution of sodium hydroxide. The solution remained quite clear, which showed that the acid was free from  $\alpha$ -crotonic acid.

(b) Two grams of the acid were dissolved in 29.5 c.c. of absolute alcohol and the solution carefully neutralised by the alcoholic sodium hydroxide solution. An exceedingly slight precipitate formed, which was found to contain sodium carbonate. After filtration, the solution was evaporated to dryness, and the solid residue was extracted with 50 c.c. of absolute alcohol; the solid dissolved completely. From the alcoholic solution, the sodium  $\beta$ -crotonate was obtained, analysed, and its solubility in the solvent was determined.

0.255, dried at  $100^\circ$ , gave 0.1657  $\text{Na}_2\text{SO}_4$ .  $\text{Na} = 21$ .

$\text{C}_4\text{H}_5\text{O}_2\text{Na}$  requires  $\text{Na} = 21.3$  per cent.

4.759 grams of a saturated 99 per cent. alcoholic solution of sodium  $\beta$ -crotonate at  $15^\circ$  contained 0.3295 gram of the salt, therefore 1 part of the salt dissolves in 14.4 parts of 99 per cent. alcohol. Michael and Schulthess found that one part of the sodium  $\beta$ -crotonate dissolves in 16.7 parts of 99.5 per cent. alcohol at  $11^\circ$ , and in 12.7 parts of 98—99 per cent. alcohol at  $15^\circ$ .

#### *The Oxidation of Liquid $\beta$ -Crotonic Acid.*

“isoCrotonic” acid, obtained from Kahlbaum, was oxidised by barium permanganate according to the directions given by Fittig and Kochs (*Annalen*, 1892, 268, 16). The  $\alpha\beta$ -dihydroxybutyric acid was obtained as a syrup, although in one preparation some crystals appeared

in the form of long prisms with domed shaped ends, identical in appearance with those described by Fittig and Kochs (*loc. cit.*) as characteristic of  $\alpha\beta$ -dihydroxybutyric acid prepared from  $\alpha$ -crotonic acid. The yield of the syrup was the same as in the case of the oxidation of  $\alpha$ -crotonic acid. The brucine salt of this  $\alpha\beta$ -dihydroxybutyric acid is identical in melting point, specific rotatory power, and solubility with the  $\alpha\beta$ -dihydroxybutyric acid described in a former paper. Fractional crystallisation of the brucine salt gave a product melting at  $285^\circ$ , which amounted to more than 50 per cent. of the total weight of the salt taken. The "isocrotonic" acid contained so much of the  $\alpha$ -crotonic acid that it was found impossible to confirm Fittig and Koch's results. Investigation of the quinine salt gave the same results as in the case of the brucine salt. The proportion of quinine *cis*- $\alpha\beta$ -dihydroxybutyrate was at least 90 per cent. of the weight of the unrecrystallised quinine salt. The silver salt of this  $\alpha\beta$ -dihydroxybutyric acid was prepared, and its solubility compared with that of the silver *cis*- $\alpha\beta$ -dihydroxybutyrate. The solubilities at  $17^\circ$  were practically the same, being 3.2 and 3.1; the solubilities of the two  $\alpha\beta$ -dihydroxybutyrates at  $15^\circ$  and  $13^\circ$  are 1.45 and 5.1 respectively (Fittig and Kochs, *loc. cit.*).

## XL.—*Certain Organic Phosphorus Compounds.*

By AUGUSTUS EDWARD DIXON, M.D.

SOME few years ago, the author called attention to the existence of a kind of tautomerism, in which the mobility of hydrogen, or other monadic radicle, plays no part. The phenomenon, which takes the form of an apparent variability in the mode of attachment of a whole group, is observable amongst the so-called "thiocyanates" of organic acids, many of these exhibiting the power to interact, according to the conditions under which they are placed, either as such or as thiocarbimides (Trans., 1901, 79, 541). Following up the study of this peculiar behaviour, which seems to be confined exclusively to members of the class named,\* the writer was led to inquire whether a like

\* The isomeric rearrangement of a thiocyanate into a thiocarbimide is well known, for instance, that of allyl thiocyanate into the corresponding thiocarbamide, a change which occurs spontaneously on keeping. Amongst paraffinoid derivatives, the tendency to change is slight; nevertheless, a case has been observed, for Hofmann has recorded (*Ber.*, 1885, 18, 2197) the partial conversion of methyl thiocyanate into methylthiocarbimide by heating for several hours at a temperature of some  $50^\circ$  above the boiling point of the former. But these rearrangements are not

power would be manifested by the thiocyanates of mineral acid radicles, and some evidence was adduced (*loc. cit.*) to show that phosphorus and phosphoryl thiocyanates (which, however, were only obtained in solution) possess to a certain extent the characters of thiocarbimides. Since then, means have been found of isolating both these compounds with but little difficulty and the present paper includes a description of the methods employed, the properties of the products, and the results obtained by bringing them into contact with nitrogenous bases.

Before proceeding to the experimental data, it should, perhaps, be recalled that many new facts have lately come to our knowledge concerning the thiocyanates of organic radicles and their isomerides, the "mustard-oils," H. L. Wheeler having especially contributed in this direction. Amongst other things, it has now been established that double decomposition between metallic thiocyanates and halogen derivatives of substituted methanes does not necessarily lead to the formation of the corresponding thiocyanates, but that thiocarbimides are sometimes produced instead. Thus, potassium thiocyanate, when heated with phenyl-*p*-tolylmethyl bromide dissolved in benzene, yields the thiocarbimide,  $C_6H_4Me \cdot CHPh \cdot NCS$ , although benzyl-*p*-tolyl bromide is mainly converted into the corresponding thiocyanate (Wheeler and Jamieson, *J. Amer. Chem. Soc.*, 1902, 24, 746).

Phenyl- $\alpha$ -naphthylmethyl bromide and di- $\alpha$ -naphthylmethyl bromide under like treatment yield the thiocarbimides  $C_{10}H_7 \cdot CHPh \cdot NCS$  and  $(C_{10}H_7)_2CH \cdot NCS$  respectively. Diphenylmethyl bromide gives either  $Ph_2CH \cdot SCN$ , or  $Ph_2CH \cdot NCS$ , according to the conditions (Wheeler, *loc. cit.*, 1901, 26, 353), but ethyl phenyl- $\alpha$ -chloroacetate yields the thiocyno-derivative,  $CO_2Et \cdot CHPh \cdot SCN$ ; the latter, however, unites with aniline, giving rise to "diphenyl- $\psi$ -thiohydantoin,"  $PhN:C \begin{smallmatrix} S \cdot CHPh \\ NH-CO \end{smallmatrix}$ .

Further evidence of the tendency of thiocyanogen compounds to alter the character of their grouping is shown by the fact that chloroacetyl- $\alpha$ -naphthalide,  $CH_2Cl \cdot CO \cdot NH \cdot C_{10}H_7$ , gives, with potassium thiocyanate, a "labile  $\alpha$ -naphthyl- $\psi$ -thiohydantoin,"

(m. p. 147°), which changes, on boiling in dilute alcoholic solution, into the stable form,  $C_{10}H_7N:C \begin{smallmatrix} S-CH_2 \\ NH \cdot CO \end{smallmatrix} >$  (m. p. 213—214°). Moreover,

tautomeric in this sense, inasmuch as when once effected they are permanent; at least, conditions have not yet been discovered under which an alkyl thiocarbimide will behave as the thiocyanate of its own radicle. It may be noted incidentally that the  $\cdot NCS$  group, when once established, cannot be transferred by any known direct method from the radicle with which it is combined to another.

from chloroacetyl-*m*-xylidide, the thiocyano-derivative,

can be isolated, which readily undergoes isomeric change into the stable form of thiohydantoin (Johnson, *loc. cit.*, 1903, 25, 483). It may be added here that the formulæ given by Wheeler and others for the stable varieties confirm those previously advanced (Dixon, *Trans.*, 1897, 71, 629) for the ordinary so-called thiohydantoins. The present writer observed many years ago that chloroacetanilide, when heated in dilute alcohol with potassium thiocyanate, yields not only phenylthiohydantoic acid, but, in addition, a considerable proportion (62 per cent. of the theoretical) of phenylthiohydantoin, a substance which is also produced either from chloroacetanilide and thiocarbamide, or from phenylthiocarbamide and ethyl chloroacetate (Meyer, *Ber.*, 1877, 10, 1965). However, the fact that this substance results indifferently from compounds containing thiocyano- or thiocarbimino-groups does not conclusively prove that the former radicle changes into the latter. Another interesting action, which shows the power of the  $\cdot\text{SCN}$  radicle to combine occasionally with a base, is the union of 1 mol. of aniline with trimethylene thiocyanate, thereby forming phenyl- $\psi$ -trimethylenedithiobiuret,  $\text{CH}_2\left\langle\begin{smallmatrix}\text{CH}_2\cdot\text{S}\cdot\text{C}(\text{NH}) \\ \text{CH}_2\cdot\text{S}\cdot\text{C}(\text{NH})\end{smallmatrix}\right\rangle\text{NPh}$  (Wheeler and Merriam, *loc. cit.*, 1902, 24, 446).

The case of acidic thiocyanates is somewhat complex. Since the electro-positive character of the unsaturated hydrocarbon groups is commonly less marked than that of the saturated, it might be anticipated that the thiocyanates of pronounced electro-negative radicles would tend still more readily to pass into the thiocarbimidic form, and to some extent this is true, for the derivatives of benzenoid acids exhibit mainly (although not exclusively) the properties of thiocarbimides; in fact, Miquel, the discoverer of benzoyl "thiocyanate" (*Ann. chim. phys.*, 1877, [v], 11, 300), states that if pure it is hydrolysed by water into benzamide and carbon oxysulphide, but yields no thiocyanic acid, and hence ought to be regarded as a true thiocarbimide.

Now, the substance in question, when formed by heating benzoyl chloride dissolved in benzene with lead thiocyanate for a few minutes, may give, by combination with alcohols or nitrogenous bases, yields of the corresponding additive products amounting to fully 90 per cent. of the theoretical (compare *Trans.*, 1896, 69, 1603; 1899, 79, 379), and hence if benzoyl thiocyanate is formed at all in the initial decomposition, which necessarily occurs at a very moderate temperature, its existence as such is short.

On the other hand, thiocyanates derived from certain fatty acids appear capable of exhibiting the kind of tautomerism previously men-

tioned, with respect to the CNS group : stearyl thiocyanate, for example, gave (*loc. cit.*, 1602) with benzylaniline more than 95 per cent. of the possible yield of the trisubstituted thiocarbamide, whilst with ammonia the products were substantially thiocyanic acid and stearamide.

Occasionally, a substance of this class can not only act separately in either form, but also simultaneously in both : acetyl thiocyanate, for instance, is decomposed by water (Miquel, *loc. cit.*), mainly into acetic and thiocyanic acids ; it can unite almost quantitatively with *p*-toluidine to form acetyl-*p*-tolylthiocarbamide ; whilst if brought into contact with aniline at the ordinary temperature, it yields acetylphenylthiocarbamide and acetanilide, together with aniline thiocyanate. In relation to aniline, Doran's observation has already been mentioned, that the power of acetyl thiocyanate to behave either as such, or as acetylthiocarbimide, is conditioned mainly by the temperature at which the interaction is brought about (*Trans.*, 1901, 79, 543 ; *Proc.*, 1904, 20, 20).\*

If any analogy may be looked for between the thiocyanates of electro-negative organic, and of electro-negative mineral radicles, it would presumably take the form of a similar capacity, on the part of members of the latter class, to manifest thiocarbimide in addition to thiocyanic functions ; or possibly, under certain conditions, to act as thiocarbimides, pure and simple. No investigation from this point of view seems as yet to have been conducted, excepting a superficial one by the writer. The present study, indeed, notwithstanding that upwards of two years have been devoted to it, has scarcely passed the preliminary stage, but circumstances having arisen which will for some little time interfere with the prosecution of this research, an account of the principal results so far attained is now submitted.

### *Phosphorus "Trithiocyanate."*

Phosphorus trichloride interacts spontaneously with dry ammonium thiocyanate ; the violence of the direct action may be suitably checked by mixing the finely-powdered thiocyanate with enough benzene to make a thin paste, and then adding the phosphorus halide diluted with three or four times its own volume of the same solvent. The mixture instantly becomes hot, and must be kept in rapid motion for a short

\* The behaviour of these substances is sometimes very puzzling. For instance, propionylthiocarbimide and benzylaniline gave (*Trans.*, 1896, 69, 859) nearly 90 per cent. of the possible yield of propionylphenylbenzylthiocarbamide, but with piperidine it afforded piperidine thiocyanate. In another experiment, sodium ethoxide was added to the acetyl compound, dissolved in benzene, in the hope of realising the change,  $\text{NaOEt} + \text{AcNCS} = \text{NaOAc} + \text{EtNCS}$  ; vigorous action occurred, the products being sodium thiocyanate and ethyl acetate, but not a trace of ethylthiocarbimide could be detected.

time, otherwise a portion of the contents may be projected out of the flask. It is well to use about one and a half times the amount of thiocyanate calculated from the equation,

if the process is successfully conducted, there is but little change of colour, and in a few minutes the benzene solution becomes practically free from chlorine. By using dilute solutions, all danger of violent action is precluded, but it may then be necessary either to allow the mixture to remain for about a day, or to boil in order to eliminate the chlorine, and in these circumstances a yellow or bright orange-coloured solid develops, which appears to consist mainly of pseudo-sulphocyanogen together with isoperthiocyanic acid. When cool, the residue of ammonium chloride and thiocyanate is filtered off at the pump, washed a few times with dry benzene, and the clear filtrate heated on the water-bath under reduced pressure until no more solvent can be extracted. On distilling the pale brown liquid thus obtained *in vacuo*, the thermometer rose quickly to about  $168^\circ$ , when a few drops of liquid passed over; the contents of the flask now became very dark and semi-solid, and from this product, by careful heating, a clear, pale yellow oil could be distilled, the whole distillate usually passing over within one or two degrees. In various preparations, the following boiling points and pressures were observed:  $170^\circ/20$  mm.;  $172^\circ/21$  mm.;  $173^\circ$  and  $175^\circ/27$  mm.;  $175^\circ/28$  mm., and  $180^\circ/30$  mm. On rectification, two specimens were obtained boiling at  $169^\circ/20$  mm. and at  $161^\circ/14$  mm. respectively; the latter sample, when again rectified, boiled at  $163^\circ/15$  mm.; in all cases, a considerable amount of dark, viscid residue was left. These figures are mentioned in detail, because, although they seem to indicate a perfectly definite compound, reasons will be assigned later on for doubting whether the product is really homogeneous.

The distillation is rather troublesome, being attended with much spirting and frothing of the viscid paste, and the slight irregularities noticeable in the boiling points are perhaps due to the projection of liquid drops against the bulb of the thermometer.

The best yield, from 14 grams of trichloride, was only 41 per cent. of the theoretical. The smaller yields obtained from larger batches were probably due to the decomposition of the substance caused by prolonged exposure at the somewhat high temperature.

Potassium thiocyanate interacts very imperfectly with phosphorus trichloride (compare Trans., 1901, 79, 545), and although the corresponding lead salt acts well enough, the mixture sometimes requires prolonged boiling in order to complete the change.

When exposed to air, the distilled oil slowly evolves fumes of thio-

cyanic acid, but does not spontaneously inflame, even on warming. In the cold, it has a faint alliaceous odour, which becomes penetrating and exceedingly disagreeable on heating the oil with water; this mixture is not luminous in a darkened room; even when very slightly impure, the liquid soon darkens and becomes turbid. A specimen, when thrice distilled, was found to have a sp. gr. 1.487 at 15.5°; this figure differs considerably from that given by Miquel (*loc. cit.*), who found a sp. gr. 1.625 at 18° for a product distilled under the ordinary pressure. In relation to solvents, it corresponded with his description in all respects, except one, which will be mentioned later.

Analysis gave: S = 46.9; N = 20.1; P = 15.0.

$C_3N_3S_3P$  requires S = 46.83; N = 20.48; P = 15.12 per cent.

When thrown into water, the oil at once commences to dissolve, but does not entirely disappear, the solution containing thiocyanic and phosphorous acids. These, however, are not the only products, for if it is mixed with silver nitrate and the precipitated silver thiocyanate dissolved by ammonia, the liquid remains dark and turbid, owing to the presence of a little silver sulphide; moreover, if it is heated with alkaline solution of lead salts, very perceptible desulphurisation occurs. Consequently, although the oil behaves mainly as a thiocyanate in so far as the aqueous extract is concerned, the latter also gives to some extent the reactions of a thiocarbimide. On the other hand, if the oil is dropped into hot alkaline solutions of lead or silver salts, copious desulphurisation occurs instantly, the substance thus exhibiting in a marked degree the characters of a thiocarbimide.

On mixing the oil (1 mol.) and aniline (3 mols.) in warm benzene, much heat was developed and a tenacious oil separated; after prolonged exposure to air, this became partly crystallised, but when the oil was removed by means of acetone, the crystalline residue proved to be merely phenylthiocarbamide. With cooled solutions, a pasty, amorphous solid was obtained, which hardened when kept out of contact with moisture, but which, when powdered and washed successively with benzene and light petroleum, still retained a trace of viscid matter; it softened at about 67° and melted somewhat indefinitely two degrees higher. The yellow powder contained a little aniline thiocyanate, for if shaken with water, in which it was practically insoluble, the liquid was distinctly reddened by ferric chloride, and gave with bleaching powder the violet reaction for aniline. When heated with water, it dissolved readily, a little hydrogen sulphide being evolved; the solution reacted freely for thiocyanic and phosphorous acids and for aniline, and deposited phenylthiocarbamide on cooling. It was easily soluble in ether, alcohol, and some other solvents, but when recovered from solution, either by evaporation or by precipitation, it always separated

either as a liquid or a paste. The indefinite melting point was suggestive of an impure compound, but as no satisfactory method of purification could be devised, the well-washed crude product was partially analysed, with the following results:

Found, S = 21.3; N = 16.5; P = 6.2.

These figures agree only indifferently with the composition  $P(SCN)_3 \cdot 3C_6H_5 \cdot NH_2$  or  $C_{21}H_{21}N_6S_3P$ , which would require S = 19.83; N = 17.35; P = 6.4 per cent.

*o*-Toluidine, when employed in a similar manner, yielded a smeary brown oil, from which only *o*-tolylthiocarbamide could be extracted. The distilled oil was soluble in alcohol, with which it interacted at once, considerable heat being developed; thiocyanic acid escaped, and a viscid paste was left which did not crystallise or become solid even after two months.

It has already been mentioned that in one respect the phosphorus thiocyanate did not correspond with Miquel's description. According to this author, the substance is but very slowly acted on by water, which decomposes it into thiocyanic and phosphorous acids. This was not exactly the present writer's experience, for cold water attacked the oil rapidly, the solution obtained by shaking the two together for a few seconds containing a large amount of thiocyanic acid. Yet, on attempting to determine quantitatively the amount of this acid, it was found that, although the oil rapidly diminished in bulk when first placed in contact with warm water, it could not be made to dissolve completely, even by prolonged boiling, nor did the substitution of fresh water for that now charged with the decomposition products appear to diminish the amount of residual oil; moreover, the latter, after repeated extractions, ceased to afford any reaction for thiocyanic acid, even if kept for several hours in contact with water, but it was copiously desulphurised by alkaline lead or silver salts. In fact, the liquid was now apparently free from phosphorus thiocyanate, although it still displayed the characteristic properties of a true thiocarbimide.

In order to ascertain the nature of this residual oil, experiments were now conducted on a larger scale: 16.4 grams of freshly distilled oil were shaken with successive amounts of about 50 c.c. of hot water and then repeatedly boiled with this solvent; the aqueous portions at first contained large quantities of phosphorous and thiocyanic acids, but after some fifteen extractions, the cold aqueous extract no longer developed any red coloration with ferric chloride. Cold water was used in this experiment, because it was found that, no matter how often the treatment with boiling water was performed, a trace of ferric thiocyanate always appeared. After a few additional extractions, the residual oil was drawn off, its amount in this experi-

ment being 54 per cent. of the weight initially taken. In another experiment with thrice-distilled oil, the yield was 65 per cent. When dried over calcium chloride, the oil was distilled under reduced pressure, the boiling points observed being  $173-174^{\circ}$  and  $168^{\circ}$  under 22 mm. and 17 mm. pressure respectively; distillation now occurred with much less bumping than before, the contents of the flask did not solidify or even thicken, and the amount of dark-coloured residue was very small. It will be noted that the former boiling point lies very close to that observed for an unwashed specimen, whilst the latter is not very far removed from the mean of  $163^{\circ}$  and  $169^{\circ}$  under 15 and 20 mm. pressure respectively, observed on rectifying the unwashed products.

The distillate was a clear, colourless, highly refractive oil; the sp. gr. of the two specimens were 1.483 and 1.488 at  $16^{\circ}$ , whilst that of the unwashed oil, as mentioned above, was 1.487 at  $15.5^{\circ}$ . Considering that only 2 to 5 c.c. of liquid were used in the determinations, these figures are practically identical; in other words, the removal, by washing, of from about one-half to one-third of the substance of the oil did not materially affect either its specific gravity or its boiling point. These facts are consistent with the view that the oil is a homogeneous compound; for, if only slowly soluble in water, a portion might be withdrawn, leaving a residue with properties unchanged, but this refers to the physical properties alone, and does not explain why hydrolysis no longer occurs after some extractions, or why water dissolves only a portion of the oil.

On examining the distillate, it was found to undergo copious desulphurisation when warmed with alkaline solutions of lead salts or when its alcoholic solution was mixed with ammoniacal silver nitrate. But when shaken with water, the aqueous portion gave not a trace of red coloration with ferric chloride, and hence, not only was the phosphorus trithiocyanate (assuming that to be the source of the thiocyanic acid produced by contact with water) completely removed by washing, but, moreover, the residual portion did not regain the power to behave as a thiocyanate after having been subjected to a moderately high temperature. Excepting that it was practically insoluble in water, the new substance had properties very similar to those of the unwashed material, and when analysed gave the following results:

Found, S = 47.2. N = 20.9; P = 15.2.

$C_3N_3S_3P$  requires S = 46.83. N = 20.49; P = 15.12 per cent.

Now if true phosphorus trithiocyanate is hydrolysed by contact with water, the liquid isolated by the foregoing method must be an isomeride, and hence, presumably, the hitherto unknown phosphorus

trithiocarbimide. Obviously, the next step was to ascertain whether it possessed the characteristic property of uniting with a primary nitrogenous base so as to yield the corresponding thiocarbamide.

In order to test this point, a benzene solution of aniline was slowly added from a burette to a weighed quantity of the pure oil, freely diluted with this solvent, and kept near the freezing point of the mixture. A finely-divided white solid at once began to separate, and the addition of the aniline was continued until a portion of the filtered liquid, when treated with a few drops of the solution, just ceased to yield any further precipitate, this stage being reached when, for each mol. of the oil taken, one mol. of aniline had been used. Excess of base was avoided, because it readily combines with the solid product, turning it into a viscid paste. The white powder was filtered off and washed thoroughly with dry benzene; on allowing the filtrate to evaporate, there was scarcely any residue, thus showing that the aniline had almost completely removed the dissolved oil; the solid product, when dry, amounted to nearly 98 per cent. of the total weight of materials used.

When heated in a narrow tube, the substance melted sharply without effervescence at  $116-117^{\circ}$  (corr.), changing into a golden-yellow liquid.

Found,  $S = 32.1$ .  $N = 18.2$ ;  $P = 10.25$ .

$C_9H_7N_4S_3P$  requires  $S = 32.21$ ;  $N = 18.79$ ;  $P = 10.40$  per cent.

Accordingly, the product was a definite additive compound,  $P(CNS)_3 \cdot C_6H_5 \cdot NH_2$ . Cold water had practically no effect on it excepting after prolonged contact, but if warmed on the water-bath the mixture gradually became clear, a little hydrogen sulphide being evolved; when this was boiled off, the solution contained a large amount of thiocyanic acid, and was freely desulphurised by heating with alkaline lead tartrate. The source of the desulphurisation was phenylthiocarbamide, which separated in large crystals as the liquid cooled; only a trace of aniline could be detected and the solution, when oxidised by nitric acid, gave the reactions of phosphoric acid with magnesia mixture and with ammonium molybdate.

It is curious to note that, whilst the parent oil is scarcely affected by water, even at the boiling point, yet after union with 1 mol. of aniline the resultant compound is easily hydrolysed, the uncombined CNS groups when thus separated making their appearance mainly as thiocyanic acid, although a little hydrogen sulphide is also formed. In order to follow more clearly the course of the hydrolysis, some quantitative experiments were carried out, a few of which may be mentioned.

To determine the amount of hydrogen sulphide liberated, a weighed

quantity of the solid was digested on the water-bath for half an hour with excess of arsenious acid solution slightly acidified with hydrochloric acid; the arsenious sulphide was collected, washed, dissolved by boiling for some hours with water, and the arsenic estimated by standard iodine; the sulphur thus precipitated amounted to about 4 per cent. Then, by boiling a weighed quantity with water, allowing to cool, and collecting the phenylthiocarbamide formed, it was found that six-sevenths of one-third of the total sulphur, or 9.2 per cent., came out in this form, instead of 10.7. The solution of a weighed quantity, hydrolysed by water alone, was next treated with excess of silver nitrate, the mixed sulphide and thiocyanate separated by means of ammonia, and the latter salt, after precipitation with dilute nitric acid, collected, dried at 110°, and weighed; the mean of three fairly concordant determinations was 18 per cent. of sulphur in the form of thiocyanic acid, thus accounting for 97 per cent. of the total sulphur. The last result was checked in another way, by colorimetric estimation with a ferric salt, using *N*/400 potassium thiocyanate as standard; although this process is not very accurate, it was thus found that approximately two-thirds of the sulphur were hydrolysed to thiocyanic acid.

Neglecting the formation of the hydrogen sulphide, the hydrolysis takes the following course: one  $\cdot\text{NCS}$  radicle is eliminated with the aniline residue as phenylthiocarbamide, and the two remaining  $\text{CNS}$  groups appear as thiocyanic acid; these results may be summed up by the equation:

Assuming, for the moment, that the parent compound is wholly thiocarbimide as to the contained  $\text{CNS}$ , it may appear strange that of the three  $\cdot\text{NCS}$  groups one alone should exhibit pronounced activity in uniting with aniline, but so far as this is concerned the case is not without a parallel, the author having already observed a similar peculiarity with carbonyldithiocarbimide,  $\text{CO}(\text{NCS})_2$ ; this substance, when treated with aniline until the precipitation of solid matter was just complete, gave carbonylthiocarbimidophenylthiocarbamide,  $\text{SCN}\cdot\text{CO}\cdot\text{NH}\cdot\text{CS}\cdot\text{NHPh}$  (*Trans.*, 1903, 83, 89). In this case, it was found possible, by allowing the thiocarbimide to remain for a day or so in contact with excess of base, to obtain the dithiocarbamide,  $\text{CO}(\text{NH}\cdot\text{CS}\cdot\text{NHPh})_2$ , but with benzyaniline only 1 mol. could thus be added. From these few data, it would be unsafe to generalise; nevertheless, so far as they go, they tend to indicate that, as  $\cdot\text{NCS}$  groups accumulate in the acid molecule, their characteristic power of uniting with primary and secondary nitrogenous bases to yield thiocarbamides becomes weakened. This may be equally true for certain combinations with inorganic radicles, and, if so, when a single phos-

phorus atom is united with three supposed thiocarbimidic radicles, the fact that one alone is capable of readily discharging the function peculiar to these groups, although no more intelligible than before, is nevertheless not quite abnormal.

Without making assumptions with regard to the nature of the contained CNS groups, it is convenient to call that portion of the phosphoretted oil which is removed and hydrolysed by water, "phosphorus thiocyanate," and that fraction which is not, "phosphorus thiocarbimide." The monophenylthiocarbamidic derivative of phosphorus thiocarbimide, when suspended in warm benzene and mixed with 2 mols. of aniline, united with the latter quantitatively, forming a viscid oil, which slowly hardened ; after powdering and washing with benzene, the ill-defined product resembled that obtained by the direct action of 3 mois. of aniline on one of the unwashed distillate, and when treated with hot water, underwent hydrolysis, yielding much aniline thiocyanate, together with phenylthiocarbamide.

Found, S = 19.7 ; P = 5.9 ;  $P(CNS)_3, 3PhNH_2$  requires 19.83 and 6.4 per cent.

That the further quantity of aniline taken up by the monophenyl compound had not entered into true thiocarbamidic combination, was made evident by the result of hydrolysis, when only 30 per cent. of the total sulphur made its appearance in the form of phenylthiocarbamide.

It has been stated above that phosphorus trithiocarbimide is not attacked by water, and this is practically true. But if the oil, repeatedly washed with boiling water until the residue, when vigorously shaken with the cold or tepid solvent, does not cause the latter to give the slightest coloration with ferric chloride, is now left in contact with cold water, thiocyanic acid slowly passes into solution, so that after a few days the colour reaction may again be produced. A few washings with hot water suffice to remove all trace of the acid, but on leaving the residue with a fresh quantity of water for two or three days, thiocyanic acid can be found in solution, just as before : a sample of washed and distilled oil, thus treated nine times at intervals of five or six days, had in the end become perceptibly reduced in bulk, but the residual oil, when thoroughly washed with boiling water and then left in contact with the cold solvent, gave the reaction apparently as markedly as at the beginning. When left for six months, with occasional changes of water, the oil had not disappeared, and what was left did not seem changed, except in amount. The solution, if decidedly reddened by ferric chloride, always gave a slight, but distinct, desulphurisation when heated with alkaline lead or silver

salts; it is therefore probable that the "phosphorus thiocarbimide" slowly dissolves in the water as such, but cannot accumulate to any appreciable extent, because the solution soon undergoes hydrolysis. If the aqueous mixture is kept for a month, it still gives only a slight desulphurisation when freed from the oil, whilst the thiocyanic reaction has now become strongly marked.

Sharply contrasted with this reversion, which is so slow and minimal that it might easily escape notice, is the copious and rapid production of thiocyanic acid, which occurs on dissolving the monophenyl compound in warm water; a possible explanation is that, when once the molecule is broken by the splitting off of the group  $\cdot\text{NH}\cdot\text{CS}\cdot\text{NHPh}$  (representing it as symmetrical), the residue becomes unstable, and decomposes forthwith into thiocyanic and phosphorous acids.

It is not easy, from the facts at present available, to understand the precise nature of the distillate first obtained from phosphorus trichloride and ammonium thiocyanate before its thiocyanic characters (with respect to water) have been practically destroyed by washing. The view that phosphorus trithiocarbimide is first formed and then decomposes partially into trithiocyanate is contrary to experience with other thiocarbimides, and is further negatived by the fact that when the trithiocarbimide has once been freed from thiocyanate, it does not afford a trace of the latter on redistillation. On the other hand, the converse assumption is not without some basis, for whilst a specimen, only once distilled, but apparently pure, judging from the analytical results, lost only about half its weight on treatment with water, another, thrice distilled, lost only about one-third. However, the preparations were not always made under precisely identical conditions as regards temperature, time, dilution, &c., so that this argument should not be pressed too far; and the direct evidence cannot yet be obtained, namely, that pure "phosphorus thiocyanate" is able to change at all into the thiocarbimide, since no means is known whereby the former can be isolated.

It might seem obvious, at first sight, that "phosphorus thiocyanate," which is acted on readily by water, must be a substance chemically distinct from "phosphorus thiocarbimide," which is not; but as the presence of much thiocyanate has scarcely any perceptible effect on either the density or the boiling point of the latter, there can be but little dissimilarity between them in respect of these physical properties. So far as the present experiments have gone, the washed oil appears to have a slightly higher boiling point than the unwashed, but the difference, if it exists, cannot exceed some two or three degrees within the limits of pressure specified. Amongst hydrocarbon derivatives, the thiocyanate of a given radicle boils, on the average,

some 11 or 12° above the thiocarbimide,\* so that, unless the difference is very small in the case of acid derivatives, the only reason for supposing the original distilled oil to be a mixture of two distinct substances lies in the fact that the rate of attack by water undergoes great retardation as the process of washing is continued. As regards the power to unite with one or three mols. of base, it does not appear to matter whether the "thiocyanate" is removed or not; moreover, it will presently be shown that a phosphoryl derivative, not washed, gives additive products precisely similar to those obtained with the washed phosphorus "trithiocarbimide."

*Phosphoryl "Thiocyanate."*

When phosphoryl chloride, diluted with dry benzene or toluene, was allowed to remain in contact with about one and a half times the amount of carefully-dried potassium or ammonium thiocyanate required according to the equation:

interaction took place spontaneously: the mixture was then separated by means of the pump into (1) a solid residue, and (2) a clear yellow filtrate, no longer smelling of oxychloride. When treated with cold water, this residue yielded chloride and unchanged thiocyanate, leaving a yellow, amorphous powder, mostly soluble in boiling water, and giving the reactions of *isoperthiocyanic* acid. The filtrate was heated on the steam-bath, under reduced pressure, until the solvent was eliminated, and the residue, a viscid, reddish-yellow syrup, was submitted to distillation in a vacuum. The clear, pale yellow, highly refractive oil thus obtained boiled at 175° (uncorr.) under 21 mm. pressure; it had a faintly pungent odour, and slowly evolved fumes of thiocyanic acid when exposed to ordinary moist air. If tolerably pure, it may be kept for weeks without material alteration, otherwise it quickly becomes turbid, depositing a red, pasty substance.

The yield of distilled product was not very satisfactory, the best attained being only 43 per cent. of the calculated quantity. As the crude oil bumps and froths considerably, a relatively large flask must be used, and the amount of material taken should not be large, for when the distillation is much retarded a good deal of black tar accumulates, which apparently is formed from the oil by prolonged heating at the boiling temperature.

A freshly distilled specimen was analysed, with the following results:

\* The difference in specific gravity is usually inconsiderable for each pair of isomerides.

Found, N = 19.15 ; S = 43.7 ; P = 14.2.

$C_3N_3S_3OP$  requires N = 19.02 ; S = 43.45 ; P = 14.02 per cent.

The sp. gr. is 1.52 at 13.5°.

When mixed with excess of cold water, the oil dissolved, undergoing hydrolysis tolerably rapidly; the solution gave with ferric chloride a deep blood-red coloration, and with ammonium molybdate or magnesia mixture the reactions of phosphoric acid. The change under these conditions is mainly that represented by the equation:  $PO(SCN)_3 + 3H_2O = 3HSCN + H_3PO_4$ , for a dilute solution, when treated successively with excess of ammonia and silver nitrate, became only slightly darkened, and was not markedly desulphurised by boiling with alkaline lead tartrate. Moreover, about half a gram of the fresh oil, when decomposed by cold water, and treated with ammonia and magnesia mixture, yielded a quantitative amount of phosphoric acid, as calculated from the above equation.

So far, therefore, the substance displays mainly the properties of a thiocyanate, but when added directly to and shaken with an alkaline solution of lead tartrate, a white precipitate was formed, which slowly became yellow and orange, and finally black; this change, which is due to the production of lead sulphide, occurred instantly on gently warming, and the alcoholic solution, when mixed with silver nitrate and ammonia, was abundantly desulphurised, even in the cold; in these circumstances, the substance exhibited markedly the characters of a thiocarbimide.

In the case of the phosphoryl compound, it was not found possible to eliminate the thiocyanate, leaving a thiocarbimidic residue, for on shaking 5 grams of the oil with about 20 c.c. of cold water, heat was developed, and the whole of the oil, except a decigram or so, rapidly dissolved, and when left for some little time, a yellow solid appeared, which was found to consist principally of *isoperthiocyanic acid*; with 14 grams of oil, a similar result was obtained.

Since a thiocarbimide, as such, could not be isolated, an attempt was made to combine the oil with organic amines, so as to obtain substituted thiocarbamides, but the experimental difficulties are very great, for, although combination occurs readily enough, the products are very unsatisfactory. Even when formed from apparently pure materials, they are often far from pure, and although usually presenting the appearance of crystallisable compounds, they have, so far, resisted every attempt made in this direction. By contact with water or with solvents containing even traces of it, they are readily hydrolysed, so that, after many failures and in the absence of any better method, carefully purified materials were used for the preparations; the products were thoroughly washed successively with benzene and

light petroleum, dried at the ordinary temperature as far as possible in the absence of moisture, and then analysed.

It will be seen from what follows that phosphoryl thiocyanate is capable of fixing primary amines, of which 1 mol. is held for each SCN group present, and this, without the formation of basic thiocyanate; nevertheless, the products are not true thiocarbamides (or, if so, differ from those at present recognised), since, when hydrolysed, they yield, not thiocarbamide alone, but a mixture of thiocarbamide with basic thiocyanate. The results obtained in the experiments were not invariably the same, although approximately so; each account given below is that of observations actually made, and not the average of a number of experiments.

*Action of Aniline.*—Eight grams of the oil were mixed with three molecular proportions of aniline, each reagent being diluted with about twice its volume of dry benzene; interaction occurred instantly, the temperature rising to the boiling point of the mixture, and a yellow, doughy paste separated, which quickly became hard, and, when broken up and dried, formed a mobile powder, the weight of which approximately equalled that of the materials taken. The substance had no definite melting point; it became translucent at 89° and frothed at 95—97°. When added to water, it was apparently quite insoluble, the mixture, even after thorough shaking, being neutral to litmus, and giving no reaction with ferric chloride or with calcium hypochlorite solution; consequently, the powder was free from aniline thiocyanate. When left for an hour or so with cold water, the mixture began to give the red thiocyanate coloration with ferric chloride, which slowly increased with the time. But if boiled with water, the solid quickly dissolved, evolving a little hydrogen sulphide and leaving a trace of viscid oil; the solution now obtained was intensely acid, contained large amounts of aniline, thiocyanate, and phosphoric acid, and on cooling deposited large crystals of phenylthiocarbamide. The production of the latter is not due to isomeric change of the aniline thiocyanate through heating, for the original solid, when dissolved in cold spirit, is desulphurised by ammoniacal silver nitrate; moreover, if it is dissolved in cold dilute aqueous caustic potash and treated with a lead salt, a white precipitate is formed, becoming successively yellow, orange, brown, and finally jet-black; the last change occurs at once on gently warming. It is unnecessary to describe in further detail the properties of this compound, for they agreed in every respect with those observed for the product obtained from the cumene solution, supposed to contain phosphoryl thiocyanate (Trans., 1901, 79, 549). Concerning the last-named product, it was mentioned (*loc. cit.*) that when hydrolysed with boiling water it

yielded barely one-third of the phenylthiocarbamide which should be formed according to the equation :

Whether the limited production of phenylthiocarbamide was normal or otherwise could not then be decided, since it was uncertain whether the cumene solution contained one substance only. This time, however, there could be little doubt as to the chemical individuality of the oil, seeing that, apart from the analytical figures, the whole 8 grams of product distilled within about  $1^\circ$ .

In repeating the experiment, 5 grams of the aniline compound were dissolved in 50 c.c. of boiling water, and the solution filtered from a trace of viscid oil ; on cooling, pure phenylthiocarbamide was deposited, the weight being 1.4 grams, corresponding with 28 per cent. of the theoretical as reckoned above ; in another experiment, 30 per cent. was obtained. A further small quantity remained in solution, but this could not safely be collected by evaporation to a small bulk, because the aniline thiocyanate present gradually changes, under the influence of heat, into phenylthiocarbamide. This result, seeing that the experiment was only a rough one, does not differ materially from that previously recorded. Although the substance used had been well washed with benzene, it was evidently not quite pure, as shown by the ill-defined melting point, and by its failure to dissolve perfectly in water ; an estimation of sulphur gave 18.9 per cent. against 19.21 calculated for  $\text{C}_{21}\text{H}_{21}\text{N}_6\text{OS}_3\text{P}$ , and the nitrogen was also too low ; the phosphorus, however, was found = 6.5, the calculated number being 6.45 per cent.

Until the methods and results now given can be improved, it may provisionally be concluded that phosphoryl thiocyanate is a definite chemical compound, which, when in contact with water, behaves as a true thiocyanate, but in presence of benzene alone can quantitatively fix three molecules of aniline, thus behaving as a typical (tri)thiocarbimide ; the product, although free from aniline thiocyanate, can, nevertheless, readily yield it by hydrolysis, together with a little hydrogen sulphide, somewhat less than one-third of the contained sulphur being simultaneously liberated in the form of phenylthiocarbamide. Of the three CNS groups present in the molecule, it appears, therefore, that only one is capable of exerting the power peculiar to the thiocarbimidic residue,  $\cdot\text{NCS}$ , of uniting with an amine so as to yield an atomic complex devoid of thiocyanic characters ; the two remaining groups, when once the former is saturated, appear to be thiocyanic in nature, although possessing a certain capacity to hold the base in combination.

It is possible to bring about union between the thiocarbimidic group alone and aniline, leaving the other two groups uncombined, as shown by the following experiment.

To a cooled solution containing 1 mol. of freshly distilled oil in about ten times its volume of benzene, 1 mol. of aniline was very slowly added with constant stirring; a minutely-divided, white, amorphous solid was precipitated, the liquor from which gave no further precipitate with aniline, and left scarcely any residue on evaporation; the solid, when thoroughly washed successively with benzene and light petroleum and dried by gently heating, was equal to 93 per cent. of the total weight of materials combined. Had the aniline combined equally with all the SCN groups, much thiocyanate must have been left, whilst the yield of solid could not have exceeded 53 per cent. of the total weight of the reagents.

The powder softened at  $119^{\circ}$  and melted at  $120\text{--}121^{\circ}$  (corr.); it was insoluble, or nearly so, in cold water, the mixture giving a feeble reaction for thiocyanic acid, but, on warming, it soon dissolved, the solution being highly acid, and containing free phosphoric and thiocyanic acids, together with phenylthiocarbamide. As usual, a trace of hydrogen sulphide was evolved, but the solution gave only a faint reaction for aniline.

Analyses gave:  $S = 30.3$ ;  $P = 9.95$ .

$C_9H_7N_4OS_3P$  requires  $S = 30.6$ ;  $P = 9.87$  per cent.

The phenylthiocarbamide produced by hydrolysis was collected and dried at  $100^{\circ}$ ; it amounted, as in the case of the phosphorous analogue, to six-sevenths of that which could be formed according to the equation:  $PhNH \cdot CS \cdot NH \cdot PO(CNS)_2 + 3H_2O = CSN_2H_3Ph + H_3PO_4 + 2HSCN$ .

When the above monophenyl compound (1 mol.) was suspended in benzene and warmed on the water-bath with aniline (2 mols.), combination occurred, a clear, brown oil being formed, which hardened to a brittle resin on cooling, the latter, when powdered, washed with benzene, and dried, amounting to 96 per cent. of the weight of materials taken; it resembled in all respects the product obtained by treating the trithiocyanate directly with 3 mols. of aniline, and gave, on analysis,  $N = 17.3$  and  $S = 18.8$  per cent., the calculated values being  $N = 16.84$  and  $S = 19.21$  for  $PO(SCN)_3, 3C_6H_5NH_2$ .

A portion, hydrolysed by warming with water for three-quarters of an hour, yielded 41 per cent. of its sulphur in the form of phenylthiocarbamide; this unusually high percentage is probably due to the transformation of a portion of the aniline thiocyanate due to prolonged heating.

*Action of p-Toluidine* (3 mols.).—When brought into contact with one

another in warm dilute benzene solution, the reagents united vigorously, the mixture boiling freely, and a trace of hydrogen sulphide being evolved; on cooling, an oil was deposited, which, when left for a few days in a vacuum, hardened to a pale yellow, amber-like resin, still smelling of benzene. The solvent evaporates very slowly, for, on analysis eight days later, the nitrogen and sulphur, although giving the ratio  $N_2 : S$ , were both found to be more than 1 per cent. below the calculated values; eventually, the solvent was removed by gently warming the powdered substance in a flask, through which a current of dry air was kept passing for some hours; it now gave the following results:

Found  $N = 15.15$ ;  $S = 17.8$ ;  $P = 5.8$ .

$C_{24}H_{27}ON_6S_3P$  requires  $N = 15.53$ ;  $S = 17.73$ ;  $P = 5.72$  per cent.

The yield of dry solid was not far from quantitative (about 95 per cent.); no definite melting point could be observed, the substance gradually softening from  $95^\circ$  onwards, until at  $100^\circ$  it formed a liquid evolving a gas.

When shaken with cold water, the mixture gave a scarcely perceptible reaction for thiocyanic acid; if boiled, it dissolved almost entirely, evolving a little hydrogen sulphide; the solution, on cooling, deposited *p*-tolylthiocarbamide, and the mother liquor gave the reactions of thiocyanic acid, phosphoric acid and *p*-toluidine. A rough experiment, made as in the case of the corresponding phenyl homologue, gave, for 1 mol. of substance, five-sixths of a mol. of *p*-tolylthiocarbamide.

*Action of  $\alpha$ -Naphthylamine* (3 mols.).—On mixing the reagents, precisely the same phenomena were observed as in the case of aniline, the product being a doughy mass, which quickly hardened; when broken up, washed, and dried, it formed a pale yellow powder, the weight of which amounted to 96 per cent. of that of the materials used.

Found,  $S = 14.85$ ;  $P = 4.6$ .

$C_{33}H_{27}ON_6S_3P$  requires  $S = 14.77$ ;  $P = 4.77$  per cent.

Heated in a narrow tube, it frothed up at  $119$ — $120^\circ$ ; cold water had no effect on the finely-powdered substance; when heated, phosphoric and thiocyanic acids passed into solution, and a bulky, white solid was left, which was recrystallised from alcohol and identified as  $\alpha$ -naphthylthiocarbamide.

Another experiment was made, using only one molecular proportion of  $\alpha$ -naphthylamine; the semi-solid product, which amounted to 96 per cent. of the weight of materials taken, presently became hard and brittle. It had properties resembling those of the corresponding aniline derivative, but was dirty orange in colour, and gave very unsatisfactory numbers on analysis, every attempt to purify the substance having failed.

*Action of Benzylaniline.*—When equal mols. were brought together in benzene solution, the mixture became warm, but remained clear. On cooling, small, white crystals separated, which were thoroughly washed with benzene; they melted sharply at 137—138° (uncorr.) and amounted to exactly the sum of the weights of the materials employed.

Found, N = 13.9; S = 21.2; P = 7.1;

$C_{16}H_{13}ON_4S_3P$  would require N = 13.89; S = 23.78; P = 7.67 per cent.

The substance was insoluble in cold water, the mixture being neutral, and giving no red coloration with ferric chloride; on boiling, there was little sign of solution, but the iron salt now produced a distinct reddening. Warm dilute caustic potash attacked the compound, forming a basic oil, probably benzylaniline, and the solution contained much thiocyanic acid. But the mixture with caustic potash was not desulphurised by boiling with lead tartrate, and the alcoholic solution darkened only slightly when treated with ammoniacal silver nitrate, so that the product of hydrolysis did not contain any considerable proportion of *aa*-phenylbenzylthiocarbamide (Trans., 1893, 63, 325). The analytical numbers for sulphur and phosphorus being unsatisfactory, an attempt was made to crystallise the substance from alcohol, but the product, an acid syrup, refused to crystallise, and the experiment was abandoned.

#### *Summary and Conclusion.*

It appears from the foregoing experimental work that phosphoryl thiocyanate is a definite chemical compound, behaving towards water exclusively as a thiocyanate. Distilled phosphorus thiocyanate, although apparently a definite substance, can be resolved, by treatment with water, into two fractions, one of which, like the whole of the phosphoryl compound, is hydrolysed with ease, whilst the other fails to undergo hydrolysis, except to a minimal extent, although its physical properties (specific gravity and boiling point) are practically the same as at first. Moreover, between that portion which no longer reacts with water and the original distillate, which may lose about half its substance by contact with this liquid, there is no material difference as regards power to combine with aniline, for either can unite with 3 mols. of this base, but holding only a portion (approximately one-third) of this amount in ordinary thiocarbamidic combination. So far, therefore, as total aniline-fixing power is concerned, it does not appear to matter whether the phosphorous derivative holds its  $\cdot CNS$  groups in a form capable of acting towards water as  $\cdot SCN$  or otherwise: in any case, one of the three will behave as  $\cdot NCS$  towards the base.

Consistently with this unexpected result, phosphoryl thiocyanate, notwithstanding that water eliminates the whole of its  $\cdot CNS$  as

thiocyanic acid (the formation of *isoperthiocyanic acid* is easily explained by the interaction of the liberated phosphoric and thiocyanic acids), can also fix three mols. of aniline, of which only one appears as phenylthiocarbamide, when the product is hydrolysed. Again, if only one molecular proportion of aniline is presented to one of phosphoryl thiocyanate, it will not distribute itself uniformly over the contained  $\cdot\text{SCN}$ , but will unite entirely with a single group, which behaves as  $\cdot\text{NCS}$  in this sense, that practically the whole of the combined base may on hydrolysis be recovered as phenylthiocarbamide. In like manner, if the phosphorous analogue, deprived by washing of practically all its power of behaving towards water as thiocyanate, is treated with one mol. of aniline, the latter will be so fixed that it may be almost completely recovered in the form of phenylthiocarbamide; but if the additive product be combined with an additional 2 mols. of aniline, the compound thus obtained will still give only one mol. of phenylthiocarbamide when hydrolysed.

The hydrolytic experiments were usually completed within a few minutes, the temperature being in the neighbourhood of  $80^\circ$ , so that the process, as conducted, could not lead to any material isomeric rearrangement of whatever basic thiocyanate might be formed; in these circumstances, the amount of substituted thiocarbamide produced was taken as a measure of the thiocarbimidic power available in each substance.

Wheeler has proposed the treatment with thiolacetic acid as a means of distinguishing between thiocyanates and thiocarbimides (*J. Amer. Chem. Soc.*, 1901, 23, 285; *Amer. Chem. J.*, 1901, 26, 348), the substances which yield carbon disulphide (and substituted amide) being regarded as thiocarbimides, and those which do not as thiocyanates. Although this appears to be a useful method of discrimination where hydrocarbon derivatives are concerned, it cannot be regarded as absolutely final in the case of acidic compounds; or, at most, it can only be used to decide how the  $\cdot\text{CNS}$  group behaves towards that particular substance at the moment of interaction, and this information does not go far enough with acidic thiocyanates, which are all more or less prone to undergo tautomeric change. Applying this method, he decides that acetyl thiocyanate is a true thiocyanate, a conclusion arrived at by Miquel from another point of view, and which is doubtless perfectly correct under certain conditions. But the totally different behaviour which it can exhibit on changing the conditions of interaction (Miquel calls it "abnormal") is most easily explained by supposing the compound to have assumed, for the time being, the thiocarbimidic configuration. It is conceivable that in the formation of acetylphenylthiocarbamide by the action of aniline, a compound,  $\text{AcS}\cdot\text{C}(\text{NH})\cdot\text{NHPh}$ , might be the first product; if, now, the acetyl group migrated to the

imino-group and the sulphur atom became doubly linked to carbon, the "abnormal" production of the disubstituted thiocarbamide could be explained. Indeed, the migration of the acetyl group in compounds already thiocarbamidic in structure is not unknown, Wheeler having adduced evidence (*Amer. Chem. J.*, 1902, 27, 274) that the change of Hugershoff's acetylphenylthiocarbamide (m. p. 139°) (*Ber.*, 1899, 32, 3649) into the isomeride melting at 171° occurs as follows :

With the data hitherto secured, it is not possible to state with certainty what is the mechanism whereby such changes are produced; but the author at present holds the view that in so far as a CNS compound unites spontaneously with aniline to yield a phenylated thiocarbamide or its immediate normal derivative it should be regarded as a thiocarbimide; from this standpoint, it becomes necessary to postulate the existence of tautomerism amongst certain "thiocyanates."

Another method of distinction proposed by Wheeler (*Amer. Chem. J.*, 1901, 26, 349) consists in reducing the alcoholic solution of the CNS compound with sodium, when thiocyanic acid is produced from a thiocyanate, but not from a thiocarbimide; this test, however, is too drastic for members of the acidic class. Thus, benzoyl thiocyanate unites directly with primary and secondary amines to form thiocarbamides; with alcohols, to form alkyl esters of thiocarbamic acid, and with phenylhydrazine to form a disubstituted thiosemicarbazide. Its behaviour towards water has already been mentioned. Even with ammonia, which often brings about double decomposition amongst the acidic thiocarbimides, it yields benzoylthiocarbamide, and consequently there can be no question as to the marked preponderance of thiocarbimidic character in this substance. Yet, as usual, a limit to the power of retaining the  $\cdot\text{NCS}$  configuration can be reached, for on treating the compound with sodium, thiocyanic acid passes into solution. Wheeler also records certain observations by T. B. Johnson, showing that when it was made to interact with ethyl sodiomalonate, sodium formanilide, sodium phenoxide or ethyl sodioacetoacetate, the  $\cdot\text{NCS}$  group was removed as sodium thiocyanate.

In the light of all the facts now available with respect to the acidic "thiocyanates" as a class, it seems tolerably safe to venture the general statement that there is no known member of this class, however pronounced its thiocarbimidic characters may be, which cannot be made to behave as a thiocyanate.

Returning now to the phosphorus compounds, it must be admitted that, since no satisfactory means of purification could be found for their derivatives, the composition of the latter has been based on the analysis of somewhat ill-defined substances; on the other hand, most

of the foregoing experiments have been repeated much oftener than appears in the paper, so that the general results may be taken as being fairly trustworthy. Probably the selection of this particular class of substances as objects of study was not a happy one, seeing that even when a single CNS group is combined with an acid radicle, it may lose its definite configuration and oscillate between  $\cdot\text{SCN}$  and  $\cdot\text{NCS}$ . When two such groups are present, one may be highly active, as  $\cdot\text{NCS}$ , whilst the other is comparatively sluggish, and easily hydrolysed out of combination, as  $\cdot\text{SCN}$ , although capable ultimately of exerting its full thiocarbimide power. Under suitable conditions, the behaviour of carbonyldithiocarbimide, referred to earlier (p. 359), may be cited as a case in point. With three such groups attached to a single mineral radicle, their limited capacity to act as  $\cdot\text{NCS}$  might perhaps almost have been anticipated. On the other hand, experiments conducted with the view of obtaining mono- and di-thiocyanates of purely inorganic acid radicles have hitherto proved unsuccessful.

In conclusion, the writer desires to express his indebtedness to Mr. R. E. Doran for assistance rendered in connection with the experimental work described above.

## XLI.—*The Action of Sodium Hypochlorite on the Aromatic Sulphonamides.*

By HENRY STANLEY RAPER, JOHN THOMAS THOMPSON, and JULIUS BEREND COHEN.

ALTHOUGH the general nature of the chemical change \* resulting from the interaction of sodium hypochlorite and the aromatic sulphonamides resembles that described by Chattaway and Orton in the case of the aromatic acylamines (Trans., 1899, 75, 1046; 1900, 77, 134, 789; Ber., 1899, 32, 3573), yet there are certain well-marked differences in the character of the products which we venture to think are not without interest.

These authors have shown that by the action of sodium hypochlorite on the acyl-anilides and -toluidides, the halogen in the first

\* A preliminary notice of this reaction has already appeared (Proc., 1901, 17, 262). We have now supplemented these experiments by extending the reaction to a number of other sulphonamides.

instance enters the para-position with respect to the amino-group if this position is free, but otherwise becomes attached to an ortho-carbon atom. The orientating effect of the sulphonic group is different; in the first instance, the halogen seeks the ortho-position with respect to the amino-group, thus the benzenesulphonamides of aniline, *p*-toluidine, *m*-4-xylydine, and  $\beta$ -naphthylamine form ortho-compounds almost exclusively. If, however, a methyl group is present and the para-position to the amino-group is free, the conditions are modified and the halogen enters either the ortho-position to the methyl group or the para-position to the amino-group. Thus, the sulphonamide of *m*-toluidine gives a derivative of 6-chloro-*m*-toluidine. There is a considerable difference also in the readiness with which the different sulphonamides react. This is very marked in the case of those bases which are substituted in the ortho-position to the amino-group. The sulphonamides of *o*-toluidine and *m*-4-xylydine are only acted on slowly, whereas the sulphonamide of  $\alpha$ -naphthylamine, which may be regarded as an *o*-substituted compound, is quite unchanged by the hypochlorite. The following table gives a list of the compounds which have been studied:

$\text{ArNH}\cdot\text{SO}_2\cdot\text{C}_6\text{H}_5$ $\text{ArNH}_2$	Melting point of the sulphonamide.	Position of the halogen relative to the amino-group.	Melting point of the chloro- sulphonamide.

*The Action of Sodium Hypochlorite on Benzenesulphonanilide.*

Twenty grams of benzenesulphonanilide were dissolved in 200 c.c. of a solution of sodium hypochlorite (1 c.c. = 0.03 gram Cl) in the cold and left for 12 hours; the brown solution was acidified with acetic acid and the semi-solid precipitate was filtered and washed. It was then dissolved in about twice its weight of glacial acetic acid, to which a few drops of strong sulphuric acid were added, and digested for an hour on the water-bath. The product was poured into water, from which a crystalline compound separated, and, when purified by recrystallisation from dilute acetic acid, melted at 129—130°; 18 grams of the crude product or 11 grams of purified substance were obtained.

The mother liquor contained a small quantity of a semi-solid substance which slowly became crystalline, and after recrystallisation from benzene and petroleum melted at  $116^{\circ}$ . This substance is probably benzenesulphon-*p*-chloroanilide (m. p.  $121^{\circ}$ ), but it is not readily freed from oily impurity. On analysis, the substance melting at  $129$ – $130^{\circ}$  gave the following numbers :

0.292 gave 14.15 c.c. moist nitrogen at  $15.5^{\circ}$  and 758 mm.  $N = 5.66$ .

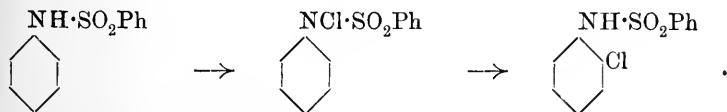

0.3185 „ 0.1764 AgCl.  $Cl = 13.57$ .

0.2097 „ 0.1820 BaSO<sub>4</sub>.  $S = 11.93$ .

C<sub>12</sub>H<sub>10</sub>O<sub>2</sub>NCIS requires  $N = 5.23$  ;  $Cl = 13.27$  ;  $S = 11.90$  per cent.

The constitution of the substance was determined by hydrolysis ; two grams were heated with about 8 c.c. of concentrated hydrochloric acid in a sealed tube at  $190^{\circ}$  for 4–5 hours. On opening the tube there was a strong odour of benzene, the presence of which was confirmed by conversion into aniline, with which sodium hypochlorite gave the usual reaction. The appearance of benzene in the decomposition of the sulphonanilide is readily accounted for, seeing that Armstrong and Field (*Ber.*, 1874, 7, 406) and Jacobsen (*Ber.*, 1876, 9, 258) have shown that sulphonic acids are converted into hydrocarbons by strong hydrochloric acid under pressure. The acid solution, after extracting with light petroleum, was made alkaline with sodium carbonate and distilled in steam ; the distillate was extracted with ether, the ether removed, and the residue dehydrated in a vacuum desiccator, when a yellow oil weighing 0.8 gram remained. The substance did not solidify on introducing a crystal of *p*-chloroaniline, even when cooled in ice ; it yielded an acetyl derivative melting at  $85$ – $86^{\circ}$  and a benzoyl derivative melting at  $102^{\circ}$ . This corresponds with *o*-chloroaniline, which was prepared for comparison and converted into the acetyl, benzoyl, and benzenesulphonyl derivatives.

The reaction probably occurs in two stages, as in the chlorination of the acetyl derivatives studied by Chattaway and Orton, although the intermediate chloroamide was too unstable to be isolated in a pure state.

The main product is therefore the *o*-chloroanilide, together with a very small quantity of the para-compound. Wallach (*Ber.*, 1877, 9, 424) found that benzenesulphonanilide, when heated at  $100^{\circ}$  with phosphorus pentachloride, yields benzenesulphon-*p*-chloroanilide (m. p.  $121^{\circ}$ ), but no reference is made to an ortho-compound. We

have repeated and confirmed Wallach's work. The product is difficult to purify, and only a small quantity of pure substance could be obtained, but we failed to detect any ortho-compound. We have also synthesised Wallach's compound from *p*-chloroaniline and benzenesulphonic chloride, and to complete the series we have also prepared benzenesulphon-*m*-chloroanilide from *m*-chloroaniline.

This anilide, which has not been previously described, melts at 121° like the para-compound.

0.2576 gave 12.85 c.c. moist nitrogen at 13° and 761 mm.;  $N = 5.76$ .

$C_{12}H_{10}O_2NClS$  requires  $N = 5.23$  per cent.

*The Action of Sodium Hypochlorite on Benzenesulphon-o-toluidide.*

Benzenesulphon-o-toluidide was described by Beckmann and Fellrath (*Annalen*, 1893, 273, 13); it crystallises from alcohol in rectangular tablets which melt at 123—124°. When treated with sodium hypochlorite in the manner already described, it gave an uncrystallisable product, but in acetic acid solution a colourless crystalline substance was obtained. If warmed with alcohol for any length of time, this compound decomposed, a portion of the alcohol being oxidised to aldehyde. From a mixture of benzene and light petroleum, the substance crystallised without any decomposition, and a product was obtained which melted at 99—100°.

0.1951 gave 0.1000 AgCl;  $Cl = 12.92$ .

$C_{13}H_{12}O_2NClS$  requires  $Cl = 12.61$  per cent.

On crystallising the foregoing compound from acetic acid solution, it becomes transformed into an isomeride melting at 124—125°.

0.1014 gave 0.0530 AgCl;  $Cl = 12.93$ .

0.1014 „ 0.0843 BaSO<sub>4</sub>;  $S = 11.41$ .

$C_{13}H_{12}O_2NClS$  requires  $Cl = 12.61$ ;  $S = 11.39$  per cent.

This substance was identified as benzenesulphon-5-chloro-*o*-toluidide, also obtained from benzenesulphonic chloride and 5-chloro-*o*-toluidine; The chlorine therefore enters the para-position to the amino-group. The isomeric substance melting at 99—100° is probably the chloro-amide,  $C_7H_7 \cdot NCl \cdot SO_2 \cdot C_6H_5$ , for on heating with alcohol it loses chlorine and reverts to the original substance. This explains both the conversion effected by acetic acid and the decomposition produced by alcohol, in which the latter reagent is oxidised to aldehyde in eliminating chlorine.

*The Action of Sodium Hypochlorite on Benzenesulphon-m-toluidide.*

Benzenesulphon-*m*-toluidide has not been previously described; it crystallises from alcohol in colourless plates melting at 95°. The action of the hypochlorite solution on this substance is much more vigorous than in the preceding cases, both mono- and di-chloro-derivatives being formed.

The *monochloro*-compound was obtained by using the theoretical quantity of sodium hypochlorite and keeping the mixture cold; after 12 hours, a large quantity of crystalline substance separated, which melted at 275—280°. This is probably a sodium derivative having the formula  $C_6H_3Cl(CH_3) \cdot NNa \cdot SO_2 \cdot C_6H_5$ ; it crystallises from ethyl acetate in fine needles.

0.8808 required 28.87 c.c. N/10  $H_2SO_4$ ; Na = 7.54.

$C_{13}H_{11}O_2NClSNa$  requires Na = 7.58 per cent.

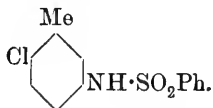

When digested for a few minutes with glacial acetic acid, the sodium compound is easily decomposed, yielding the mono-chloro-derivative, which crystallises in long, colourless prisms and melts at 130°. Five grams of the toluidide yielded 3.2 grams of the pure mono-chloro-compound.

0.3790 gave 0.1970 AgCl; Cl = 12.86.

0.3790 „ 0.3144 BaSO<sub>4</sub>; S = 11.39.

$C_{13}H_{12}O_2NClS$  requires Cl = 12.60; S = 11.37 per cent.

The constitution of the substance was determined by hydrolysis as in the previous cases. A crystalline base was obtained which melted at 83° and gave an acetyl derivative melting at 89°. These numbers correspond with the melting points of 6-chloro-*m*-toluidine and its acetyl derivative. The formula of the original compound is therefore

No other mono-chloro-compound could be detected.

*The Dichloro-compound.*—Five grams of the sulphon-*m*-toluidide were dissolved in excess of the hypochlorite solution; the whole mass subsequently solidified and was collected at the pump. After crystallisation from acetic acid, 3 grams of pure substance (m. p. 114°) and 1.7 grams of an impure product melting at about 80° were obtained. The latter is probably a mixture of the mono- and di-chloro-compounds, which are separated with difficulty. A better yield of the dichloro-compound was obtained either by warming the mixture of hypochlorite

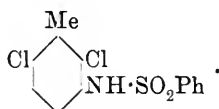

and *m*-toluidide at about 40° for a short time or by adding sodium hypochlorite solution to the monochloro-compound. The substance melting at 114° was analysed with the following result:

0.2640 gave 0.2303 AgCl. Cl = 21.60.

0.2640 „ 0.2030 BaSO<sub>4</sub>. S = 10.53.

C<sub>13</sub>H<sub>11</sub>O<sub>2</sub>NCl<sub>2</sub>S requires Cl = 22.4; S = 10.10 per cent.

On hydrolysis, a crystalline base was obtained, which was recrystallised from alcohol and melted at 58°, its acetyl derivative melting at 121°. The base was further identified by successive conversion into 2:3:6-trichlorotoluene (m. p. 45—46°), 2:3:6-trichlorobenzoic acid (m. p. 165°), and dinitro-2:3:6-trichlorotoluene (m. p. 141—142°) (compare Cohen and Dakin, Trans., 1902, 81, 1333). The structure of the sulphon dichloro-*m*-toluidide is accordingly represented as follows:

It is interesting to compare the action of the hypochlorite on the benzenesulphonyl and acetyl derivatives of *m*-toluidine. In the acetyl derivative, the hypochlorite produces substitution in the ortho- and para-positions to the methyl group (Cohen and Dakin, Trans., 1902, 81, 1332); in the sulphonamide, the chlorine atoms enter the two ortho-positions.

#### *Action of Sodium Hypochlorite on Benzenesulphon-p-toluidide.*

Benzenesulphon-*p*-toluidide was described by Wallach (*Ber.*, 1876, 9, 424), who states that it does not yield a halogen derivative with phosphorus pentachloride, and attributes the fact to the presence of the methyl group in the para-position to the amino-group. With sodium hypochlorite, the reaction goes quite smoothly, and benzenesulphon-3-chloro-*p*-toluidide (m. p. 110°) is obtained, 5 grams of the toluidide giving 3.5 grams of pure product.

0.4020 gave 0.2068 AgCl. Cl = 12.73.

0.4020 „ 0.3383 BaSO<sub>4</sub>. S = 11.54.

C<sub>13</sub>H<sub>12</sub>O<sub>2</sub>NClS requires Cl = 12.60; S = 11.37 per cent.

On hydrolysis with hydrochloric acid, 2 grams of the compound gave 0.9 gram of a yellow, oily base, which solidified on cooling in ice, and yielded an acetyl derivative melting at 118°. These properties agree with those of the 3-chloro-*p*-toluidine. The chlorine, therefore, enters the ortho-position to the amino-group. An excess of hypochlorite produced no further substitution.

*The Action of Sodium Hypochlorite on Benzenesulphon-m-4-xylylide.*

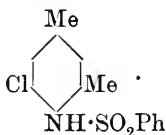

Benzenesulphon-*m*-4-xylylide, which has not been previously described, is prepared in the usual way, and crystallises in colourless prisms melting at 124—125°. When treated with sodium hypochlorite solution, it remained unchanged, but in acetic acid a small amount of chlorination product was obtained, the yield being augmented by carrying out the reaction at about 50°. The white solid which separated was recrystallised from alcohol and melted at 148—149°. Six grams of the *m*-xylylide gave 4·2 grams of pure product.

0·1293 gave 0·0619 AgCl. Cl = 11·84.

0·1293 „ 0·1004 BaSO<sub>4</sub>. S = 10·66.

C<sub>14</sub>H<sub>14</sub>O<sub>2</sub>NClS requires Cl = 11·89 ; S = 10·72 per cent.

On hydrolysis, 2 grams of the chlorination product gave 0·8 gram of a colourless, crystalline base melting at 39—40°, which formed an acetyl derivative melting at 200—201°. The base obtained on hydrolysis is identical with 5-chloro-*m*-4-xylidine.\* The sulphon-5-chloro-*m*-4-xylylide has therefore the following structure :

An excess of sodium hypochlorite had no further action.

*Sodium Hypochlorite and Benzenesulphon-α-naphthalide.*

The sulphon-α-naphthalide obtained by the action of benzenesulphonic chloride on α-naphthylamine crystallises from alcohol in colourless needles melting at 168°; it dissolves in aqueous sodium hypochlorite forming a deep brown solution, which, when poured into acetic acid, yielded a precipitate of the original substance. No change was effected by the hypochlorite in the presence of acetic acid.

*The Action of Sodium Hypochlorite on Benzenesulphon-β-naphthalide.*

Benzenesulphon-β-naphthalide crystallises from alcohol in colourless plates, which melt at 97—98°. On adding sodium hypochlorite, a yellow oil separated, which quickly solidified, the product being a

\* For purposes of identification, the preparation of the three isomeric monochloro-derivatives of *m*-4-xylidine was undertaken, and an account of these substances will appear separately.

sodium derivative of benzenesulphonchloro- $\beta$ -naphthalide, which crystallises in glistening needles from benzene containing about 5 per cent. of alcohol.

0.8837 required 2.45 c.c.  $\text{NH}_4\text{SO}_4$ .  $\text{Na} = 6.38$ .

$\text{C}_{16}\text{H}_{11}\text{O}_2\text{NClSNa}$  requires  $\text{Na} = 6.76$  per cent.

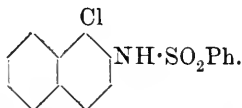

The sodium compound was decomposed by boiling for a few minutes with dilute mineral acid; the product dissolved in alcohol, from which it crystallised in colourless needles melting at  $130\text{--}131^\circ$ ; 5 grams of  $\beta$ -naphthalide gave 4 grams of pure substance.

0.1843 gave 0.0840  $\text{AgCl}$ .  $\text{Cl} = 11.28$ .

0.1843 „ 0.1355  $\text{BaSO}_4$ .  $\text{S} = 10.10$ .

$\text{C}_{16}\text{H}_{12}\text{O}_2\text{NClS}$  requires  $\text{Cl} = 11.18$ ;  $\text{S} = 10.08$  per cent.

The compound is more easily hydrolysed than the benzenesulphonotoluidides, a temperature of  $140^\circ$  for one hour being sufficient for the purpose; 1.8 grams gave 0.7 gram of solid base, which melted at  $60^\circ$  and formed an acetyl derivative melting at  $147\text{--}148^\circ$ . These data correspond with the melting points of 1-chloro- $\beta$ -naphthylamine and its acetyl derivative. The sulphonamide, therefore, has the following structure:

In this case, the chlorine atom enters the  $\alpha$ -position contiguous to the amidic nitrogen.

## XLII.—*The Esterification of r-Mandelic Acid by Menthol and Borneol.*

By ALEXANDER McKENZIE.

It has been shown by Marckwald and Chwolle (Ber., 1898, 31, 783) that the resolution of an *i*-acid into its optically active components by means of alkaloids is due solely to the difference in solubility between the alkaloidal salts of the *d*- and *l*-acids respectively, and not, as Pasteur supposed, to any difference in affinity exhibited by the two enantiomorphous acids towards one and the same base. This conclusion was based on the following observations: (1) that corresponding

amounts of the acid cinchonine salts of *d*- and *l*-tartaric acids respectively exhibited in solution the same rise of boiling point, (2) that the rate of hydrolysis of methyl *d*-tartrate by nicotine was the same as that of methyl *l*-tartrate, and (3) that, when methylethylacetic acid in aqueous solution was shaken with a quantity of brucine insufficient for complete neutralisation, the uncombined acid was optically inactive. The formation of a salt, therefore, by union of an active acid with an active base takes place practically instantaneously, and may be considered as being essentially an ionic reaction.

Whilst, then, a *d*-acid combines with an active base with the same velocity as its *l*-isomeride, the case might conceivably be different when the action depends on the spacial arrangement of the atoms in the molecule. That ester formation is a case in point is sufficiently indicated by the experiments of Menschutkin on the dependence of the rate of ester formation on the structure of the carbon chain, and by those of V. Meyer on diortho-substituted aromatic acids. The basis of Pasteur's two crystallisation methods for resolving *i*-compounds is undoubtedly physical, but his third method, the use of micro-organisms, is probably biochemical (compare E. Fischer, *Zeit. physiol. Chem.*, 1898, 26, 60). On those considerations, Marckwald and McKenzie (*Ber.*, 1899, 32, 2120) studied the esterification of *r*-mandelic acid by *l*-menthol and isolated *l*-mandelic acid by a chemical method, distinct from Pasteur's biological method in so far that the substances concerned are of known composition.

When *r*-mandelic acid was heated with *l*-menthol at 155°, the unesterified acid was lævorotatory, and from it a specimen of *l*-mandelic acid was prepared. The rate of ester formation of the enantiomorphous acids towards one and the same active alcohol was accordingly different, since *l*-menthyl *d*-mandelate was formed more quickly than *l*-menthyl *l*-mandelate. The esterified product, on the other hand, which was expected to contain an excess of *l*-menthyl *d*-mandelate, did not, however, yield a dextrorotatory acid on hydrolysis, but was either inactive or feebly lævorotatory. It appeared, in fact, as if the *r*-acid was being converted into the *l*-isomeride without a corresponding production of the *d*-isomeride. In order to account for this confusing result, experimental evidence was subsequently (*Ber.*, 1901, 34, 469) submitted to show that *l*-menthyl *d*-mandelate suffers partial racemisation during its formation more quickly than *l*-menthyl *l*-mandelate. Similar results were obtained (*loc. cit.*) with *i*-phenylethoxyacetic acid, but with *i*-ethoxypropionic acid there was no abnormality, since the rotation of the acid recovered from the esterified product was of the opposite sign to that of the unesterified acid.

Now Victor Meyer has found that in the case of two isomeric aromatic esters, the particular one which is formed with the greater

difficulty is also the less readily hydrolysable. His conclusion is based on experiments made with chloronaphthoic, bromobenzoic, and other acids (*Ber.*, 1895, 28, 1262), and has been confirmed by Wegscheider (*Ber.*, 1895, 28, 1468) and by Brühl (*Ber.*, 1895, 28, 1913, 2868). Accordingly, *l*-menthyl *d*-mandelate and *l*-menthyl *l*-mandelate, which are not mirror-images, undergo hydrolysis by the same inactive base at different rates. Of the two, the former is the more quickly produced and is the more quickly hydrolysable. The mixture of unequal amounts of the two esters, which, on complete hydrolysis, yielded a feebly lævorotatory acid, gave, on partial hydrolysis, a dextrorotatory acid.

The applicability of this method for resolving inactive compounds was further exemplified (*Ber.*, 1901, 34, 469) in [the case of *sec*-octyl alcohol. Whilst the difference in the rate of formation of the tartrates of *d*- and *l*-octyl alcohols was slight, there was a marked difference in their rate of hydrolysis, so that, by the method of fractional hydrolysis, a partial resolution of the *i*-alcohol was effected. In this connection, attention has already been directed (*Ber.*, 1900, 33, 210) to the fact that Frankland and Price, in the esterification of racemised amyl alcohol by *d*-glyceric acid, observed that the unesterified alcohol was feebly lævorotatory (*Trans.*, 1897, 71, 253).

In the light of the results obtained by Marckwald and the author, Walden has interpreted observations made by him during the investigation, firstly, of the action of active amyl alcohol on inactive  $\alpha$ -bromopropionic bromide, and, secondly, of the action of active amyl iodide on inactive silver methylsuccinate (*Ber.*, 1899, 32, 2703). Scholtz has studied the action of active amyl iodide on inactive 1-methyl-2-pipecoline in the hope that the formation of the quaternary iodide of the *d*-base would take place with a velocity different from that of the formation of the iodide of the *l*-base (*Ber.*, 1901, 34, 3015); he obtained, however, only negative results.

The following experiments include an examination of the action of borneol on *r*-mandelic acid, whilst the interaction of *l*-menthol and *r*-mandelic acid has also been further investigated.

## EXPERIMENTAL.

### *Esterification of r-Mandelic Acid by Borneol.*

*Expt.* 1.—The borneol employed had the rotation  $[\alpha]_D^{18} - 37.4^\circ$  ( $c = 17.374$ ) in ethyl-alcoholic solution, a value in agreement with that of Haller (*Ann. Chim. Phys.*, 1892, [vi], 27, 395). Twenty grams of *r*-mandelic acid were heated with 20 grams of *l*-borneol in an oil-bath at  $150^\circ$  for  $1\frac{1}{4}$  hours. The product was dissolved in ether and the

unesterified acid separated from the esters by shaking the ethereal solution with a dilute aqueous solution of sodium carbonate. In order to separate effectively any traces of borneol or borneol esters present in the solution of sodium mandelate, the latter was concentrated by evaporation on the water-bath and then extracted with ether. It was next acidified and extracted with ether, when 9.3 grams of mandelic acid were obtained with the following specific rotation in aqueous solution:  $l=2$ ;  $c=7.48$ ;  $\alpha_D^{20^\circ} - 0.58^\circ$ ;  $[\alpha]_D^{20^\circ} - 3.9^\circ$ .

After distilling the ether from the ethereal solution containing the esters, the latter were hydrolysed by heating with an excess of alcoholic potassium hydroxide. When the alcohol had been removed, water was added and the precipitated borneol drained off. The filtrate was completely freed from borneol as before; the mandelic acid isolated from it by acidification and extraction with ether was slightly lævorotatory, the following data being obtained in aqueous solution:  $l=2$ ;  $c=8.54$ ;  $\alpha_D^{20^\circ} - 0.25^\circ$ ;  $[\alpha]_D^{20^\circ} - 1.5^\circ$ .

This experiment shows that *d*-mandelic acid is esterified by *l*-borneol more quickly than is *l*-mandelic acid. The unesterified acid is lævorotatory, but the mixture of esters formed did not yield a dextro-rotatory acid, but a feebly lævorotatory one. The latter result is to be attributed to the unequal rates of racemisation of *l*-bornyl *d*-mandelate and *l*-bornyl *l*-mandelate, the former being racemised during its formation more quickly than the latter.

*Expt. 2.*—In order that the esterification might be more complete than in the previous case, 20 grams of *r*-mandelic acid were heated with 20 grams of *l*-borneol for 6 hours at  $150^\circ$ . The product was manipulated as before; 3.7 grams of unesterified acid were recovered, and a determination of its specific rotation gave the following result:  $l=2$ ;  $c=7.4$ ;  $\alpha_D^{14^\circ} - 1.07^\circ$ ;  $[\alpha]_D^{14^\circ} - 7.2^\circ$  (in aqueous solution).

The acid (15.5 grams) obtained by hydrolysing the mixed esters by an excess of alcoholic potassium hydroxide was feebly lævorotatory, thus,  $l=2$ ;  $c=10$ ;  $\alpha_D^{14^\circ} - 0.27^\circ$ ;  $[\alpha]_D^{14^\circ} - 1.3^\circ$  (in aqueous solution).

*Expt. 3.*—The effect of esterifying for a longer time at a lower temperature was next examined. Ten grams of *r*-acid were heated with 30 grams of *l*-borneol for 28 hours in a water-bath heated to boiling. The unesterified acid (2.6 grams) had the following rotation:  $l=2$ ;  $c=10.4$ ;  $\alpha_D^{13^\circ} - 2.18^\circ$ ;  $[\alpha]_D^{13^\circ} - 10.5^\circ$  (in aqueous solution).

The acid (6.6 grams) obtained from the esters was again feebly lævorotatory,  $l=4$ ;  $c=10.4$ ;  $\alpha_D^{18^\circ} - 0.17^\circ$ . This sign of rotation was confirmed by crystallising the 6.6 grams from water, withdrawing a crop of the *r*-acid and finding that the filtrate was lævorotatory.

The 3.7 grams of acid from *Expt. 2* and the 2.6 grams from *Expt. 3* were united and crystallised from water. After the removal of 3.1 grams of *r*-acid, the filtrate was converted into magnesium

salt; a small crop of magnesium *r*-salt was withdrawn, and the filtrate from this acidified and extracted with ether. The resulting acid was next converted into cadmium salt, from the aqueous solution of which a crop of cadmium *r*-mandelate was withdrawn, and the filtrate then decomposed by hydrogen sulphide. The resulting acid gave the following result:  $l=2$ ;  $c=1.586$ ;  $\alpha_D^{18} - 3.53^\circ$ ;  $[\alpha]_D^{18} - 111.3^\circ$  (in aqueous solution). The isolation of the pure *l*-acid was not, however, attempted in this case, the object of the experiment being simply to show how the *r*-acid may be gradually eliminated from a mixture containing a large excess of it, together with a little of the *l*-isomeride.

*Expt. 4.*—When *r*-mandelic acid (1 mol.) was heated with Kahlbaum's dextrorotatory borneol (1 mol.) for 1 hour at  $155^\circ$ , the unesterified acid was dextrorotatory,  $l=4$ ;  $c=10$ ;  $\alpha_D^{20} + 1.80^\circ$ ;  $[\alpha]_D^{20} + 4.5^\circ$ ; whilst the esterified product yielded a slightly dextrorotatory acid.

The rotation of the borneol used,  $[\alpha]_D^{18} + 23^\circ$  for  $c=18.144$  in ethyl alcoholic solution, indicated that it was a mixture of *d*- and *iso*-borneols.

*Expt. 5.*—*r*-Mandelic acid was next so completely esterified by *l*-borneol in such a manner that no fractional esterification took place. The *l*-bornyl *d**l*-mandelate was then submitted to fractional hydrolysis. Ten grams of *r*-acid were heated in a boiling water-bath for seven hours with 30 grams of *l*-borneol, a current of dry hydrogen chloride being passed into the mixture from time to time. The product was dissolved in ether and shaken with dilute aqueous sodium carbonate until all the free acid had been removed. The esterification was practically complete, since only 0.2 gram of mandelic acid was recovered. After expulsion of the ether from the ethereal solution, the resulting oil was dissolved in ethyl alcohol and heated on a boiling water-bath for 10 hours with 1 gram of potassium hydroxide, an amount insufficient for the complete hydrolysis of the esters. The potassium salt, when freed completely from the residual borneol and unesterified oil, yielded 1.7 grams of a laevorotatory acid:  $l=2$ ;  $c=6.8$ ;  $\alpha_D^{13} - 0.90^\circ$ ;  $[\alpha]_D^{13} - 6.6^\circ$  (in aqueous solution).

The residual esters, on the other hand, after being heated with a large excess of alcoholic potassium hydroxide, gave 6.8 grams of an acid, a saturated aqueous solution of which, when examined with a polarimeter, reading to  $0.01^\circ$ , was inactive, as also was the filtrate obtained after removing a crop of 5 grams.

A similar result was obtained in a subsequent experiment, where a larger amount of alkali was used in the initial hydrolysis. The mixed esters from 10 grams of acid were hydrolysed by 3.1 grams of potassium hydroxide, when 5.5 grams of acid were obtained, giving

the following data:  $l = 2$ ;  $c = 14$ ;  $\alpha_D^{20} - 1.08^\circ$ ;  $[\alpha]_D^{20} - 3.9^\circ$  (in aqueous solution).

The second hydrolysis, with excess of alkali, again gave an inactive product.

The fractional hydrolysis of *l*-bornyl *dl*-mandelate thus proceeded in an unexpected manner. Although *l*-bornyl *d*-mandelate is more readily formed than *l*-bornyl *l*-mandelate, the latter appeared to be the more readily hydrolysable of the two. The formation of *r*-mandelic acid as the product of the final hydrolysis is discussed in the sequel.

#### *Esterification of r-Mandelic Acid by l-Menthol.*

Marckwald and the author (*loc. cit.*) had previously isolated *l*-mandelic acid by means of the fractional esterification of the *r*-acid. In the following experiment, the isolation of the *d*-acid was effected by the method of fractional hydrolysis. The esterification of *r*-mandelic acid with *l*-menthol according to the Fischer-Speier method was practically complete. After removal of the mineral acid and a trace of mandelic acid, the product was hydrolysed by a calculated amount of alcoholic potassium hydroxide solution sufficient for the hydrolysis of about half of the ester mixture. The resulting solution of potassium salt was separated from the residual esters and menthol and then yielded a mixture of mandelic acids, with  $[\alpha]_D^{17} + 4.5^\circ$  ( $c = 10.075$ ) in aqueous solution. From the latter product, a specimen of *d*-mandelic acid, with the correct melting point and specific rotation, was isolated by the method of separation for the *l*-acid indicated by Marckwald and the author.

The difference in the rate of hydrolysis of the two esters under consideration is more marked towards the beginning of the hydrolysis than later, since a more active product than in the case just described may be obtained by lessening the amount of alkali in the initial hydrolysis. Thus, when 10 grams of *r*-acid were heated with 30 grams of menthol in the presence of hydrochloric acid, and the product, after the removal of the free acid, was partially hydrolysed by an amount of alkali considerably less than half that required for complete hydrolysis, 1.2 grams of acid were obtained having  $[\alpha]_D^{10} + 11.3^\circ$  ( $c = 4.8$ ) in aqueous solution. The residual esters yielded 6.5 grams of an acid with  $[\alpha]_D - 2.5^\circ$  ( $c = 13$ ) in aqueous solution. It should be noted, however, that the latter hydrolysis was quickly conducted by heating on the water-bath for half an hour with an amount of alcoholic potassium hydroxide just sufficient for the purpose.

*l*-Menthyl *dl*-mandelate was prepared by heating *r*-mandelic acid on a boiling water-bath for 10 hours with 3 times its weight of *l*-menthol in presence of hydrogen chloride. From the ethereal solution of the

product, the free acid was removed by dilute sodium carbonate, when it was found that only a trace of mandelic acid was obtained, from which it was concluded that the esterification was practically complete. After the ethereal solution had been dried, the ether was expelled and the oil distilled under diminished pressure. The menthol was completely removed and finally an oil, boiling at  $225^{\circ}$  under 30 mm. pressure, distilled over; this quickly solidified to a hard cake, which on analysis gave  $C=74.4$ ;  $H=9.0$ ;  $C_{18}H_{26}O_3$  requires  $C=74.5$ ;  $H=9.0$  per cent.

The product, which dissolves only sparingly in light petroleum, from which it separates in feathery, asbestos-like crystals, is readily soluble in benzene, chloroform, ethyl acetate, acetone, or pyridine, and moderately so in ethyl alcohol, from which it crystallises in needles. It is practically insoluble in water, with which it may be boiled for several hours without undergoing any appreciable hydrolysis. It melts at  $85-86^{\circ}$ . A determination of its rotation in ethyl alcoholic solution gave the following result:  $l=2$ ;  $c=10.890$ ;  $\alpha_D^{18} - 16.17^{\circ}$ ;  $[\alpha]_D^{18} - 74.2^{\circ}$ .

Frankland first suggested the possibility of the resolution of esters of this type by submitting them to fractional crystallisation (*Pasteur Memorial Lecture*, Trans., 1897, 71, 696. Compare also Wohl, *Ber.*, 1898, 31, 2394), and Frankland and Price have shown (Trans., 1897, 71, 253) that, although the ester formed from active amyl alcohol and *i*-dibenzoylglyceric acid is distinctly crystalline, no separation took place on crystallisation. A similar experience to the latter was encountered when the mandelate just described was crystallised from light petroleum and when the individual crops were allowed to separate at the temperature of the laboratory. The crystalline form of successive crops appeared to be perfectly homogeneous. After 10 crystallisations, the melting point of the product was the same as that of the original substance, whilst  $[\alpha]_D^{21}$  in ethyl alcoholic solution was  $-72.7^{\circ}$  ( $c=4.5624$ ), a value agreeing with that previously quoted; the result was the same when the ester was repeatedly crystallised from ethyl alcohol, no resolution having been effected.

*l*-Menthyl *dl*-mandelate is accordingly a partially racemic compound, and further attempts are being made to resolve it by varying the temperature conditions.

When *l*-menthyl *dl*-mandelate is hydrolysed with an excess of alcoholic potassium hydroxide, it yields *r*-mandelic acid. When hydrolysed with an amount of alkali insufficient for complete hydrolysis, but in considerable excess of that necessary for the hydrolysis of half the ester, the resulting potassium salt yields a *l*-vortatory acid: 14.5 grams of the ester (corresponding with 7.6 grams of acid) were hydrolysed in the manner indicated and, from

the potassium salt, 6 grams of acid were recovered giving the following data:  $l = 4$ ;  $c = 12$ ;  $\alpha_D - 2.08^\circ$ ;  $[\alpha]_D - 4.3^\circ$  in aqueous solution.

The residual esters, when hydrolysed with an excess of alkali, yielded 1.1 grams of inactive acid.

It is therefore possible by the fractional hydrolysis of *l*-menthyl *d**l*-mandelate to obtain either a dextrorotatory or levorotatory acid from the initial hydrolysis, according to the amount of alkali used. When the amount of alkali used is much less than that required for the hydrolysis of half the mixed esters, the acid resulting from the potassium salt formed is dextrorotatory. When the concentration of the alkali is increased, a larger quantity of dextrorotatory acid is obtained, the specific rotation of which is smaller than in the former case. Finally, by increasing still further the concentration of the alkali, a levorotatory acid is obtained.

In the experiments on fractional hydrolysis described in this paper, it has been repeatedly observed that the final hydrolysis of the mixed esters with alcoholic potassium hydroxide in excess led to the formation of a totally racemised product, and the following experiments were accordingly conducted. Five grams of *l*-mandelic acid, melting at  $133^\circ$  and having  $[\alpha]_D - 158^\circ$  in aqueous solution, were esterified by heating on a boiling water-bath for 7 hours with 15 grams of *l*-menthol in presence of hydrogen chloride. Alcoholic potassium hydroxide was then added to the product and the mixture boiled for 2 hours. After removal of the alcohols, the acid, recovered from the potassium salt, melted at  $116-118^\circ$  and gave  $[\alpha]_D - 3.3^\circ$  ( $c = 7.7436$ ) in aqueous solution.

In an experiment conducted with *l*-borneol in an analogous manner, the recovered acid gave  $[\alpha]_D - 9.7^\circ$  ( $c = 6.432$ ) in aqueous solution.

Although it has been shown that *l*-mandelic acid yields *i*-phenylchloroacetic acid when heated with fuming hydrochloric acid at  $95-100^\circ$  in a sealed tube (Easterfield, Trans., 1891, 59, 72), and that *d*-mandelic acid by the action of phosphorus pentachloride sometimes yields *i*-phenylchloroacetyl chloride (Kipping, Trans., 1903, 83, 1005), it was not considered probable that the partial racemisation observed in the experiments quoted took place during the actual esterification of the acid, but rather during the subsequent hydrolysis. That excess of alkali does actually racemise potassium *l*-mandelate was shown by experiment.

One gram of *l*-mandelic acid was added to a solution of 4 grams of potassium hydroxide in 30 c.c. of water. The solution, examined in a 2-dm. tube, gave about  $\alpha_D^{15^\circ} - 7.6^\circ$ , and did not appear to racemise after 12 hours at the temperature of the laboratory. After being heated for several hours on the water-bath, the solution was quite inactive and yielded *r*-mandelic acid melting at  $119^\circ$ .

Similarly, when *l*-mandelic acid was heated with a considerable excess of alcoholic potassium hydroxide, the solution became quite inactive and yielded *r*-mandelic acid.

The action of alkali on optically active esters and on the salts of optically active acids is being further examined.

*Summary.*

(1) When *r*-mandelic acid was heated with *l*-borneol, the unesterified acid was lævorotatory. The mixture of esters yielded a lævorotatory acid.

(2) When *l*-bornyl *dl*-mandelate was submitted to fractional hydrolysis, a lævorotatory acid was obtained from the initial hydrolysis, and an inactive acid from the final hydrolysis.

(3) *d*-Mandelic acid was isolated from the dextrorotatory acid obtained from the initial hydrolysis of *l*-menthyl *dl*-mandelate.

(4) *l*-Menthyl *dl*-mandelate yields either a dextrorotatory or a lævorotatory acid from the initial fractional hydrolysis, according to the amount of alkali used.

(5) *l*-Menthyl *dl*-mandelate is a partially racemic compound, which is not resolved into *l*-menthyl *d*-mandelate and *l*-menthyl *l*-mandelate when repeatedly crystallised from light petroleum at the temperature of the laboratory.

(6) Potassium *l*-mandelate undergoes complete racemisation when heated with a large excess of potassium hydroxide in aqueous or in alcoholic solution.

The author desires to express his thanks to the Research Fund Committee of the Chemical Society for a grant, which defrayed the cost of this research.

### XLIII.—*Isomeric Change of Diacylanilides into Acyl-aminoketones.*

By FREDERICK DANIEL CHATTAWAY.

A LARGE number of derivatives of aromatic amines in which aminic hydrogen is replaced by various atoms or groups readily undergo an intramolecular rearrangement, the substituting atom or group changing place with a hydrogen atom of the nucleus. Such exchange invariably occurs between the substituting atom or group and a

hydrogen attached to the nucleus in an ortho- or a para-position with respect to the amino-group, interchange between a group attached to the nitrogen and a hydrogen atom in either meta-position never having been observed. The transformations which have been most thoroughly studied are those in which alkyl, nitroxyl, or halogen radicles are concerned; the ready substitution of aromatic amines by agents such as nitric acid, chlorine, or bromine is due to changes of this type which are brought about with great ease.

Although the acyl groups very readily replace aminic hydrogen, these radicles have up to the present not been observed to migrate into the nucleus, although the diacylanilides are well known. Such intramolecular changes, however, can be effected readily, and the reactions, in so far as they have been studied, follow a course exactly similar to that of other analogous transformations, thus:

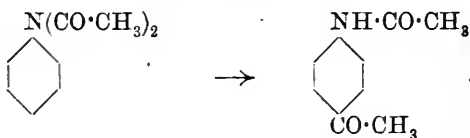

These intramolecular rearrangements take place at somewhat high temperatures and under the influence of catalytic agents, hydrogen chloride being always effective, whilst in some cases zinc chloride gives a better yield. Transference of more than one acyl group into the nucleus has, however, not yet been effected.

Owing to the reactive character of the resulting ketones, the yields are never quantitative, and resinous or tarry by-products are always produced. When acetylation or benzylation of an aromatic amine is effected by heating the base with the acid chloride, the product is invariably coloured and small quantities of tarry matters may be formed. This is without doubt due to the occurrence, to a slight extent, of the isomeric change under consideration, and to the formation of resinous products from the resulting ketone.

The transformation of dibenzanilide into benzoylaminobenzophenone is the only one in which both the ortho- and the para-isomerides have been isolated in quantity, and it is this case which brings these changes into complete accord with other analogous intramolecular rearrangements. This transformation is the only simple method by which *o*-aminobenzophenone has yet been obtained.

The change of diacetanilide into acetylaminacetophenone and of dipropionanilide into propionylaminopropiophenone where only the para-derivatives have been satisfactorily isolated have also been studied.

*Transformation of Diacetanilide into Acetyl-p-aminoacetophenone,*

Acetanilide, when heated with an equivalent quantity of acetic anhydride or acetyl chloride for some time, yields diacetanilide, which can be obtained pure by distillation.

If diacetanilide is mixed with about 10 per cent. of dry powdered zinc chloride and heated at 150—160° for several hours, or if at this temperature, it is treated with a slow current of dry hydrogen chloride, transformation takes place, and a considerable amount of the isomeric acetyl-*p*-aminoacetophenone is produced. There are clear indications of the simultaneous formation of the isomeric acetyl-*o*-aminoacetophenone, but the compound cannot be isolated with certainty, very probably because during the heating it becomes hydrolysed to some extent, and then, under the influence of the zinc chloride, reacts with the *p*-aminoacetophenone simultaneously formed to produce  $\alpha$ -*p*-aminophenyl- $\gamma$ -lepidine. This substance is always found as a product of the reaction and, as O. Fischer has shown (*Ber.*, 1886, 19, 1038), it is formed almost quantitatively when a mixture of *o*- and *p*-aminoacetophenones is heated together with zinc chloride. Some difficulty is experienced in isolating the different products, as much tarry or resinous matter is produced which is probably formed either by some complicated condensation of the aminoketones or from the unstable aminophenylacetylenes derived from these compounds by the action of the condensing agent (compare Baeyer, *Ber.*, 1882, 15, 2174).

The following process is found to give the best results: diacetanilide is heated at about 140—150° for 8—10 hours and a very slow current of hydrogen chloride is passed through the melted mass; a viscid, brown liquid is produced which solidifies on cooling, and from which acetyl-*p*-aminoacetophenone can be obtained by long-continued crystallisation, but as the process is very tedious the base is best extracted in the following manner. The product is completely dissolved in excess of alcohol containing about one-third of its bulk of concentrated hydrochloric acid and hydrolysed by boiling for 6—8 hours; the resulting liquid is made slightly alkaline with caustic soda and distilled in a current of steam, which removes the aniline obtained from the untransformed diacetanilide, about 50 per cent. of the aniline used being thus recovered. The alkaline liquid in the distilling

flask is cooled and the tarry residue collected, the *p*-aminoacetophenone being obtained from this by repeated extractions with boiling water. These solutions can be decolourised by heating with animal charcoal and concentrated, if necessary, when the para-base, which separates on cooling, can be extracted with ether.

If the steam distillation is continued for some time after the aniline has passed over, a pale yellow distillate is obtained having an intensely penetrating odour and reddening a pine splinter previously moistened with hydrochloric acid. This distillate undoubtedly contains a little of the ortho-base, and a yellow oil can be extracted from it by ether, but the amount produced is so extremely small that it cannot be identified with certainty. The yield of *p*-aminoacetophenone is not good and seldom exceeds 5 per cent. of the weight of diacetanilide used.

With zinc chloride as catalyst, the yield is better, being generally about 25 per cent. Diacetanilide is intimately mixed with about an eighth of its weight of zinc chloride and heated at 150° for 12 hours. The product is poured into boiling water, washed several times to remove the zinc chloride, and then treated in the foregoing manner.

This method is similar to that employed by Klingel (*Ber.*, 1885, 18, 2687) in preparing *p*-aminoacetophenone, except that diacetanilide is used in place of acetanilide and acetic anhydride in order to demonstrate the transformation. Klingel regarded the action as consisting of a direct introduction of the acetyl group into the ring without the formation of any intermediate product. There can, however, be no doubt that diacetanilide is formed in his method, the *p*-aminoacetophenone being produced by the transformation of the diacetyl compound.

A number of derivatives of *p*-aminoacetophenone have been prepared; these are formed by the ordinary processes, but in the preparation of the nitrogen-halogen derivatives great care must be taken to avoid the liberation of free halogen. The chloroamino-derivatives are prepared by suspending or dissolving the acylamino-ketone in chloroform and shaking it for some time with a well-cooled solution of potassium hypochlorite containing an excess of potassium hydrogen carbonate. On separating the chloroform solution, drying with calcium chloride, and evaporating off the solvent in a current of dry air, a yellow, viscid liquid is left, which, if pure, at once solidifies to a colourless, crystalline mass, on cooling and stirring with a little light petroleum.

The bromoamino-derivatives are made and treated in a similar way, using a solution of hypobromous acid to which a little freshly precipitated mercuric oxide has been added to prevent any liberation of free bromine.

The compounds, unless otherwise stated, were crystallised from a mixture of chloroform and petroleum (b. p. 60—80°).

*Acetyl-p-chloroaminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NCl} \cdot \text{CO} \cdot \text{CH}_3$ , crystallises in clusters of glistening, pearly plates and melts at 92°.

0.2056 liberated I from 19.5 c.c. *N*/10 solution. Cl (as NCl) = 16.81.

$\text{C}_{10}\text{H}_{10}\text{O}_2\text{NCl}$  requires Cl (as NCl) = 16.75 per cent.

*Acetyl-p-bromoaminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NBr} \cdot \text{CO} \cdot \text{CH}_3$ , crystallises from petroleum (b. p. 60—80°) in yellow, glistening, rhombic plates which melt at 83°.

0.2298 liberated I from 17.9 c.c. *N*/10 solution. Br (as NBr) = 31.14.

$\text{C}_{10}\text{H}_{10}\text{O}_2\text{NBr}$  requires Br (as NBr) = 31.22 per cent.

*Propionyl-p-aminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH} \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{CH}_3$ , crystallises from alcohol in glistening, transparent, colourless prisms and melts at 136°; its composition was established by estimating the chlorine in the corresponding chloroamino-derivative.

*Propionyl-p-chloroaminoacetophenone*,

forms colourless, transparent plates which melt at 42°.

0.3020 liberated I from 26.6 c.c. *N*/10 solution. Cl (as NCl) = 15.61.

$\text{C}_{11}\text{H}_{12}\text{O}_2\text{NCl}$  requires Cl (as NCl) = 15.71 per cent.

*Benzoyl-p-aminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ , crystallises from alcohol or chloroform in colourless, pearly plates melting at 205°.

*Benzoyl-p-chloroaminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NCl} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$ .

Benzoyl-p-aminoacetophenone is so sparingly soluble in cold chloroform that it is better to add its alcoholic solution to potassium hypochlorite solution containing excess of hydrogen carbonate, the mixture being then shaken with a little chloroform until all the solid has disappeared. To remove the alcohol and to ensure the conversion of all the benzoyl derivative, the chloroform solution is repeatedly shaken with fresh hypochlorous acid. *Benzoyl-p-chloroaminoacetophenone* crystallises in clusters of colourless plates which melt at 77°.

0.2511 liberated I from 18.1 c.c. *N*/10 solution. Cl (as NCl) = 12.77.

$\text{C}_{15}\text{H}_{12}\text{O}_2\text{NCl}$  requires Cl (as NCl) = 12.96 per cent.

*Benzenesulphon-p-aminoacetophenone*,  $\text{CH}_3 \cdot \text{CO} \cdot \text{C}_6\text{H}_4 \cdot \text{NH} \cdot \text{SO}_2 \cdot \text{C}_6\text{H}_5$ , crystallises from alcohol in clusters of slender, colourless needles melting at 128°.

*Benzenesulphon-p-chloroaminoacetophenone*,

forms small, colourless, transparent plates, which are apparently flattened rhombs melting at  $91^{\circ}$ .

0.1804 liberated I from 11.6 c.c. *N*/10 solution. Cl (as NCl) = 11.39.

$C_{14}H_{12}O_3NClS$  requires Cl (as NCl) = 11.45 per cent.

*Toluene-p-sulphon-p-aminoacetophenone*,

crystallises from alcohol in colourless, transparent, flattened prisms which melt at  $203^{\circ}$ .

*Toluene-p-sulphon-p-chloroaminoacetophenone*,

forms clusters of irregular, colourless plates melting at  $93^{\circ}$ .

0.2909 liberated I from 18.1 c.c. *N*/10 solution. Cl (as NCl) = 11.03.

$C_{15}H_{14}O_3NClS$  requires Cl (as NCl) = 10.95 per cent.

*Transformation of Dipropionanilide into Propionyl-p-aminopropiophenone*,

Under comparable conditions, dipropionanilide is transformed into the corresponding aminoketone exactly like diacetanilide, but only propionyl-*p*-aminopropiophenone could be isolated from the product in any quantity, although in this case also the ortho-compound is probably formed in small amount. When hydrogen chloride is used as a catalyst, the yield is small, but it is much increased by the employment of zinc chloride. The yield is better when the propionic acid formed is not separated from the dipropionanilide, about 50 per cent. of the theoretical amount being obtained in the following manner.

Propionanilide (1 mol.) is heated at  $140$ — $150^{\circ}$  for some hours with the equivalent amount (1 mol.) of propionic anhydride, then about a third of its weight of dry powdered zinc chloride is added and the heating continued for about twelve hours. The pale brown liquid produced, which solidifies on cooling, is washed with warm water to remove zinc chloride and hydrolysed by boiling for 8 hours with an excess of alcohol containing about one-sixth of its bulk of concentrated hydrochloric acid. After distilling off the alcohol in a current of steam, the residue is made slightly alkaline with caustic soda and again distilled in steam to remove any anilide obtained from unchanged dipropionanilide. On filtering the hot alkaline liquid from a very little tarry matter, the base separates from it on cooling in pale reddish-brown plates. A further

quantity can be extracted from the mother liquor by ether together with a very small amount of a pungent, oily substance which is probably the ortho-isomeride.

*p*-Aminopropiophenone as it first separates from the alkaline liquid has a somewhat reddish-brown colour, which is, however, due to slight impurity and can be completely removed by recrystallisation. The substance is moderately soluble in alcohol or chloroform, and sparingly so in ether; it crystallises from alcohol or a mixture of alcohol and ether in thick, colourless, transparent plates which are highly refractive, and separates from chloroform in colourless, transparent, four-sided, flattened rhombs melting at  $142^{\circ}$ . It readily dissolves in hydrochloric acid forming a very soluble hydrochloride which crystallises in colourless, flattened prisms.

On mixing alcoholic solutions of *p*-aminopropiophenone hydrochloride and platinic chloride, the platinichloride,

crystallises out in small, flattened, bright orange-coloured prisms with domed ends. The double salt is sparingly soluble in hot water and in alcohol and blackens just above  $200^{\circ}$ , but does not melt.

0.3813 yielded 0.1037 Pt.  $\text{Pt} = 27.19$ .

$\text{C}_{18}\text{H}_{24}\text{O}_2\text{N}_2\text{Cl}_6\text{Pt}$  requires  $\text{Pt} = 27.52$  per cent.

*p*-Aminopropiophenone easily dissolves in a hot dilute solution of sulphuric acid, and, on cooling, the sulphate,

crystallises out in glistening, colourless, pearly plates which are transparent when thin. On heating rapidly, it melts with decomposition at about  $223^{\circ}$ , turning a bright red colour; if heated slowly, it melts a few degrees lower with similar decomposition.

0.4716 yielded 0.2771  $\text{BaSO}_4$ .  $\text{SO}_4 = 24.18$ .

$\text{C}_{18}\text{H}_{24}\text{O}_6\text{N}_2\text{S}$  requires  $\text{SO}_4 = 24.24$  per cent.

Acetyl-*p*-aminopropiophenone,  $\text{C}_2\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{CO}\cdot\text{CH}_3$ , is easily prepared by adding the calculated quantity of acetic anhydride to the base, when considerable heat is developed and a crystalline mass separates. On completing the action by warming for a short time on the water-bath, freeing from acid by a dilute solution of potassium hydrogen carbonate, and repeatedly crystallising from alcohol, the compound is obtained in perfectly colourless, long, glistening, six-sided prisms terminated by pyramids which melt at  $175^{\circ}$ .

Kunckell (*Ber.*, 1900, 33, 2641), who first prepared acetyl-*p*-aminopropiophenone by the action of propionyl chloride on acetanilide in the presence of a large excess of aluminium chloride, states that it forms pale yellow needles melting at  $161^{\circ}$ , and that the *p*-aminopropio-

phenone obtained from this formed long, yellow needles melting at  $140^{\circ}$ . The colour noted in both cases is without doubt due to a slight impurity. In this method of preparation also, it is probable that the aminoketone is formed by the transformation of propionylacetanilide under the influence of the aluminium chloride, and the very low melting point given by Kunckell for the acetyl derivative ( $14^{\circ}$  below that obtained by the author) seems to support this view, as in the transformation of the mixed anilide it is almost certain that the acetyl group as well as the propionyl group would be transferred to the ring, and that the product, however carefully purified, would retain a small quantity of admixed propionyl-*p*-aminoacetophenone.

From the base obtained in the above transformation, a number of derivatives have been made.

The nitrogen chloride and bromide derivatives of the acylamino-propionophenones were all prepared by adding an alcoholic solution of the acylaminoketone to a cooled solution of potassium hypochlorite containing hydrogen carbonate or to a solution of hypobromous acid containing suspended mercuric oxide. In the case of the benzoyl derivatives, a large quantity of warm alcohol was required.

*Acetyl-p-chloroaminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot CH_3$ , crystallises in colourless plates melting at  $75^{\circ}$ .

0.2262 liberated I from 20 c.c. *N*/10 solution. Cl (as NCl) = 15.67.

$C_{11}H_{12}O_2NCl$  requires Cl (as NCl) = 15.71 per cent.

*Acetyl-p-bromoaminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot CH_3$ , forms brilliant, short, yellow prisms which melt at  $115^{\circ}$ .

0.2704 liberated I from 19.9 c.c. *N*/10 solution. Br (as NBr) = 29.42.

$C_{11}H_{12}O_2NBr$  requires Br (as NBr) = 29.60 per cent.

*Propionyl-p-aminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NH \cdot CO \cdot C_2H_5$ , crystallises from alcohol in slender, colourless prisms melting at  $153^{\circ}$ ; it is easily soluble in alcohol and chloroform, sparingly so in ligroin.

*Propionyl-p-chloroaminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot C_2H_5$ , forms colourless, transparent plates and melts at  $80^{\circ}$ .

0.1450 liberated I from 12.1 c.c. *N*/10 solution. Cl (as NCl) = 14.79.

$C_{12}H_{14}O_2NCl$  requires Cl (as NCl) = 14.79 per cent.

*Propionyl-p-bromoaminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot C_2H_5$ , separates in clusters of pale yellow, elongated plates which melt at  $120^{\circ}$ .

0.1258 liberated I from 8.8 c.c. *N*/10 solution. Br (as NBr) = 27.96.

$C_{12}H_{14}O_2NBr$  requires Br (as NBr) = 28.14 per cent.

*Benzoyl-p-aminopropionophenone*,  $C_2H_5 \cdot CO \cdot C_6H_4 \cdot NH \cdot CO \cdot C_6H_5$ , crys-

callises from alcohol, in which it is sparingly soluble, in thin, colourless, elongated plates melting at  $190^{\circ}$ .

*Benzoyl-p-chloroaminopropiophenone*,  $\text{C}_2\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{NCl}\cdot\text{CO}\cdot\text{C}_6\text{H}_5$ , crystallises in clusters of colourless, transparent plates melting at  $70^{\circ}$ .

0.1323 liberated I from 9.15 c.c. *N*/10 solution. Cl (as NCl) = 12.25.

$\text{C}_{16}\text{H}_{14}\text{O}_2\text{NCl}$  requires Cl (as NCl) = 12.32 per cent.

*Benzoyl-p-bromoaminopropiophenone*,  $\text{C}_2\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{NBr}\cdot\text{CO}\cdot\text{C}_6\text{H}_5$ , forms bright yellow, rhombic plates and melts at  $111^{\circ}$ .

0.1372 liberated I from 8.2 c.c. *N*/10 solution. Br (as NBr) = 23.89.

$\text{C}_{16}\text{H}_{14}\text{O}_2\text{NBr}$  requires Br (as NBr) = 24.07 per cent.

When heated quickly, all the nitrogen halogen derivatives of the acyl *p*-aminopropiophenones undergo transformation at about  $200\text{--}230^{\circ}$ , this change being accompanied by much decomposition.

*Benzenesulphon-p-aminopropiophenone*,  $\text{C}_2\text{H}_5\cdot\text{CO}\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{SO}_2\cdot\text{C}_6\text{H}_5$ , separates in colourless, glistening plates melting at  $165^{\circ}$ .

*Benzenesulphon-p-chloroaminopropiophenone*,

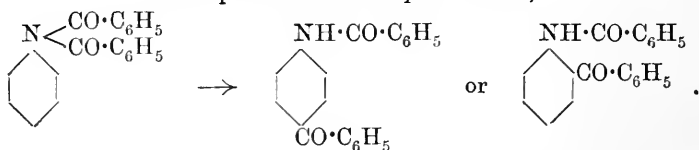

crystallises in colourless, transparent plates which melt at  $81^{\circ}$ .

0.1556 liberated I from 9.2 c.c. *N*/10 solution. Cl (as NCl) = 10.48.

$\text{C}_{15}\text{H}_{14}\text{O}_3\text{NClS}$  requires Cl (as NCl) = 10.95 per cent.

*Transformation of Dibenzanilide into Benzoylo- and -p-aminobenzophenones,*

It was not thought necessary in this case to isolate the dibenzanilide, as this is known to be the first product of the action of benzoyl chloride on benzanilide (*Compt rend.*, 1853, 37, 90; *Ber.*, 1893, 26, 2853). The transformation and isolation of the products are best effected as follows.

The equivalent quantity of benzoyl chloride (2 mols.) is added to aniline (1 mol.) and the whole heated in an oil-bath; the temperature is gradually raised as the interaction takes place, until it reaches  $220\text{--}230^{\circ}$ , at which point it is maintained for about 20 hours. A brown liquid is thus produced, which, on cooling, sets to a viscid, tarry mass. As it is difficult to isolate the isomeric benzoylaminoketones from this, it is best to hydrolyse the whole by dissolving it in a large excess of alcohol mixed with about one-third of its volume of con-

centrated hydrochloric acid. Complete hydrolysis is very difficult to effect, and 14 to 16 hours' boiling is required. After the hydrolysis is complete, steam is blown rapidly through the liquid, when the alcohol first distils over and is followed by a considerable amount of ethyl benzoate. When this has all been removed, the acid liquid is rendered distinctly alkaline with sodium hydroxide, and steam is again passed in; aniline is first expelled and then *o*-aminobenzophenone slowly distils over and either collects as a crystalline solid or separates in bright yellow needles from the cooled distillate. This product is perfectly pure after one crystallisation from alcohol. The para-compound is not volatile in steam and remains behind in the distilling flask; a considerable amount crystallises out on filtering and cooling the hot liquid, and a further quantity can be obtained by repeatedly extracting the tarry residue with very dilute sulphuric acid, from which, on cooling, the base crystallises in a nearly pure state. It can be obtained pure by crystallisation from water containing a few drops of sulphuric acid, in which it dissolves only sparingly, or from alcohol, in which it is readily soluble.

The yields of *o*- and *p*-aminobenzophenones are respectively about 15 per cent. and 45 per cent. of the weight of the aniline used.

As in the analogous transformations of diacetanilide and dipropionanilide, the presence of a little zinc chloride (compare Higgin, Trans., 1882, 41, 132) facilitates the transformation, and a slightly better yield of both isomerides is obtained. The process is carried out in the manner indicated above, about 10 per cent. of finely powdered, dry zinc chloride being added. This process of intramolecular rearrangement, which follows a precisely similar course to the other well-known migrations of groups from the aminic nitrogen atom into the ortho- and para-positions of the ring, could in all probability be carried to the further stage, in which two acyl groups would be introduced into the nucleus in these positions.

Although the use of a larger amount of benzoyl chloride (3 or 4 mols. to 1 mol. of aniline) leads to a somewhat diminished yield of the benzoyl-*o*- and -*p*-aminobenzophenones, which may be due to the occurrence of this additional transformation, yet no disubstituted product has been isolated.

The isomeric change of dibenzanilide is of further interest since it affords the only simple method yet described of preparing *o*-aminobenzophenone, the process described being much less laborious than that employed by Ullmann and Bleier (*Ber.*, 1903, 35, 4273), who converted toluene-*p*-sulphonanthranilic acid into its chloride, and treated benzene with this compound in the presence of aluminium chloride, finally liberating the base by hydrolysis with dilute sulphuric acid.

The following compounds have been prepared from the *o*- and *p*-aminobenzophenones obtained in the foregoing transformation.

The chloroamino- and bromoamino-derivatives of the acylamino-benzophenones were prepared respectively by adding an alcoholic solution of the acylaminoketone to a well-cooled solution of potassium hypochlorite containing an excess of potassium hydrogen carbonate, or to a solution of hypobromous acid containing a little suspended mercuric oxide; the products were then extracted with chloroform and the solution treated as previously described.

*Acetyl-o-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot CH_3$ , separates from a mixture of chloroform and petroleum in brilliant, colourless, flattened prisms with domed ends; it melts at  $102^\circ$ .

0.2022 liberated I from 14.7 c.c. *N*/10 solution. Cl (as NCl) = 12.88.

$C_{15}H_{12}O_2NCl$  requires Cl (as NCl) = 12.96 per cent.

*Acetyl-o-bromoaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot CH_3$ , crystallises from a mixture of chloroform and petroleum in short, transparent, yellow prisms melting at  $121^\circ$ .

0.1660 liberated I from 10.5 c.c. *N*/10 solution. Br (as NBr) = 25.28.

$C_{15}H_{12}O_2NBr$  requires Br (as NBr) = 25.13 per cent.

*Propionyl-o-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot C_2H_5$ , crystallises from light petroleum in clusters of colourless, flattened prisms which melt at  $107^\circ$ .

0.1788 liberated I from 12.6 c.c. *N*/10 solution. Cl (as NCl) = 12.49.

$C_{16}H_{14}O_2NCl$  requires Cl (as NCl) = 12.32 per cent.

*Propionyl-o-bromoaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot C_2H_5$ , crystallises from light petroleum in bright yellow, transparent plates melting at  $90^\circ$ .

0.1375 liberated I from 8.15 c.c. *N*/10 solution. Br (as NBr) = 23.69.

$C_{16}H_{14}O_2NBr$  requires Br (as NBr) = 24.07 per cent.

*Benzoyl-o-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot C_6H_5$ , separates from light petroleum in colourless, glistening, rhombic plates which melt at  $98^\circ$ .

0.1611 liberated I from 9.7 c.c. *N*/10 solution. Cl (as NCl) = 10.67.

$C_{20}H_{14}O_2NCl$  requires Cl (as NCl) = 10.56 per cent.

*Acetyl-p-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot CH_3$ , crystallises from petroleum (b. p.  $60-80^\circ$ ) in groups of colourless, flattened, elongated plates melting at  $124^\circ$ .

0.2396 liberated I from 17.3 c.c. *N*/10 solution. Cl (as NCl) = 12.79.

$C_{15}H_{12}O_2NCl$  requires Cl (as NCl) = 12.96 per cent.

*Acetyl-p-bromoaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot CH_3$ , is less soluble than its analogues in chloroform; it crystallises from a mixture of about 1 part of chloroform and 3 parts of petroleum (b. p. 60—80°) in groups of pale yellow, six-sided plates melting at 151°.

0.1624 liberated I from 10.2 c.c. *N*/10 solution. Br (as NBr) = 25.11.  
 $C_{15}H_{12}O_2NBr$  requires Br (as NBr) = 25.13 per cent.

*Propionyl-p-aminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NH \cdot CO \cdot C_2H_5$ , crystallises from alcohol in clusters of thin, colourless, elongated plates which melt at 139°. The composition of this and other acyl derivatives is found by the analysis of their chloroamino-derivatives.

*Propionyl-p-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot C_2H_5$ , separates from light petroleum in glistening, colourless, flattened prisms melting at 129°.

0.1730 liberated I from 12 c.c. *N*/10 solution. Cl (as NCl) = 12.29.  
 $C_{16}H_{14}O_2NCl$  requires Cl (as NCl) = 12.32 per cent.

*Propionyl-p-bromoaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot C_2H_5$ , crystallises from light petroleum in pale yellow, transparent plates which melt at 123°.

0.1828 liberated I from 11 c.c. *N*/10 solution. Br (as NBr) = 24.06.  
 $C_{16}H_{14}O_2NBr$  requires Br (as NBr) = 24.08 per cent.

*Benzoyl-p-chloroaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot CO \cdot C_6H_5$ , separates from petroleum (b. p. 60—80°) in clusters of small, colourless, rhombic plates melting at 107°.

0.2382 liberated I from 14 c.c. *N*/10 solution. Cl (as NCl) = 10.42.  
 $C_{20}H_{14}O_2NCl$  requires Cl (as NCl) = 10.56 per cent.

*Benzoyl-p-bromoaminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NBr \cdot CO \cdot C_6H_5$ , crystallises from a mixture of chloroform and petroleum in clusters of bright yellow, transparent, rhombic plates and melts at 93°.

0.2288 liberated I from 12 c.c. *N*/10 solution. Br (as NBr) = 20.97.  
 $C_{20}H_{14}O_2NBr$  requires Br (as NBr) = 21.03 per cent.

*Benzenesulphon-p-aminobenzophenone*,  $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NH \cdot SO_2 \cdot C_6H_5$ , crystallises from alcohol in colourless, transparent plates and melts at 156°.

*Benzenesulphon-p-chloroaminobenzophenone*,  
 $C_6H_5 \cdot CO \cdot C_6H_4 \cdot NCl \cdot SO_2 \cdot C_6H_5$ ,  
 separates from a mixture of chloroform and petroleum in colourless, short, flattened prisms which melt at 114°.

0.2969 liberated I from 16 c.c. *N*/10 solution. Cl (as NCl) = 9.55.

$C_{19}H_{14}O_3NClS$  requires Cl (as NCl) = 9.54 per cent.

*Toluene-p-sulphon-p-aminobenzophenone*,

crystallises from alcohol in colourless, thin, flattened prisms melting at 184°.

*Toluene-p-sulphon-p-chloroaminobenzophenone*,

crystallises from a mixture of chloroform and petroleum in clusters of somewhat irregular, colourless plates melting at 116°.

0.3264 liberated I from 16.9 c.c. *N*/10 solution. Cl (as NCl) = 8.97.

$C_{20}H_{16}O_3NClS$  requires Cl (as NCl) = 9.19 per cent.

## XLIV.—*The Constitution of Phenolphthalein.*

By ARTHUR GEORGE GREEN and ARTHUR GEORGE PERKIN.

THE well-known behaviour of phenolphthalein with alkalis—the production of a deeply-coloured salt from a colourless acid and the disappearance of the colour on the addition of an excess of alkali or of alcohol—is generally explained on the theory of electrolytic dissociation. It is supposed that whilst phenolphthalein itself and its undissociated salts are colourless, its ions are red, and that the disappearance of the colour on adding an excess of alkali or alcohol denotes the suppression or retrogression of ionisation. This view, first put forward by Ostwald (*Wissenschaftl. Grundlagen der Analyt. Chemie*, II<sup>te</sup> Aufl., p. 116), has been adopted by Herzig and Meyer (Herzig, *Ber.*, 1895, 28, 3258; 1896, 29, 138; *Monatsh.*, 1896, 17, 429; 1902, 23, 709; R. Meyer, *Jahrbuch d. Chem.*, 1899, 9, 404) and by O. Fischer (*Zeit. Farb. Text. Chem.*, 1902, 1, 281); whilst quite recently R. Meyer and O. Spendler (*Ber.*, 1903, 36, 2949), after a careful re-examination of the facts, have come to the conclusion that it still offers the best explanation, and that the quinonoid theory does not give a satisfactory solution.

On the other hand, the quinonoid theory of colour has received its strongest experimental support from the work of Nietzki on the ethers of fluorescein, a compound itself closely allied to phenolphthalein, whilst the constantly increasing weight of evidence in general favour

of this theory should lead us to question its lack of application in this case.

With the view of testing the validity of the ionic explanation, we have carried out the following experiments. If the ionisation of the phenolphthalein alkali salt is suppressed by the presence of an excess of free alkali, it appears to follow that the red colour should return if this excess be neutralised. We have found, however, that if an aqueous solution of phenolphthalein containing an excess of caustic potash sufficient to decolorise it (or nearly so) is carefully cooled and gradually neutralised by a weak organic acid, such as acetic or carbonic acid, the solution may be rendered quite neutral without any return of the red coloration. Nor does the colour return on again rendering the solution alkaline. On the other hand, if the solution is acidified and heated or left for some time at the ordinary temperature, then on again rendering alkaline, the colour returns in its full intensity.

In order to ascertain the point at which neutrality occurs, and thereby gain some insight into the nature of the colourless compound present, a weighed quantity of phenolphthalein was dissolved in a measured volume of standard caustic potash sufficient to decolorise it all but a slight pink colour. The solution was cooled in ice and carefully titrated with dilute acetic acid of known strength until neutral to litmus paper. This point exactly coincides with the disappearance of the residual pink colour. The experiment was repeated several times, and it was always found that the quantity of acetic acid required corresponded with the presence in the neutral solution of a potassium salt,  $C_{20}H_{15}O_5K$ .

For example, 0.5 gram of phenolphthalein was dissolved in 10 c.c. of caustic potash solution, of which 1 c.c. = 0.194 gram of KOH and titrated to neutrality with dilute acetic acid, of which 1 c.c. = 0.146 gram  $H_4C_2O_2$ , namely, 14.3 c.c. corresponded with 10 c.c. of the caustic potash solution used. The volume of acetic acid required was 13.65 c.c.

Percentage of KOH neutralised by phenolphthalein.

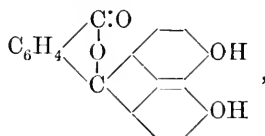

Found	Calculated for $C_{20}H_{15}O_5K$
17.6	17.6

The freshly prepared cold solution of the potassium salt was a clear, colourless liquid which soon became turbid through separation of free phenolphthalein. When rendered alkaline, it only gave a slight pink coloration, but if first allowed to remain until turbidity had set in a more or less intense red was produced. Further, if the colourless neutral solution was simply heated to boiling, it assumed the deep red

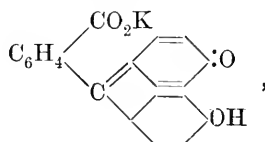

colour of alkaline phenolphthalein, whilst a colourless precipitate of free phenolphthalein separated out. At the same time, the solution is found to have become strongly alkaline to litmus paper. The red colour remains on cooling.

All these facts seem to be quite inconsistent with the electrolytic hypothesis. On the other hand, they are capable of simple explanation by means of the quinonoid theory, according to which the phenomena must be regarded as hydration and dehydration changes accompanied by a transition from the benzenoid to the quinonoid type and *vice versa*.

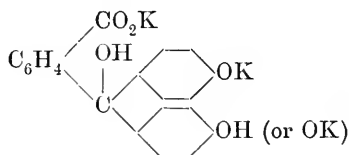

If we assign to free phenolphthalein the usual lactonic constitution,

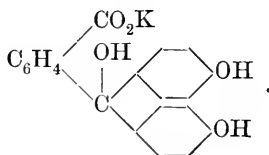

we may assume that the first action of an alkali is to neutralise one of the phenolic hydroxyl groups. The phenolic salt thus formed would be unstable, and may be considered to undergo an immediate rearrangement by the transference of the metal from the phenolic to the carboxylic group. In this way, the red quinonoid salt,

would be formed without intermediate production of the hydrol. On the addition of a further quantity of an alkali, the elements of potassium (or sodium) hydroxide are taken up, giving rise to the colourless compound

If, now, the cooled alkaline solution be neutralised with acetic acid, the metal attached to the phenolic oxygen will be removed and the colourless solution will contain the potassium salt of the carbinol-carboxylic acid,

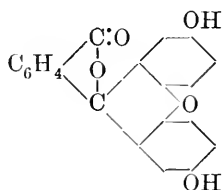

This compound is unstable, and on boiling or when left at the ordinary temperature it undergoes dehydration. This change seems to take place in two directions, partly by formation of the red quinonoid salt, and partly by formation of the colourless lactone. The latter reaction is accompanied by the liberation of potassium hydroxide, which causes the solution to become alkaline. It is, in fact, very probable that the dehydration occurs solely in the second sense, and that the quinonoid compound is only formed from the intermediate lactone by the action of the free alkali simultaneously produced.

We have made many attempts to isolate the colourless carbinol-carboxylic acid (or its salt) in a solid state, but owing to its instability and great solubility in water we have not succeeded in doing so. Nevertheless, there can scarcely be a doubt as to its presence in the neutral colourless solution.

The view of the quinonoid structure of the red salts of phenolphthalein does not, in our opinion, run counter to any of the observed facts. Thus the formation of colourless lactone derivatives by alkylation (Herzig and Meyer) or benzylation (Bistrzycki and Nenki), which have been brought forward as arguments against it, are readily explained if we assume the intermediate formation of the carbinol salt. The difference in the behaviour towards alkalis of phenolphthalein as compared with other triphenylmethane derivatives is only one of degree, and is readily explicable as being due to the presence of the carboxyl group and its tendency to form a lactone with the carbinol hydroxyl group. All the acid colouring matters of the triphenylmethane series (acid violets, acid greens, soluble blues, &c.) are similarly decolorised by an excess of alkali, although with the individual colouring matters there is a large variation in the time required to destroy the colour completely, some requiring only 2 or 3 minutes, whilst others need several days. Even with phenolphthalein, an appreciable time is necessary, which in itself renders the ionisation explanation improbable. The decolorised solutions of the various dyes can be rendered quite neutral by careful addition of acetic acid in the cold without the colour returning, but as soon as the neutral point is passed the colour returns immediately. In the case of erioglaucine, however, the colour does not at once return on acidifying, but only when the solution is heated. This exceptional behaviour is very analogous to that of phenolphthalein, to which erioglaucine may be considered to be similarly constituted, since it contains an  $\text{SO}_3\text{H}$  group instead of a  $\text{CO}_2\text{H}$  group in the ortho-position to the methane carbon atom.

The only difficulty arising from the above view of the constitution of the coloured phenolphthalein salts lies in the behaviour of quinolphthalein, which, according to the researches of R. Meyer and others (R. and H.

Meyer, *Ber.*, 1895, 28, 2959; R. Meyer and L. Friedland, *Ber.*, 1898, 31, 1739; R. Meyer and O. Spendler, *Ber.*, 1903, 36, 2949), has, in the free state, the constitution of a dioxyfluoran:

This compound behaves in a very similar manner to phenolphthalein, although the possibility of a change to a para-quinonoid form is excluded. In order to ascertain whether quinolphthalein exhibits in all respects a completely similar behaviour to phenolphthalein, we have carried out with it the same experiments as recorded above.

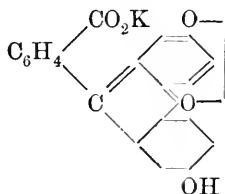

Thus 0.5 gram of quinolphthalein was dissolved in 10 c.c. of caustic potash solution (1 c.c. = 0.194 gram KOH). A violet-red solution was first formed, which quickly became nearly colourless. It was then immersed in a freezing mixture and carefully titrated to neutrality with dilute acetic acid, of which 14.3 c.c. corresponded with 10 c.c. of the caustic potash used; the volume of acetic acid thus required was 13.7 c.c.

Percentage of KOH neutralised by quinolphthalein.

Found	Calculated for $C_{20}H_{13}O_6K$
16.94	16.86

The solution therefore contained the potassium salt of the carbinol-carboxylic acid. The cold neutral solution was quite colourless, but, on heating, the violet-red colour returned, whilst simultaneously the solution became alkaline. The behaviour is therefore exactly similar to that of phenolphthalein.

In order to bring these facts into harmony, we should suggest for the coloured salts of quinolphthalein the ortho-quinonoid structure:

The changes which take place with alkalis would then be represented in a similar manner to those suggested above for phenolphthalein.

Such a view is exactly analogous to that put forward by Kehrman with regard to the constitution of the rosindones and their analogues of the oxazine series.

# XLV.—Freezing Point Curves of Dynamic Isomerides : Ammonium Thiocyanate and Thiocarbamide.

By ALEXANDER FINDLAY.

NOTWITHSTANDING the importance of many of the substances, comparatively few investigations of the mutual relationships of dynamic isomerides have been carried out from the point of view of the phase rule, and the following short study is therefore offered as a contribution to our knowledge of these (compare Carveth, *J. Physical Chem.*, 1898, 2, 159; 1899, 3, 437; Soch, *ibid.*, 1898, 2, 364; Cameron, *ibid.*, 1898, 2, 409; Hollmann, *Zeit. physikal. Chem.*, 1903, 43, 129).

In the case of all pairs of dynamic isomerides, the different solid forms correspond with a single definite constitution, but in the liquid state, a condition of dynamic equilibrium is established between the two modifications. When, therefore, the fusion and solidification of such substances are studied, the phenomena which are observed will vary according as reversible isomeric transformation takes place with measurable velocity at temperatures in the neighbourhood of the melting points, or only at some higher temperature. The relative velocity of transformation, as compared with the time required to carry out the determination of the melting or freezing point, will also have an influence on the character of the system. If isomeric transformation is relatively rapid, the system will behave like a one-component system, but if the velocity of change is comparatively slow, the behaviour will be that of a two-component system (see Bancroft, *J. Physical Chem.*, 1898, 2, 143; Roozeboom, *Zeit. physikal. Chem.*, 1899, 28, 494). Since it is probable that in all cases the velocity of change can be accelerated by means of catalytic agents, it may be possible to cause a two-component system to behave like a system of one component. This has been effected, for example, in the case of acetaldehyde and paraldehyde (Hollmann, *Zeit. physikal. Chem.*, 1903, 43, 129) by means of sulphuric acid.

If no isomeric transformation takes place in the neighbourhood of

the freezing points, the freezing-point curve obtained will be of the ordinary form exhibited by non-isomeric substances. If, however, isomeric transformation takes place with appreciable velocity, the extent to which these curves will be realised will depend on the velocity with which the change occurs as compared with the rapidity with which the determination of the freezing point can be effected. The general behaviour may be explained with the help of Fig. 1.

If one of the modifications is heated, a temperature will be reached at which it will melt, but this melting point (represented by *A*) will be sharp only if the velocity of isomeric transformation is relatively slow. If the substance is maintained in the fused condition for some time, a certain amount of the isomeric form will be produced, and on lowering the temperature the pure *A*-form will be deposited, not at the temperature of its melting point, but at some lower temperature, depending on the concentration of the *B*-form in the liquid phase. If isomeric transformation takes place slowly in comparison with the rate at which deposition of the solid occurs, the liquid will become increasingly rich in the *B*-modification, and the freezing point will therefore sink continuously until the eutectic point is reached. A similar behaviour will be found if we start with the second isomeric form.

The curve *DE* represents the variation of the equilibrium in the liquid phase with the temperature. This curve may be perpendicular, or may slope either to the right or left, its direction depending on whether or not a heat effect accompanies transformation of the one isomeride into the other (Le Chatelier's Theorem). The point *D* at which this equilibrium curve cuts the freezing-point curve is called the "natural freezing point." This is the only point at which a solid phase (in this case the *A*-modification) can exist in stable equilibrium with the fused mixture (solution), and if isomeric transformation takes place with sufficient rapidity, this is the only freezing point which will be realisable, no matter from which form we start. Evidently, therefore, the degree of completeness with which the freezing point curve can be obtained will depend on the rapidity with which the determinations can be carried out.

Finally, since the natural freezing point is the only temperature at which the system solid—liquid is in stable equilibrium, a little consideration will show that on starting with the pure *B*-form and heating it for varying periods of time so as to cause the formation of the *A*-form, the freezing point which is obtained will first fall until the eutectic point is reached, and then rise until the natural freezing point is attained.

The recent work of Emerson Reynolds and Werner (Trans., 1903, 83, 1) on the equilibrium between ammonium thiocyanate and thiocarb-

amide showed that the velocity of isomeric transformation is comparatively slow at temperatures below about  $140^{\circ}$ . As these investigators did not study the freezing points of ammonium thiocyanate and thiocarbamide, and as they informed me of their intention of not proceeding further with the investigation, the matter seemed to be of sufficient interest and importance to warrant a short study of these isomerides on the lines just laid down, and I now lay the results of this research before the Society.

#### EXPERIMENTAL.

The ammonium thiocyanate and the thiocarbamide employed were obtained from Kahlbaum, and were recrystallised from water, the thiocarbamide being well washed with absolute alcohol. The materials were carefully dried, and the attraction of moisture by the ammonium thiocyanate during the preparation of the mixtures was guarded against by carrying out the operations in a large hot-air chamber. For the determination of the freezing points, about 20 grams of the mixture of thiocarbamide and ammonium thiocyanate were placed in a test-tube fitted with a cork, through which passed a glass stirrer and a thermometer graduated in tenths of a degree. The tube was heated by means of a glycerin bath, also furnished with a stirrer. After the complete liquefaction of the mixture had been effected, the temperature of the bath was allowed to fall slowly, and the determination of the freezing point carried out in the ordinary manner. This determination was made several times with the same quantity of substance, the temperature of the bath being maintained at not more than about  $1^{\circ}$  below the freezing point of the mixture. If the mixture was stirred, surfusion was not found to occur to any great extent (not more than about  $0.5^{\circ}$ ).

In the first set of experiments which were carried out, varying quantities of ammonium thiocyanate and thiocarbamide were intimately mixed, and a portion of the mixture was used for the freezing point determination, whilst the other portion was analysed. The method of analysis was that used by Emerson Reynolds and Werner. In these cases, it was necessary to make sure that incorrect values of the freezing point were not obtained, owing to change occurring in the composition of the mixture through isomeric transformation. A series of freezing point determinations were therefore made with each mixture extending over a period of 30—40 minutes, the times at which the different freezing points were determined being noted. It was found, however, that at temperatures below about  $130^{\circ}$ , the change of the freezing point was very small.

In later experiments, however, the composition of the mixture was

ascertained from samples withdrawn in small tubes from the fused mass, after the freezing point had been determined. In this way, greater certainty was obtained that the composition thus determined corresponded with the particular freezing point. More especially was this method of procedure necessary with mixtures containing as much as 50 per cent. of thiocarbamide, for, in this case, very appreciable alteration of the composition took place at the temperature of the freezing point. By noting the time at which the last freezing point was determined and the time at which the sample was withdrawn, a fairly accurate estimate of the freezing point could be made corresponding with the ascertained composition.

The values of the freezing point obtained are given in the following table, and represented graphically in Fig. 1.

*Freezing Point of Mixtures of Ammonium Thiocyanate and Thiocarbamide.*

Percentage of thiocarbamide.	Freezing point.	Percentage of thiocarbamide.	Freezing point.
9.1	135.5°	30.4	106.2°
12.8	131.0	32.94	105.9
16.6	127.4	35.7	110.5
17.4	124.0	40.2	117.5
22.3	118.2	51.9	131.3
25.9	113.4		

Apart from the numbers given in the table, a series of other determinations were made at different times, which also confirm the course of the curve.

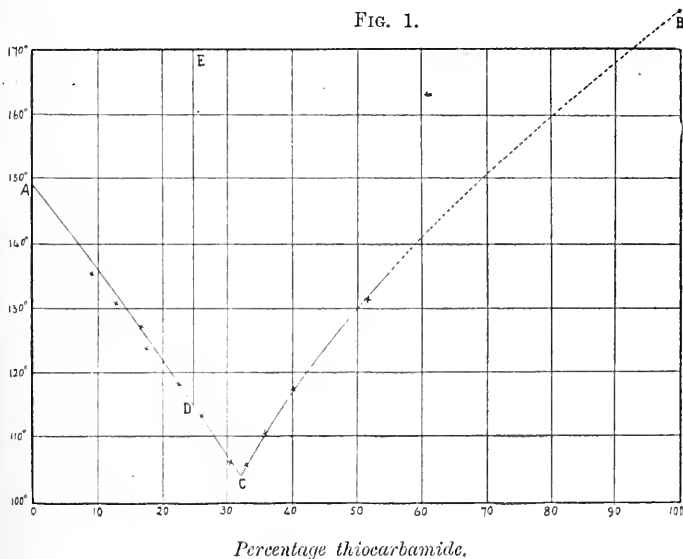

Although the values of the freezing point are given in tenths of a degree, no claim is made that these figures are accurate to less than about 0.5°, and in the case of the higher temperatures the error may be greater.

As is evident from Fig. 1 (p. 407), the freezing point curve of ammonium thiocyanate and thiocarbamide is of the simplest form, indicating the non-formation of a compound between the two components. From all solutions of the composition represented by *AC*, ammonium thiocyanate separates out in the form of crystalline scales. From solutions of the composition represented by *BC*, thiocarbamide separates in fine, crystalline needles, which are quite different in appearance from those of ammonium thiocyanate. By allowing the mixture containing 30 per cent. of thiocarbamide to cool, the eutectic point was found to be 104.5°. This was confirmed in a later experiment.

*Melting Point of Ammonium Thiocyanate and of Thiocarbamide.*

Even at the melting points of these two substances, isomeric transformation can take place with quite appreciable velocity in the case of ammonium thiocyanate, and with very considerable velocity in the case of thiocarbamide. The determination of the melting point, therefore, cannot be carried out with any great degree of accuracy, since the temperature found will depend on the rapidity with which the operation is carried out. By carrying out the determination rapidly, the melting point of ammonium thiocyanate was found to be

FIG. 1.

149°, as also found by other investigators. With regard to thiocarbamide, I believe that the true melting point, if it could be obtained, would be found to lie much higher than 159°, the value given by Emerson Reynolds and Werner, and higher even than 170°, the value given by Prätorius-Seidler (*J. pr. Chem.*, 1880, [ii], 21, 141). This conclusion has been arrived at from determinations of the melting point carried out rapidly in the ordinary apparatus, which yielded values between 172° and 178°. To lessen as far as possible the inaccuracy introduced by too rapid heating, the melting points of the thiocarbamide and of camphor were taken at the same time in the same bath. The camphor was found to melt first. A determination of the melting point of camphor carried out more slowly in the ordinary

manner gave a value  $177^{\circ}$ . The melting point of thiocarbamide is, therefore, probably higher than this.

This conclusion is also supported by the position of the eutectic point; for it is well known that the more nearly coincident are the melting points of two substances, the closer does the eutectic point, as a rule, correspond with the 50 per cent. mixture. Although this rule is only approximately true, one would nevertheless expect that if the melting points of ammonium thiocyanate and thiocarbamide were  $149^{\circ}$  and  $159^{\circ}$  respectively, the eutectic point would correspond with 50 rather than with 30 per cent. of thiocarbamide.

### *Natural Freezing Point.*

The natural freezing point is the point at which the curve of equilibrium in the liquid phase cuts the freezing-point curve. This point could be readily determined if transformation took place with sufficient velocity, since the natural freezing point would then be the temperature at which all mixtures of the two isomerides would freeze. But in the present case, transformation does not occur sufficiently rapidly. If, however, the equilibrium composition is determined at two temperatures, the natural freezing point can be obtained with sufficient accuracy by joining the equilibrium points so determined and prolonging the line downwards to meet the freezing-point curve. In the case of ammonium thiocyanate and thiocarbamide, the equilibrium composition in the fused state has been found both by Waddell (*J. Physical Chem.*, 1898, 2, 525) and by Emerson Reynolds and Werner (*loc. cit.*) to be independent of the temperature, although the value of the equilibrium found by the different investigators was not the same. From the fact that the latter investigators carried out their determination with larger quantities of substance, preference may be given to their value. Moreover, a determination which I also made gave a value agreeing with their result.

Assuming, then, that the equilibrium in the liquid phase at the temperature  $170-180^{\circ}$  occurs when the mixture contains 25 per cent. of thiocarbamide, and also that the equilibrium is not altered by change of temperature, it is evident that the natural freezing point is about  $114-115^{\circ}$ , the stable solid form at this temperature being ammonium thiocyanate. This fact is of interest on account of the difference in behaviour as compared with polymorphous forms of a substance. In the latter case, the more stable form in the neighbourhood of the melting point is that with the higher melting point. Here, however, it is the more fusible form. A similar behaviour has been found in the case of the isomeric benzaldoximes (Cameron, *J. Physical Chem.*, 1898, 2, 409), and, wherever found, it is a sure sign

that isomeric or polymeric, and not polymorphous forms of a substance are being studied.

Finally, from the fact that the equilibrium in the liquid phase is independent of the temperature, the conclusion can be drawn that, in accordance with Le Chatelier's theorem, reciprocal transformation of ammonium thiocyanate and thiocarbamide is not accompanied by any heat effect. This is apparently not unusual in the case of dynamic isomerides, and has been met with in the case of the isomeric benzaldoximes (Cameron, *loc. cit.*) and the isomeric anisaldoximes (Carveth, *J. Physical Chem.*, 1899, 3, 437).

#### *Passage from the Curve BC to AC.*

As has already been pointed out, it should be possible in the case of dynamic isomerides by starting with the less stable form to obtain, on heating, first a fall and then a rise of the freezing point. Hitherto, this had been experimentally verified only in the case of the isomeric benzil-*o*-carboxylic acids (Soch, *J. Physical Chem.*, 1898, 2, 364). It is, however, also found in the case of ammonium thiocyanate and thiocarbamide.

Thiocarbamide was fused and the liquid maintained at a temperature of 160—170° for a certain time, and the freezing point then determined. The temperature was again raised and the freezing point again determined. In this way, the following freezing points were obtained: 108°, 103°, 104°, 105.5°, 106.5°. In the case of the first two determinations, the solid separated out in needle-shaped crystals like thiocarbamide, but in the case of the others, apparently in scales, like ammonium thiocyanate.

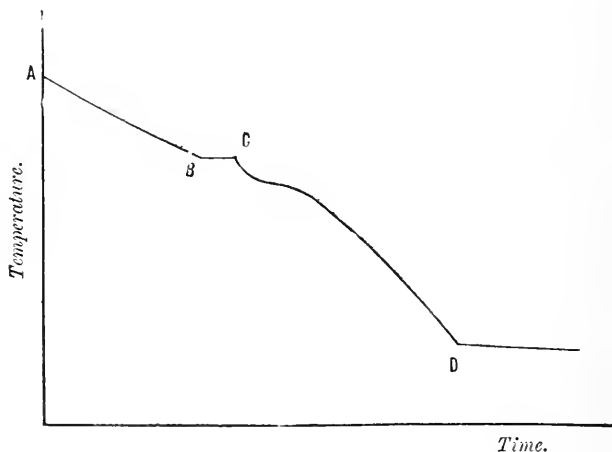

#### *Cooling Curve.*

From the form of the cooling curve of a mixture, valuable conclusions can be drawn with regard to the changes which take place in the system. Indeed, as has recently been emphasised by Tammann (*Zeit. anorg. Chem.*, 1903, 37, 303), it is possible, from a study of the cooling curve and from the "halts" which such a curve exhibits, to get a complete insight into the mutual relations of mixtures of two substances, and to determine the composition of any compounds formed, without the necessity of making a single analysis.

I have therefore supplemented the determinations of the freezing points by ascertaining the form of the cooling curve, starting with a mixture containing about 22 per cent. of thiocarbamide. The curve obtained is shown in Fig. 2 (p. 410). The mixture was first of all fused completely, the temperature thereby rising to about 125°. The tempera-

ture was then allowed to fall slowly, and the rate of cooling noted. So long as only liquid was present, the cooling curve remained continuous as shown by the curve *AB*. The portion *BC*, which ascends slightly, indicates the separation of solid at the freezing point. This is then followed by a rapid fall owing to the temperature of the bath having meanwhile sunk considerably below the temperature of the mixture, whereby rapid separation of the solid phase is caused and a consequent fall in the temperature owing to the increase in the concentration of thiocarbamide in the liquid phase. Cooling then goes on regularly until the eutectic point is reached at which the temperature remained constant ( $104.3^{\circ}$ ) until complete solidification had occurred. This curve, therefore, agrees with the freezing point

FIG. 2.

curve in giving no indication of the formation of a compound  $(\text{NH}_4 \cdot \text{CNS})_3 \cdot \text{CS}(\text{NH}_2)_2$ , since the appearance of such a compound would be indicated by a "break" in the cooling curve between *C* and *D*.

#### *Analysis of the Solid Phase.*

For the purpose of confirming the conclusions which can be drawn from the freezing-point curve as to the non-formation of a compound between ammonium thiocyanate and thiocarbamide, a mixture containing about 27—28 per cent. of the latter isomeride was prepared, completely fused, and allowed to cool down until solid began to separate out. The bath temperature was kept at  $107$ — $108^{\circ}$ , and the solid which separated was filtered off through platinum gauze. On analysis, only about 10 per cent. of thiocarbamide was found. The presence of

this fairly large amount of thiocarbamide is to be accounted for by the difficulty of filtration with the apparatus employed. It is evident, however, that the solid which separated from the fused mixture could not be the compound  $(\text{NH}_4 \cdot \text{CNS})_3 \cdot \text{CS}(\text{NH}_2)_2$ .

### *Stability Limits.*

The term "stability limit" was introduced by Knorr (*Annalen*, 1896, 293, 88) to indicate that temperature above which liquefaction and isomeric change take place. As employed by Knorr and others, however, the term does not have a precise meaning, since it is used to denote not the temperature at which these changes *can* occur, but the temperature at which the change is appreciable, and the introduction of an indefinite velocity of change renders the temperature of the stability limit also indefinite. This indefiniteness has also been recognised by Knorr (*ibid.*, 1899, 306, 334).

Since, however, the stable modification can always undergo isomeric change and liquefy at temperatures above the natural freezing-point, but not below it, and, moreover, since the less stable modification can undergo isomeric transformation and liquefy at temperatures above the eutectic point, but will not liquefy below it, it would appear better, as the author has suggested, to identify the natural freezing point and the eutectic point with the stability limits of the stable and unstable modifications respectively. The opinion expressed by Knorr (*loc. cit.*) that "theoretically" the stability limits of most desmotropic forms, with the exception of enantiomorphous substances, will probably coincide with the melting points, does not appear to me to be justified, since, as stated above, liquefaction and transformation can "theoretically" take place at temperatures below the melting points of either isomeride.

### *Summary.*

1. The freezing-point curve of ammonium thiocyanate (m. p.  $149^\circ$ ) and thiocarbamide (m. p. above  $177^\circ$ ) is of the simplest form, consisting of two branches meeting at a eutectic point ( $104.3^\circ$ ).
2. The natural freezing point is  $114$ — $115^\circ$ , the stable solid form being ammonium thiocyanate.
3. Neither the freezing-point curve, nor the cooling curve, nor the analysis of the solid phase gives any indication of the formation of a compound of ammonium thiocyanate and thiocarbamide stable at temperatures in the neighbourhood of the freezing-point curve.
4. The transformation of ammonium thiocyanate into thiocarbamide and *vice versa* does not appear to be accompanied by any heat effect.

5. The "stability limits" of dynamic isomerides (including desmotropic forms) are defined as the natural freezing point and the eutectic point for the stable and unstable forms respectively.

## XLVI.—*A Note on Phenylldimethylallylammonium Compounds.*

By ALFRED WILLIAM HARVEY.

The work which forms the subject of this note was commenced some eight months ago, but its completion was unavoidably delayed, and in the meanwhile a paper was published on the subject by H. O. Jones (Trans., 1903, 83, 1400) which contained results differing in some respects from those obtained by the author.

In this investigation, an attempt has been made to prepare and resolve into their optically active components, substituted quaternary compounds containing two similar groups.

Phenylldimethylallylammonium iodide was prepared by mixing molecular proportions of dimethylaniline (48 grams) and allyl iodide (67 grams). After a few days, the semi-solid product was finely ground and filtered, 67 grams of solid phenylldimethylallylammonium iodide being obtained. The impure product, which rapidly deliquesced on exposure to air, was further purified by washing with acetone, the final purification being effected by solution in absolute alcohol and precipitation by the cautious addition of ether. Phenylldimethylallylammonium iodide, when pure, melts at 86–88°, and when crystallised from acetone forms large, pink tables, which were never obtained colourless; the pure substance was not deliquescent.

Phenylldimethylallylammonium *d*-camphorsulphonate was prepared by mixing molecular proportions of the iodide and silver *d*-camphorsulphonate; both constituents were finely powdered before mixing, and the mixture was boiled for one hour in a mixture of equal parts of ethyl acetate and acetone. The precipitated silver iodide was filtered off and the salt, which crystallised very readily, was obtained in six fractions by successive crystallisations. No alcohol was used in the preparation and the product was never gummy. The salt crystallised in fine, colourless needles melting at 156°.

The rotatory power, for sodium light, of each of these fractions, in a two per cent. solution, was found to be the same, and the calculated  $[M]_D$  was identical, within the limits of experimental error, with that

of the activity due to the active acid ion, namely,  $[M]_D + 51.7^\circ$ . It was repeatedly observed that an alteration in the concentration of the solution caused a different value for the specific rotation to be obtained at the same temperature, thus, a 1 per cent. solution gave  $[\alpha]_D + 11.9^\circ$ , whilst a 2 per cent. solution had  $[\alpha]_D + 13.3^\circ$ .

As it was possible that a separation of the dextro- and lævo-isomerides might be effected by crystallisation at a higher temperature, search was made for a suitable solvent having a high boiling point. Pyridine was chosen, as phenyldimethylallylammonium *d*-camphorsulphonate is fairly soluble in this solvent in the cold and readily so at the boiling point. A crop of crystals was thus obtained at about the temperature of boiling water. This fraction was not, however, found to exhibit any optical activity due to the basic ion.

As this substance was found to be very sparingly soluble in ethyl acetate, and as Jones described it as readily soluble in ethyl acetate, its solubility in this solvent was determined and found to be less than 8 parts in 5000 parts of a boiling solution of the salt in ethyl acetate. Four separations of the *d*-camphorsulphonate were obtained by the successive addition of quantities of ethyl acetate to a cold solution of the salt in pyridine, and these four fractions also showed no activity due to the basic ion.

0.2006 gave 0.4697  $\text{CO}_2$  and 0.1423  $\text{H}_2\text{O}$ .  $\text{C} = 63.8$  ;  $\text{H} = 7.8$ .  
 $\text{N}(\text{C}_6\text{H}_5)(\text{CH}_3)_2 \cdot \text{C}_3\text{H}_5 \cdot \text{C}_{10}\text{H}_{15} \cdot \text{O} \cdot \text{SO}_3$  requires  $\text{C} = 64.1$  ;  $\text{H} = 7.8$  per cent.

Phenyldimethylallylammonium platinichloride was obtained as a pale yellow crystalline precipitate on adding the requisite quantity of platinic chloride to an aqueous solution of the final fraction from ethyl acetate and acetone of phenyldimethylallylammonium *d*-camphorsulphonate, acidified with hydrogen chloride. The precipitated salt, which was collected and thoroughly washed with water, when dried in the air, melted at  $162\text{--}165^\circ$  with decomposition.

0.5130 gave 0.1439 Pt.  $\text{Pt} = 26.9$ .

$[\text{N}(\text{C}_6\text{H}_5)(\text{CH}_3)_2 \cdot \text{C}_3\text{H}_5]_2\text{PtCl}_6$  requires  $\text{Pt} = 26.6$  per cent.

A cold aqueous solution of the platinichloride, which is slightly soluble in water, was examined in the polarimeter, but was found to be quite inactive. A further examination was made by suspending about half a gram of the salt in water, slightly acidified with hydrogen chloride ; the platinichloride was then decomposed by passing a current of hydrogen sulphide through the cold solution ; the precipitated platinum sulphide was filtered off and the solution examined in the polarimeter. This solution, also, was found to be inactive.

As Jones has succeeded in obtaining *d*- and *l*-isomerides of phenylbenzylmethylethylammonium salts having optical rotations of similar

arithmetical value (Trans., 1904, 85, 223), the author proposes to revise the work of Pope, Peachey, and himself, who failed to find such a close agreement in the case of the *d*- and *l*-phenylbenzylmethylallylammonium salts.

The author's thanks are due to the Research Fund Committee of the Chemical Society for a grant which defrayed the expenses of this research.

## XLVII.—*A Note on the Composition of Distilled Oil of Limes and a New Sesquiterpene.*

By HERBERT EDWARD BURGESS and THEODORE HENRY PAGE.

An investigation of terpeneless or concentrated oil of distilled limes\* showed that this product contained about 40 per cent. of free alcohols. The oil was separated by distillation *in vacuo* into two fractions.

(1) The lower fraction, which boiled at about 100—105°/17 mm. and had a sp. gr. 0.930 at 15°, was viscous and retained the distinctive odour of the oil. By repeated fractionation, it was obtained in quantities approximating to those found for the alcohols by direct estimation, and had the following constants: sp. gr. 0.934 at 15°,  $\alpha$ —19°30' (100 mm. tube), and  $n_D$  1.4806 at 20°.

When cooled in a freezing mixture and sown with a crystal of terpeneol, this fraction became nearly solid. After separation and crystallisation from dilute alcohol, the product melted at 35°. In a supercooled state, the substance had the following constants: sp. gr. 0.941 at 15°,  $[\alpha]_D$ —20°, and  $n_D$  1.4829 at 20°; it boiled at 214°/762 mm.

The terpeneol was further characterised by the preparation of certain of its derivatives. Several of these were found to melt a little low, but this is stated to be the case for the derivatives of the active terpeneols as compared with those of the inactive variety.

The nitrosochloride was obtained in practically quantitative yield by adding hydrochloric acid diluted with glacial acetic acid to a well-cooled solution of the terpeneol and amyl nitrite in glacial acetic acid, the product being precipitated with ice-water. After recrystallisation from ethyl acetate, it melted at 105—106°.

\* The oil obtained after distilling off the terpenes.

The nitroleanilide, prepared from the preceding compound by warming with an alcoholic solution of aniline, crystallised from alcohol and melted at 150—151°.

The phenylurethane slowly separated from a mixture of equal volumes of terpineol and phenylcarbimide. After crystallisation from alcohol it melted at 111°.

The terpineol was successively oxidised with 2·5 per cent. potassium permanganate solution and chromic acid mixture (sp. gr. 1·25), the latter reagent being carefully added to the first oxidation product dissolved in a little water. The oil, which separated, solidified after some days, and when recrystallised from water melted at 62°. This product corresponds with the ketolactone from terpineol (m. p. 35°), and was further characterised by conversion into the oxime (m. p. 77°).

These results indicate that laevorotatory terpineol (m. p. 35°) forms a considerable proportion of the oxygenated compounds in distilled oil of limes.

Although the peculiar odour of distilled oil of limes is attached to the terpineol fraction, the terpineol isolated is either practically odourless or has a faint odour of lilac. The aroma is probably due to an isomeric liquid terpineol having a slightly lower boiling point, but at present this supposition is not supported by conclusive evidence.

(2) The second fraction boiled at 130—140°/17 mm., and had a lower sp. gr. than the first, the value of this constant being under 0·900. This fraction was found to give only a slight action with sodium, and hence consisted almost entirely of hydrocarbons, which from their boiling point seemed to be sesquiterpenes. It was diluted with two volumes of dry ether, saturated with hydrogen chloride, and left for several days. On evaporating off the diluent, crystals separated which were collected, and, after crystallisation from ethyl acetate, melted constantly at 79—80°. This product forms colourless crystals readily soluble in ethyl acetate, acetone, or ether, but less so in alcohol, acetic acid, or chloroform; it is characterised by a remarkable power of crystallisation, and is never obtained in an oily state, although its melting point is comparatively low.

The hydrochloride was mixed with  $1\frac{1}{2}$  parts by weight of sodium acetate and 6 parts of acetic acid, and heated nearly to the boiling point for an hour. The crystals first dissolved, but after a time sodium chloride separated. The cooled mixture was then poured into water, washed, and distilled in steam. The dried distillate was fractionated, the last time over sodium, and obtained as a colourless oil with a slight, but peculiar odour; it resinified with great readiness, even when left in a partially filled flask. It boiled at 131° under 9 mm. and at 262—263° (uncorr.) under 756 mm. pressure, in the latter case with slight decomposition; the following constants were

also determined : sp. gr. 0.873 at  $15^\circ$ ,  $[\alpha]_D \pm 0^\circ$ ,  $n_D$  1.4935 at  $15^\circ$ , and 1.4910 at  $19.5^\circ$ ; mol. refract. 68.2, whereas  $C_{15}H_{24}$  (with three double linkings) requires 67.76.

0.2768 gave 0.8970  $CO_2$  and 0.2986  $H_2O$ . C = 88.38; H = 11.99.

$C_{15}H_{24}$  requires C = 88.24; H = 11.76 per cent.

In dilute solution in acetic acid, the hydrocarbon combined with approximately 6 atoms of bromine.

The hydrochloride gave Cl = 34.2.

$C_{15}H_{24}, 3HCl$  requires 34.0 per cent.

This was the only derivative successfully prepared. The nitroschloride, nitrite, bromide, and acetate were unsatisfactory.

From the above data, it seems apparent that distilled oil of limes contains a sesquiterpene, not hitherto described, and differing materially from the other members of the series, especially in specific gravity, which is much lower than the usual value for sesquiterpenes, but approximates to those found for olefinic or partially olefinic sesquiterpenes.

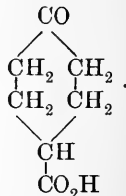

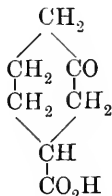

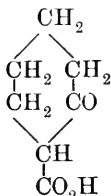

The name "*limene*" is suggested for this sesquiterpene, as having first been found in oil of limes.

Limene is also present in hand-pressed lime oil and in lemon oil in the fraction boiling between  $120^\circ$  and  $140^\circ$  under 9 mm. pressure. The characteristic hydrochloride (m. p.  $79-80^\circ$ ) was readily obtained by saturating this fraction with hydrogen chloride. Other oils of this series are being examined with the view of ascertaining whether limene is present or not.

### XLVIII.— $\delta$ -Ketohehexahydrobenzoic Acid.

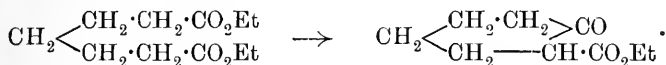

By WILLIAM HENRY PERKIN, jun.

OF the three possible ( $\beta$ -,  $\gamma$ -, and  $\delta$ -)-ketohehexahydrobenzoic (*cyclohexanonecarboxylic*) acids,

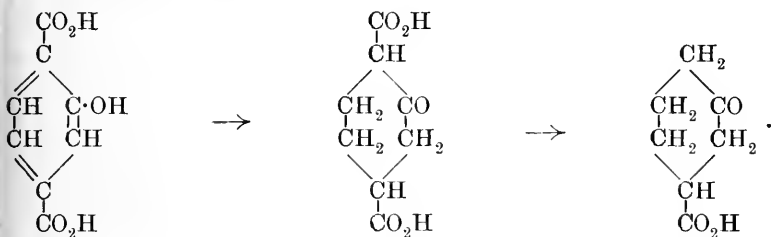

only the first two are known. The ester of the  $\beta$ -acid was synthesised

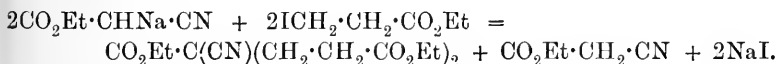

by Dieckmann (*Ber.*, 1894, 27, 103; 1900, 33, 2683) from ethyl pimelate by the action of sodium:

$\gamma$ -Keto-hexahydrobenzoic acid was obtained by Baeyer and Tutein (*Ber.*, 1889, 22, 2182) by first reducing hydroxyterephthalic acid to keto-hexahydroterephthalic acid and then eliminating carbon dioxide by boiling with water:

Since the unknown  $\delta$ -keto-acid might be expected to exhibit unusually interesting properties, the author has been engaged for some time in devising a method for its synthesis, and has ultimately succeeded in preparing it in considerable quantities by the following series of reactions. When ethyl  $\beta$ -iodopropionate and ethyl sodio-cyanoacetate are allowed to interact in molecular proportions at the ordinary temperature, a curious reaction takes place, which results in the formation of ethyl  $\gamma$ -cyanopentane- $\alpha\gamma\epsilon$ -tricarboxylate and regeneration of half of the ethyl cyanoacetate:

Under the conditions employed, it was to be expected that the mono-substitution product, ethyl  $\alpha$ -cyanopropane- $\alpha\gamma$ -dicarboxylate,

would be formed, but no trace of this substance could be isolated, the reaction proceeding apparently quantitatively in the direction shown above.\* Ethyl cyanopentane-tetracarboxylate is hydrolysed by boiling with concentrated hydrochloric acid with the formation of pentane- $\alpha\gamma\epsilon$ -tricarboxylic acid,  $\text{CO}_2\text{H} \cdot \text{CH}(\text{CH}_2 \cdot \text{CH}_2 \cdot \text{CO}_2\text{H})_2$ , which

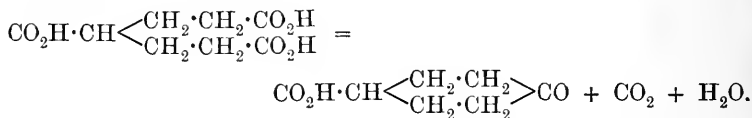

\* In the case of the very similar action of ethyl  $\beta$ -bromopropionate on ethyl sodiomalonate, Emery (*Ber.*, 1891, 24, 282) showed that the principal product of the reaction was the normal mono-substitution product, namely, ethyl propane- $\alpha\gamma$ -tricarboxylate,  $\text{CO}_2\text{Et} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}(\text{CO}_2\text{Et})_2$ , but he also noticed that small quantities of ethyl pentane- $\alpha\gamma\epsilon$ -tetracarboxylate,

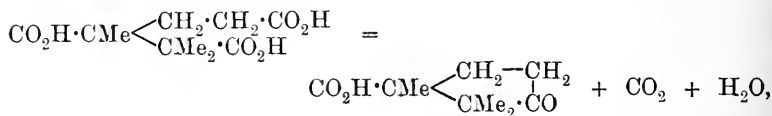

were produced at the same time.

melts at 116—118°, and has already been described by Emery (*Ber.*, 1891, 24, 384) and by Bottomley and Perkin (*Trans.*, 1900, 77, 299).

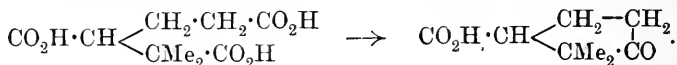

When the sodium salt of this acid is heated with acetic anhydride, or when the acid itself is digested with acetic anhydride and then distilled, a remarkable decomposition takes place with elimination of carbon dioxide and water and formation of  $\delta$ -keto $\delta$ hexahydrobenzoic acid (m. p. 68°):

Similar cases of ring formation from dibasic acids have already been observed on one or two occasions, thus Lapworth and Chapman (*Trans.*, 1900, 77, 464) showed that homocamphoronic acid, when slowly distilled, is converted into camphoronic acid,

and Perkin and Thorpe (*Trans.*, 1904, 85, 138) recently obtained ketodimethylpentamethylenecarboxylic acid by heating the sodium salt of dimethylbutanetricarboxylic acid with acetic anhydride:

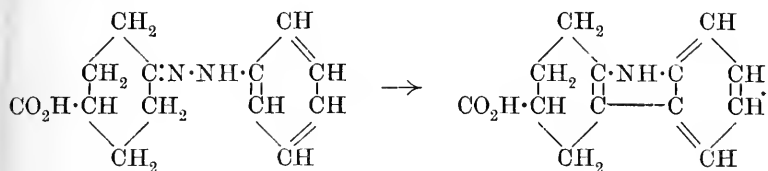

Experiments are in progress, which, it is hoped, will indicate to what extent this valuable method may be employed in the formation of closed chain compounds containing the keto-group.

$\delta$ -Keto $\delta$ hexahydrobenzoic acid crystallises with 1 molecule of water and shows all the properties of a keto-acid; it yields the following derivatives, the preparation and properties of which are described in the experimental part of this paper: *methyl  $\delta$ -keto $\delta$ hexahydrobenzoate*,  $\text{CO}(\text{CH}_2 \cdot \text{CH}_2)_2\text{CH} \cdot \text{CO}_2\text{Me}$  (b. p. 140°/20 mm.); *ethyl  $\delta$ -keto $\delta$ hexahydrobenzoate*,  $\text{CO}(\text{CH}_2 \cdot \text{CH}_2)_2\text{CH} \cdot \text{CO}_2\text{Et}$  (b. p. 158°/40 mm.);  *$\delta$ -ketoxime $\delta$ hexahydrobenzoic acid*,  $(\text{OH})\text{N} \cdot \text{C}(\text{CH}_2 \cdot \text{CH}_2)_2\text{CH} \cdot \text{CO}_2\text{H}$  (m. p. 147°); the *semicarbazone*,  $\text{NH}_2 \cdot \text{CO} \cdot \text{NH} \cdot \text{N} \cdot \text{C}(\text{CH}_2 \cdot \text{CH}_2)_2\text{CH} \cdot \text{CO}_2\text{H}$  (m. p. 194°).

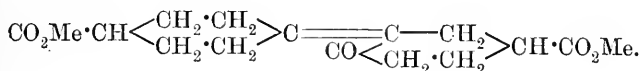

When treated with phenylhydrazine,  $\delta$ -keto $\delta$ hexahydrobenzoic acid yields a yellow oil, which is doubtless the hydrazone, and this, when boiled with hydrochloric acid, loses ammonia and is converted into a sparingly soluble crystalline substance having the formula  $\text{C}_{13}\text{H}_{13}\text{O}_2\text{N}$ . This decomposition is evidently analogous to the well-known conversion of phenylhydrazones into indole derivatives discovered by Emil

Fischer, and the substance  $C_{13}H_{13}O_2N$  is obviously *tetrahydrocarbazole-p-carboxylic acid*, formed according to the scheme :

It is interesting to observe that Baeyer and Tutein (*Ber.*, 1889, 22, 2184) had previously described the exactly similar conversion of  $\gamma$ -keto-hexahydrobenzoic acid into tetrahydrocarbazole-*m*-carboxylic acid by the action of phenylhydrazine and subsequent treatment with hydrochloric acid.

*Carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoic Acid.*—During a series of experiments on the preparation of the methyl and ethyl esters of  $\delta$ -keto-hexahydrobenzoic acid (see above) it was noticed that, when the acid was boiled with methyl alcohol and sulphuric acid, a large quantity of an oil was formed which, on account of its high boiling point ( $255^\circ$  under 20 mm. pressure), was evidently a condensation product. The examination of this oil proved that it was *methyl carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoate*, formed by the elimination of water from two molecules of methyl  $\delta$ -keto-hexahydrobenzoate, and therefore its constitution is obviously that represented by the formula :

On hydrolysis, this methyl ester yields the free *carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoic acid*, a colourless, crystalline substance which melts at  $170^\circ$ . Although it is well known that ketopolymethylene ring compounds readily condense with substances containing the  $>\text{CO}$  group, no case, like the above, seems to have been observed in which condensation of two molecules of the substance is brought about simply by boiling with methyl alcohol and sulphuric acid.

*Reduction of  $\delta$ -Keto-hexahydrobenzoic Acid. Formation of  $\delta$ -Hydroxy-hexahydrobenzoic Acid and the Conversion of this Acid into  $\Delta^3$ -Tetrahydrobenzoic Acid.*

$\delta$ -Keto-hexahydrobenzoic acid is readily reduced by sodium amalgam with formation of  *$\delta$ -hydroxy-hexahydrobenzoic* (cyclohexanol-4-carboxylic) acid,

(m. p.  $121^\circ$ ), and, since this acid shows no tendency to form a lactone, it is evidently the *trans*-modification. It was to be expected that both the *cis*- and *trans*-forms of this acid would be produced by the reduction of the keto-acid, but, although a careful search was made, no trace of the *cis*-acid could be isolated.

When the hydroxy-acid is heated with hydrobromic acid, it is converted into  $\delta$ -bromohexahydrobenzoic (bromocyclohexane-4-carboxylic) acid (m. p.  $167^\circ$ ), and this, when digested with sodium carbonate, readily loses hydrogen bromide with formation of  $\Delta^3$ -tetrahydrobenzoic ( $\Delta^3$ -cyclohexenecarboxylic) acid,

This new acid melts at about  $13^\circ$  and distils at  $237^\circ$  (748 mm.); it shows all the properties of an unsaturated acid, since it reduces permanganate, combines with hydrogen bromide yielding  $\gamma$ -bromohexahydrobenzoic acid (m. p.  $122^\circ$ ), and at once decolorises bromine with formation of  $\gamma\delta$ -dibromohexahydrobenzoic (3:4 dibromocyclohexanecarboxylic) acid (m. p.  $86^\circ$ ),

The above synthesis of  $\Delta^3$ -tetrahydrobenzoic acid is a welcome addition to our knowledge of the chemistry of the tetrahydrobenzoic acids, since all the possible isomerides have now been prepared and carefully investigated. The  $\Delta^1$ -acid (m. p.  $29^\circ$  and b. p.  $240$ – $243^\circ$ ) was obtained by Aschan (*Annalen*, 1892, 271, 267) from bromohexahydrobenzoic acid by elimination of hydrogen bromide,

whereas the  $\Delta^2$ -acid (b. p.  $235^\circ$ ),

is formed by the direct reduction of benzoic acid with sodium amalgam (Hermann, *Annalen*, 1864, 132, 75; Aschan, *loc. cit.*, p. 236).

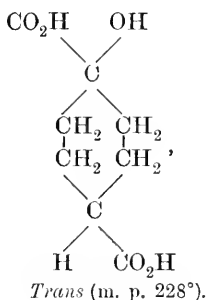

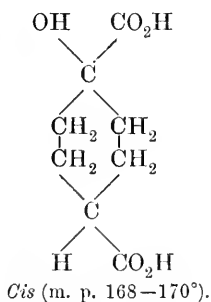

#### *Action of Hydrogen Cyanide on $\delta$ -Keto-hexahydrobenzoic Acid.*

*Formation of the cis- and trans-Modifications of  $\alpha$ -Hydroxyhexahydroterephthalic Acid and of  $\Delta^1$ -Tetrahydroterephthalic Acid.*

When  $\delta$ -keto-hexahydrobenzoic acid is treated with hydrogen cyanide in the presence of potassium cyanide (compare Lapworth, *Trans.*, 1903,

83, 995), addition takes place readily with formation of an oil, which consists of the mixed nitriles of the *cis*- and *trans*-modifications of  $\alpha$ -hydroxyhexahydroterephthalic acid, and from which the *trans*-nitrile (m. p.  $140^\circ$ ) was isolated in a crystalline condition.

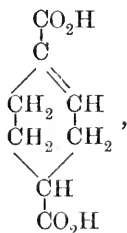

By hydrolysing the mixed nitriles under the conditions described in the experimental part of this paper (p. 435), the corresponding hydroxy-acids,

were easily separated in a state of purity. In the absence of definite proof of their configurations, the more sparingly soluble and less fusible isomeride was taken as being the *trans*-modification.

It is remarkable that when  $\delta$ -ketohehexahydrobenzoic acid is reduced, that is, when the keto-group,  $>\text{CO}$ , is converted into  $>\text{CH}\cdot\text{OH}$ , only one modification of hydroxyhexahydrobenzoic acid should result, whereas, in the very similar addition of hydrogen cyanide, converting the keto-group into  $>\text{C}(\text{CN})\cdot\text{OH}$ , both the *cis*- and *trans*-modifications of the nitrile of  $\alpha$ -hydroxyhexahydroterephthalic acid should be formed. It is also interesting that in the latter case very much more of the *cis*-modification is produced than of the *trans*-modification.

Both the *cis*- and *trans*-modifications of hydroxyhexahydroterephthalic acid are decomposed on distillation, with loss of water and formation of  $\Delta^1$ -tetrahydroterephthalic acid,

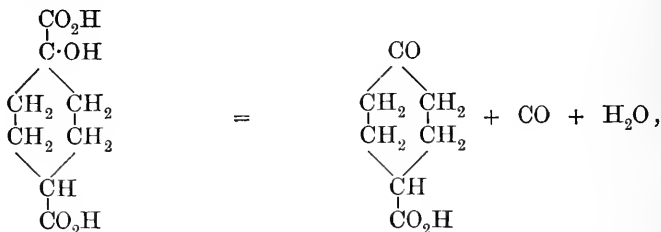

and the acid thus synthesised is identical with the  $\Delta^1$ -tetrahydroterephthalic acid which Baeyer (*Annalen*, 1888, 245, 160) obtained directly from terephthalic acid by reduction with sodium amalgam.

The *cis*- and *trans*-modifications of  $\alpha$ -hydroxyhexahydroterephthalic

acid are readily acted on by concentrated sulphuric acid, decomposition taking place in both cases in two distinct directions.

Part of the acid is decomposed with elimination of carbon monoxide and water and formation of  $\delta$ -keto-hexahydrobenzoic acid,

whereas the remainder is converted into  $\Delta^1$ -tetrahydroterephthalic acid by the simple elimination of water.

The investigation of  $\delta$ -keto-hexahydrobenzoic acid and its derivatives is being continued in various directions.

#### EXPERIMENTAL.

*Ethyl  $\gamma$ -Cyanopentane- $\alpha\gamma\epsilon$ -tricarboxylate,*

In preparing this cyano-ester, the quantities usually employed were sodium (25 grams), alcohol (400 c.c.), ethyl cyanoacetate (125 grams), and ethyl  $\beta$ -iodopropionate\* (250 grams).

The sodium is dissolved in the alcohol in a two-litre flask, and, after cooling, the ethyl cyanoacetate added all at once; the flask is then cooled again in running water and the ethyl  $\beta$ -iodopropionate added in three portions, care being taken that the temperature never rises above  $25^\circ$ , as otherwise some of the ethyl  $\beta$ -iodopropionate is liable to be decomposed with formation of ethyl acrylate (compare *Trans.*, 1904, 85, 120). After being left overnight, the mixture is heated for half an hour on the water-bath, diluted with three times its volume of water, and extracted three times with ether.

The ethereal solution is washed until free from alcohol, dried over

\* Owing to the costliness of  $\beta$ -iodopropionic acid, a number of comparative experiments were made with the object of discovering the best conditions for converting it into its ethyl ester, and the following process was found to give excellent results. The acid (500 grams) is dissolved in alcohol (400 c.c.) and mixed with a cold solution of sulphuric acid (150 grams) in alcohol (200 c.c.) and the whole allowed to remain for four days at the ordinary temperature. The product, which will have separated into two layers, is mixed with three volumes of water, extracted twice with ether, the ethereal solution washed with water containing a little sulphurous acid (to remove iodine), and fractionated under reduced pressure.

The boiling point is  $136^\circ$  under 100 mm. pressure, and the yield 525—535 grams, or 94 per cent. of that theoretically possible.

calcium chloride, and evaporated, and the residual oil fractionated under 20 mm. pressure. At first, unchanged ethyl cyanoacetate passes over, then the temperature rises rapidly to  $220^{\circ}$ , almost the whole of the residue passing over between this and  $240^{\circ}$ ; on repeating the fractionation, the pure substance is then easily obtained, distilling almost constantly at  $228^{\circ}$  (20 mm.).

0.1888 gave 0.3881  $\text{CO}_2$  and 0.1245  $\text{H}_2\text{O}$ .  $\text{C} = 57.0$ ;  $\text{H} = 7.4$ .

0.2880 „ 12.3 c.c. nitrogen at  $15^{\circ}$  and 756 mm.  $\text{N} = 4.9$ .

$\text{C}_{15}\text{H}_{23}\text{O}_6\text{N}$  requires  $\text{C} = 57.5$ ;  $\text{H} = 7.3$ ;  $\text{N} = 4.5$  per cent.

*Ethyl cyanopentanetricarboxylate* is a viscid, colourless oil, which, when placed in a freezing mixture, showed no signs of solidifying.

It is formed apparently quantitatively, according to the equation, given in the introduction (p. 417), since on one occasion, when four of the above quantities were worked up together, the yields obtained were ethyl cyanoacetate (190 grams), and ethyl cyanopentanetricarboxylate (680 grams), whereas the theoretical quantities are 240 and 686 grams respectively.

*Pentane- $\alpha\gamma$ -tricarboxylic Acid*,  $\text{CO}_2\text{H}\cdot\text{CH}(\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H})_2$ .

Ethyl cyanopentanetricarboxylate is with difficulty completely hydrolysed by boiling with mineral acids, especially when the operation is carried out in a reflux apparatus, and the alcohol formed cannot escape. This behaviour caused great difficulties at first, and a number of experiments had to be made before the best conditions for hydrolysis were discovered; now that these have been determined, the yield of acid is almost quantitative.

The pure cyano-ester (100 grams) is mixed with concentrated hydrochloric acid (200 c.c.) in a litre flask fitted with a ground-in air condenser, and carefully heated just to boiling on a sand-bath.

In the course of about half an hour, the oil will have completely dissolved, and care is necessary at this stage to avoid loss owing to frothing due to the elimination of carbon dioxide. After 1 hour, the air-tube is removed and the alcohol allowed to escape, a further quantity of hydrochloric acid (50—100 c.c.) is added, and the boiling continued in the open flask for 8 hours. The crystals of pentanetricarboxylic acid mixed with ammonium chloride, which will have separated overnight, are collected at the pump, washed with concentrated hydrochloric acid, and the filtrate again boiled in an open flask, when a further crop of crystals will be obtained. These are treated in the same way as the first crop, and the boiling of the filtrate and the whole cycle of operations continued as long as crystals continue to separate. The last mother liquors, which have a brown colour, are evaporated on the water-bath and the viscid syrup set aside to crystal-

lise; the crude acid is then placed in contact with porous porcelain, when in the course of a few days it will have become almost white. The crops of crystals are combined, thoroughly dried on the water-bath, powdered, and extracted with pure ether,\* preferably in a Soxhlet apparatus, by which means the acid is dissolved, and separated from the insoluble ammonium chloride. The concentrated ethereal solution deposits the pure acid in crystalline crusts, which are collected and washed with ether, and from the mother liquors the remainder of the acid is obtained by concentrating and recrystallising either from ether or from hydrochloric acid.

0.1627 gave 0.2801  $\text{CO}_2$  and 0.0874  $\text{H}_2\text{O}$ .  $\text{C} = 47.0$ ;  $\text{H} = 6.0$ .

$\text{C}_8\text{H}_{12}\text{O}_6$  requires  $\text{C} = 47.1$ ;  $\text{H} = 5.9$  per cent.

*Pentane- $\alpha,\gamma,\epsilon$ -tricarboxylic acid* melts at  $116\text{--}118^\circ$ , and has already been prepared by Emery (*Ber.*, 1891, 24, 284) from ethyl pentanetetracarboxylate,  $(\text{CO}_2\text{Et})_2\text{C}(\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{Et})_2$ , and by Bottomley and Perkin (*Trans.*, 1900, 77, 299) from ethyl pentanehexacarboxylate,  $(\text{CO}_2\text{Et})_2\text{CH}\cdot\text{CH}_2\cdot\text{C}(\text{CO}_2\text{Et})_2\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{Et})_2$ , by hydrolysis, but the previously observed melting points were rather too low.

The process given in this paper is by far the most suitable for the preparation of large quantities of this acid.

This acid may be obtained in a variety of ways from pentanetricarboxylic acid, as, for example, by the distillation of the ammonium salt or, better, by heating the sodium salt with acetic anhydride under exactly the same conditions as those described in the preparation of ketodimethylpentamethylenecarboxylic acid from dimethylbutanedicarboxylic acid (*Trans.*, 1904, 85, 138), but, as the result of a large number of experiments, the following process, which should be followed exactly, was found to give by far the most satisfactory results. The pure tribasic acid, in quantities of not more than 15 grams, is heated with twice its weight of acetic anhydride for 6 hours, the acetic acid and excess of acetic anhydride are then distilled off, the heating being continued until a thermometer, immersed in the liquid, registers  $180^\circ$ .

The residue is then transferred to a distilling flask connected with the pump and heated in a metal-bath under 15 mm. pressure, the thermometer being in the liquid during the first stages of the opera-

\* It is important that the acid should be heated until every trace of hydrogen chloride has been removed and the ether quite free from alcohol; otherwise, partial etherification takes place and the acid does not crystallise.

tion. Some acetic anhydride passes over, and when the temperature reaches 200—210°, at which it is kept for 10 minutes, carbon dioxide is evolved and the pressure rises. The operation is suspended until the pressure is again reduced to 15 mm., when the heating at 220° is continued and, as soon as the evolution of carbon dioxide is seen to slacken considerably, the thermometer is drawn up to the usual position and the contents of the flask rapidly distilled until the temperature rises to 250°, the considerable brown residue remaining in the flask being neglected.

The distillate, which from 15 grams of tribasic acid weighs about 7 grams, is dissolved in a little water, mixed with semicarbazide hydrochloride (5 grams) and sodium acetate (5 grams), and heated just to boiling. After remaining overnight, the sparingly soluble semicarbazone (p. 427) is collected, washed with water, dissolved in hot dilute hydrochloric acid, and repeatedly extracted with ether. On evaporating the ethereal solution, a pale yellow oil is obtained which solidifies completely on cooling and consists of practically pure  $\delta$ -keto-hexahydrobenzoic acid.

This is the most direct way, if small quantities only of the keto-acid are required, but in preparing the large quantities employed in this research the following method of purification was found to be more convenient and economical.

The distillate from the decomposition of 50 grams of the tribasic acid is fractionated under reduced pressure (15 mm.), when a large fraction passes over at 200—225°, leaving a viscid, brown residue in the flask. On refractionating, practically the whole distils at 205—215° under the same pressure and solidifies almost completely on cooling, and the acid thus obtained, after remaining in contact with porous porcelain for a few days, is pure enough for most purposes, and in this form\* it was, unless otherwise stated, used in the experiments described in this paper. For the analysis, the acid was purified by conversion into the semicarbazone and then recrystallised from a mixture of benzene and light petroleum.

0.1711 gave 0.3689  $\text{CO}_2$  and 0.1092  $\text{H}_2\text{O}$ . C = 58.8; H = 7.1.

0.1523 „ 0.3288  $\text{CO}_2$  „ 0.0960  $\text{H}_2\text{O}$ . C = 58.8; H = 7.0.

$\text{C}_7\text{H}_{10}\text{O}_3$  requires C = 59.1; H = 7.0 per cent.

*$\delta$ -Keto-hexahydrobenzoic acid* melts at about 67—68° with a slight previous softening, and is readily soluble in alcohol, ether, or benzene, but sparingly so in light petroleum; it dissolves readily in cold water, and is soluble in almost all proportions in hot water, from which it separates, on cooling, in magnificent groups of needles.

\* When purified in this way, the yield of keto-acid from 1 kilo. of ethyl  $\beta$ -iodo-propionate varied, in different experiments, from 130—160 grams.

The crystals thus obtained were dried at  $40^\circ$  and found to contain one molecule of water of crystallisation.

0.1782 gave 0.3433  $\text{CO}_2$  and 0.1176  $\text{H}_2\text{O}$ .  $\text{C} = 52.5$ ;  $\text{H} = 7.3$ .

$\text{C}_7\text{H}_{10}\text{O}_3 \cdot \text{H}_2\text{O}$  requires  $\text{C} = 52.5$ ;  $\text{H} = 7.5$  per cent.

The direct determination of the water of crystallisation was difficult, owing to the fact that the acid is slightly volatile at  $100^\circ$ , but, after heating at  $80^\circ$  until practically constant, 0.5096 gram lost 0.0592 gram, or 11.5 per cent., whereas the formula  $\text{C}_7\text{H}_{10}\text{O}_3 \cdot \text{H}_2\text{O}$  requires 11.3 per cent. of water. On titration, 0.2177 of the crystals neutralised 0.0539  $\text{NaOH}$ , whereas this amount of an acid,  $\text{C}_7\text{H}_{10}\text{O}_3 \cdot \text{H}_2\text{O}$ , should neutralise 0.0544 of the alkali.

*Formation of  $\delta$ -Ketohehexahydrobenzoic Acid from the Sodium Salt of Pentane- $\alpha\gamma\epsilon$ -tricarboxylic Acid by the Action of Acetic Anhydride, and from the Ammonium Salt by Distillation.*

In the first experiment, the pure tribasic acid (41 grams) was dissolved in water, mixed with sodium carbonate (33 grams), and evaporated to dryness; the dry salt was powdered and passed through a fine sieve and then heated with acetic anhydride at  $165^\circ$  for 4 hours, when large quantities of carbon dioxide were eliminated.

The product was dissolved in water, mixed with semicarbazide hydrochloride (20 grams), when, after two days, a cake of the semicarbazone of  $\delta$ -ketohehexahydrobenzoic acid had separated, and this was found to weigh 7 grams.

In the second experiment, 14 grams of the pure acid were dissolved in excess of ammonia and evaporated to dryness. The viscid semi-solid mass was first heated under the ordinary pressure, when a quantity of ammonia and steam was given off and, as soon as the temperature of the liquid had risen to  $150^\circ$ , the whole was transferred to the vacuum distillation apparatus and the heating continued under 20 mm. pressure. The mass soon solidified completely, then melted again and gave off a quantity of gas, and much oil distilled over. The distillate, on treatment with semicarbazide hydrochloride and sodium acetate, yielded 3 grams of the semicarbazone of  $\delta$ -ketohehexahydrobenzoic acid.

*The Methyl and Ethyl Esters, the Oxime, and the Semicarbazone of  $\delta$ -Ketohehexahydrobenzoic Acid.*

*Methyl  $\delta$ -Ketohehexahydrobenzoate*,  $\text{CO}(\text{CH}_2 \cdot \text{CH}_2)_2\text{CH} \cdot \text{CO}_2\text{Me}$ .—A quantity of this ester was prepared by digesting the keto-acid with methyl alcohol and sulphuric acid in the usual way, but the yield was

very poor owing to the formation of considerable quantities of methyl carboxyhexamethenylketohexahydrobenzoate (see p. 429).

It is a colourless oil which boils at  $140^\circ$  under 20 mm. pressure.

0.1824 gave 0.4089  $\text{CO}_2$  and 0.1295  $\text{H}_2\text{O}$ .  $\text{C} = 61.2$ ;  $\text{H} = 7.9$ .

$\text{C}_8\text{H}_{12}\text{O}_3$  requires  $\text{C} = 61.5$ ;  $\text{H} = 7.7$  per cent.

*Ethyl  $\delta$ -Keto-hexahydrobenzoate*,  $\text{CO}(\text{CH}_2\cdot\text{CH}_2)_2\text{CH}\cdot\text{CO}_2\text{Et}$ .—This ester may be obtained, in an almost quantitative yield, by digesting the keto-acid (10 grams) with 40 grams of a 3 per cent. solution of hydrogen chloride in absolute alcohol in a reflux apparatus for 6 hours. The product is mixed with 3 times its volume of ether, water is then added, and the ethereal solution separated and washed 3 times with water and once with dilute sodium carbonate.

After drying over calcium chloride and distilling off the ether, an oil is obtained which distils almost constantly at  $158^\circ$  (40 mm.), and consists of pure ethyl  $\delta$ -keto-hexahydrobenzoate.

0.1417 gave 0.3279  $\text{CO}_2$  and 0.1061  $\text{H}_2\text{O}$ .  $\text{C} = 63.1$ ;  $\text{H} = 8.3$ .

$\text{C}_9\text{H}_{14}\text{O}_3$  requires  $\text{C} = 63.5$ ;  $\text{H} = 8.2$  per cent.

*$\delta$ -Ketoximehexahydrobenzoic Acid*,  $(\text{OH})\text{N}:\text{C}(\text{CH}_2\cdot\text{CH}_2)_2\text{CH}\cdot\text{CO}_2\text{H}$ .—In preparing this oxime, the pure acid (2 grams) was dissolved in a little water, mixed with a strong solution of hydroxylamine hydrochloride (2 grams) and caustic potash (4 grams), and after remaining for 2 days, the product was acidified and extracted at least 15 times with ether. The ethereal solution was dried over calcium chloride and evaporated, and the viscid, oily residue, which gradually became semi-solid, left in contact with porous porcelain until quite dry. The substance was then dissolved in ether and the ethereal solution evaporated to a small bulk, when, on cooling, the oxime gradually separated in crystalline crusts.

0.1704 gave 0.3336  $\text{CO}_2$  and 0.1080  $\text{H}_2\text{O}$ .  $\text{C} = 53.4$ ;  $\text{H} = 7.0$ .

0.2014 „ 14.8 c.c. nitrogen at  $11^\circ$  and 748 mm.  $\text{N} = 8.6$ .

$\text{C}_7\text{H}_{11}\text{NO}_3$  requires  $\text{C} = 53.5$ ;  $\text{H} = 7.0$ ;  $\text{N} = 8.9$  per cent.

*$\delta$ -Ketoximehexahydrobenzoic acid*, melts at about  $147^\circ$  and is sparingly soluble in dry ether, chloroform, light petroleum, or benzene, but readily so in hot water or methyl alcohol.

*The Semicarbazone of  $\delta$ -Keto-hexahydrobenzoic acid*,

$\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{N}:\text{C}(\text{CH}_2\cdot\text{CH}_2)_2\text{CH}\cdot\text{CO}_2\text{H}$ .

When keto-hexahydrobenzoic acid is dissolved in a little water and mixed with a solution of semicarbazide hydrochloride and sodium

acetate, the semicarbazone separates at once as a sandy, crystalline powder.

0.1605 gave 28.7 c.c. nitrogen at  $17^\circ$  and 761 mm.  $N = 20.8$ .

$C_9H_{13}O_3N_3$  requires  $N = 21.2$  per cent.

This semicarbazone softens at about  $194^\circ$  and decomposes at  $200^\circ$ ; it is very sparingly soluble in water and in alcohol. It dissolves readily in hydrochloric acid with liberation of the keto-acid, which may then be extracted with ether (see p. 425).

*Action of Phenylhydrazine on  $\delta$ -Keto-hexahydrobenzoic Acid. Formation of Tetrahydrocarbazole-p-carboxylic Acid.\**

A solution of the pure keto-acid (1 gram) in water was mixed with freshly distilled phenylhydrazine (2 grams) dissolved in dilute acetic acid, when, in a short time, pale yellow drops separated which, doubtless, consisted of hydrazone of the keto-acid. The substance showed, however, no signs of crystallising, and therefore no attempts were made to analyse it; it is also evidently an unstable substance, since it rapidly became brown and gave off gas. The freshly prepared oily hydrazone dissolves in warm concentrated hydrochloric acid, and, if the solution is heated just to boiling and then poured into cold water, an ochre-coloured precipitate of crude tetrahydrocarbazolecarboxylic acid separates.

The precipitate was collected at the pump, washed well with water, and left in contact with porous porcelain until quite dry; it was then digested with benzene, filtered from a brown, amorphous impurity, and the benzene solution evaporated to a small bulk.

The concentrated solution gradually deposited a crust of warty crystals which was collected, washed with benzene, dried at  $100^\circ$ , and analysed.

0.1635 gave 0.4364  $CO_2$  and 0.0890  $H_2O$ .  $C = 72.8$ ;  $H = 6.0$ .

0.2184 „ 11.4 c.c. nitrogen at  $15^\circ$  and 749 mm.  $N = 6.1$ .

$C_{13}H_{13}O_2N$  requires  $C = 72.6$ ;  $H = 6.0$ ;  $N = 6.5$  per cent.

*Tetrahydrocarbazole-p-carboxylic acid* melts at about  $195^\circ$  and is readily soluble in alcohol, but sparingly so in chloroform, light petroleum, or benzene. The solution in sodium carbonate decolorises permanganate instantaneously. The finely powdered substance dissolves readily in concentrated hydrochloric acid and is reprecipitated in flocks on dilution with water. When the acid is heated in a test-tube, it gives off gas and yields a crystalline sublimate which is only partially soluble in sodium carbonate and has a pronounced odour of indole.

\* For the constitution of this acid, see p. 419.

*Carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoic Acid.*

As explained in the introduction (p. 419), the ester of this acid was accidentally obtained in the course of an experiment made with the object of preparing methyl  $\delta$ -keto-hexahydrobenzoate from the acid by treatment with methyl alcohol and sulphuric acid in the usual way; the details of the experiment are as follows.

The acid (70 grams) was dissolved in methyl alcohol (200 c.c.), and concentrated sulphuric acid (50 c.c.) gradually added, the whole being well cooled during the addition. The mixture was digested for 4 hours in a reflux apparatus, and, when cold, mixed with 3 volumes of ether; water was then added and the ethereal solution separated and washed successively with water and dilute sodium carbonate. After drying over calcium chloride and evaporating, a viscid oil remained which, on fractionating under 20 mm. pressure, was readily separated into methyl  $\delta$ -keto-hexahydrobenzoate boiling at  $140^{\circ}$  (see p. 426) and a yellow, viscid liquid boiling at  $255^{\circ}$ . The latter was analysed with the following results:

0.266 gave 0.6356  $\text{CO}_2$  and 0.178  $\text{H}_2\text{O}$ .  $\text{C} = 65.2$ ;  $\text{H} = 7.4$ .

$\text{C}_{16}\text{H}_{22}\text{O}_5$  requires  $\text{C} = 65.3$ ;  $\text{H} = 7.5$  per cent.

In order to obtain the free acid, this *methyl carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoate* was dissolved in methyl alcohol mixed with a methyl alcoholic solution of caustic potash (8 grams) and heated to boiling for half an hour. Water was then added and the solution evaporated until free from methyl alcohol; it was then acidified, when a viscid syrup separated which gradually solidified.

After remaining in contact with porous porcelain until quite free from oily impurity, the acid was dissolved in dry ether, the ethereal solution concentrated and allowed to remain, when the acid gradually separated as a hard, crystalline crust.

0.1508 gave 0.3474  $\text{CO}_2$  and 0.0958  $\text{H}_2\text{O}$ .  $\text{C} = 62.8$ ;  $\text{H} = 7.0$ .

$\text{C}_{14}\text{H}_{18}\text{O}_5$  requires  $\text{C} = 63.1$ ;  $\text{H} = 6.8$  per cent.

*Carboxyhexamethenyl- $\delta$ -keto-hexahydrobenzoic acid* melts at about  $170^{\circ}$ , but not sharply, since it softens a good deal below that temperature.

It is readily soluble in alcohol, but sparingly so in ether and cold water; it dissolves, however, in hot water, and separates on cooling, in colourless, microscopic needles. The solution in dilute sodium carbonate instantly decolorises permanganate, and when the aqueous solution of the acid is boiled with semicarbazide hydrochloride and sodium acetate, a very sparingly soluble semicarbazone is formed which was not further examined.

*Reduction of  $\delta$ -Keto-hexahydrobenzoic Acid. Formation of  
trans- $\delta$ -Hydroxyhexahydrobenzoic Acid,*

Sodium amalgam readily reduces  $\delta$ -keto-hexahydrobenzoic acid to the above hydroxy-acid, and, in studying this reduction, the keto-acid, in quantities of 5 grams, was dissolved in a slight excess of dilute sodium carbonate solution and treated with 150 grams of 4 per cent. sodium amalgam. The reduction was carried out in a large porcelain beaker, fitted with a mechanical stirrer and cooled externally by ice, and the sodium amalgam was added in quantities of 30 grams, a stream of carbon dioxide being passed during the whole operation. The product from 5 of these operations was separated from the mercury, acidified and extracted 10 times with ether, and since, even then, 8 grams of the reduced acid remained in the mother liquor, the extraction was continued by shaking on the machine with large quantities of ether. The combined ethereal extracts were dried over calcium chloride and evaporated to a small bulk, when the hydroxy-acid (15 grams) gradually separated in colourless nodules, and was further purified by a second recrystallisation from ether.

0.1860 gave 0.3982  $\text{CO}_2$  and 0.1391  $\text{H}_2\text{O}$ . C = 58.4; H = 8.3.

0.1676 „ 0.3574  $\text{CO}_2$  „ 0.1254  $\text{H}_2\text{O}$ . C = 58.2; H = 8.3.

$\text{C}_7\text{H}_{12}\text{O}_3$  requires C = 58.3; H = 8.3 per cent.

*trans- $\delta$ -Hydroxyhexahydrobenzoic acid* melts at 120—121°, and is readily soluble in water or alcohol, but sparingly so in cold dry ether, chloroform, or benzene. This acid shows no tendency to yield a lactone; when heated, it distils, and the oily distillate, which solidifies on rubbing, is completely soluble in cold sodium carbonate solution, and when the acid is boiled with 25 per cent. sulphuric acid, no signs of lactone formation could be detected.

The ethereal mother liquors of the *trans*-hydroxy-acid were evaporated to dryness and left for some days until the whole had become semi-solid. The mass was then spread on porous porcelain, and, when quite free from oil, recrystallised from ether, and in this way 5 grams of the pure *trans*-hydroxy-acid were obtained.

In order to see whether any *cis*-hydroxy-acid had been formed during the reduction of the keto-acid, the porous porcelain was broken up and extracted in a Soxhlet apparatus with ether, but only a small quantity of oil was obtained, and after distilling this under 30 mm. pressure the distillate was found to be completely soluble

in cold dilute sodium carbonate solution, showing that no trace of lactone was present, and thus proving that no *cis*-hydroxy-acid had been formed.

*trans*- $\delta$ -Bromohexahydrobenzoic Acid and its Conversion into  $\Delta^3$ -Tetrahydrobenzoic Acid,

and into  $\gamma$ -Bromohexahydrobenzoic Acid and  $\gamma\delta$ -Dibromohexahydrobenzoic Acid.

When finely-powdered  $\delta$ -hydroxyhexahydrobenzoic acid is mixed with hydrobromic acid (saturated at  $0^\circ$ ), it dissolves, and even after several hours no separation takes place.

If, however, the solution is heated in a sealed tube at  $100^\circ$  for 30 minutes, a viscid, oily layer forms on the surface of the hydrobromic acid, and this gradually becomes semi-solid. After washing with water, contact with porous porcelain readily removes the oily impurity, and the residue crystallises readily from light petroleum (b. p.  $70$ — $80^\circ$ ) in colourless, glistening plates.

0.1388 gave 0.1254 AgBr. Br = 38.4.

$\text{C}_7\text{H}_{11}\text{O}_2\text{Br}$  requires Br = 38.6 per cent.

*trans*- $\delta$ -Bromohexahydrobenzoic acid softens at  $160^\circ$  and melts at about  $167^\circ$ , and is readily soluble in chloroform, benzene, or alcohol, but less so in cold light petroleum.

When the bromo-acid is boiled with water, hydrogen bromide is only slowly eliminated, and, indeed, the acid crystallises well from water if the operation is carried out moderately rapidly, and is then obtained in plates having a satiny lustre and exactly resembling benzoic acid, and, like this acid, the bromo-acid is also volatile in steam.

$\Delta^3$ -Tetrahydrobenzoic Acid.—In preparing this acid,  $\delta$ -bromohexahydrobenzoic acid was dissolved in a considerable excess of moderately concentrated sodium carbonate and the solution heated to boiling for half an hour. On acidifying,  $\Delta^3$ -tetrahydrobenzoic acid was precipitated as a colourless oil, and, after extracting [with ether, the ethereal solution was dried over calcium chloride, evaporated, and the residue distilled under 25 mm. pressure.

With the exception of a small quantity of a higher boiling substance (probably  $\delta$ -hydroxyhexahydrobenzoic acid, produced from the bromo-acid by hydrolysis), the whole passed over at  $145$ — $150^\circ$ , and, on

subsequently distilling under the ordinary pressure, the acid was readily obtained pure as a colourless oil boiling constantly at  $237^{\circ}$  (748 mm.).

0.2348 gave 0.5700  $\text{CO}_2$  and 0.1686  $\text{H}_2\text{O}$ .  $\text{C} = 66.2$ ;  $\text{H} = 8.0$ .

0.1490 „ 0.3626  $\text{CO}_2$  „ 0.1064  $\text{H}_2\text{O}$ .  $\text{C} = 66.4$ ;  $\text{H} = 7.9$ .

$\text{C}_7\text{H}_{10}\text{O}_2$  requires  $\text{C} = 66.6$ ;  $\text{H} = 7.9$  per cent.

When placed in a freezing mixture, the distilled acid solidified completely, and the melting point, determined by placing a thermometer in the melting acid, was about  $13^{\circ}$ . Possibly, if the acid were left in contact with porous porcelain in order to remove any trace of oily impurity, a higher melting point than this might be observed, but the amount of material at my disposal did not allow of this being done.  $\Delta^3$ -Tetrahydrobenzoic acid has a most unpleasant odour, closely resembling that of allylacetic acid; it shows the properties of an unsaturated acid, since its solution in sodium carbonate decolorises permanganate instantly and the acid itself combines directly with both bromine and hydrogen bromide (see below). When the acid is exposed on a watch glass to the action of the air, very little change is noticed until after some days, and then a thin film of crystals forms on the surface, and these crystals appear to consist of benzoic acid, although this could not be established with certainty.

In any case, oxidation takes place only very slowly, and in this respect the  $\Delta^3$ -acid resembles the  $\Delta^1$ -acid and differs from the  $\Delta^2$ -acid, as the latter is rapidly oxidised to benzoic acid in contact with air.  $\Delta^3$ -Tetrahydrobenzoic acid shows no signs of being converted into a lactone when it is digested with dilute sulphuric acid.

*$\gamma$ -Bromohexahydrobenzoic Acid.*— $\Delta^3$ -Tetrahydrobenzoic acid dissolves readily and completely in four times its volume of aqueous hydrobromic acid (saturated at  $0^{\circ}$ ) with evolution of heat, but the solution soon becomes cloudy, and in a short time a viscid oil separates on the surface of the hydrobromic acid. The oil gradually solidifies, and the aqueous layer becomes filled with colourless crystals.

After 12 hours, water is added, the pasty, crystalline mass collected at the pump, washed well, and left in contact with porous porcelain until quite dry. The residue crystallises from its warm dilute solution in light petroleum (b. p.  $60$ – $80^{\circ}$ ) in groups of flat needles, but from a hot concentrated solution the substance separates in glistening plates.

0.1712 gave 0.1552 AgBr.  $\text{Br} = 38.6$ .

$\text{C}_7\text{H}_{11}\text{O}_2\text{Br}$  requires  $\text{Br} = 38.6$  per cent.

*$\gamma$ -Bromohexahydrobenzoic acid* shrinks together at  $110^{\circ}$  and melts at about  $122^{\circ}$ , and repeated crystallisation did not alter this behaviour or make the melting point any sharper; it is practically insoluble in cold

light petroleum or cold water, but readily soluble in benzene, alcohol, or ether. It dissolves to a considerable extent in boiling water, and separates, on cooling, as a voluminous mass of glistening plates which closely resemble benzoic acid.

In its behaviour towards sodium carbonate, this  $\gamma$ -bromo-acid differs in a marked manner from the  $\delta$ -bromo-acid (see above), since, after boiling for half an hour and acidifying, no sparingly soluble tetrahydrobenzoic acid separates. On extracting with ether, a very soluble oily acid is obtained, which rapidly becomes insoluble in sodium carbonate and develops the odour of a lactone. It is probable that the neutral oil produced in this way is the lactone of  $\gamma$ -hydroxyhexahydrobenzoic acid.

*$\gamma\delta$ -Dibromohexahydrobenzoic Acid.*—When the solution of tetrahydrobenzoic acid in chloroform is cooled to  $-10^\circ$  and treated with bromine, the colour of the halogen disappears instantly, and only traces of hydrogen bromide are formed. As soon as the solution had acquired a permanent pale yellow tint, it was transferred to a large watch glass and left until the chloroform had evaporated. A viscid, colourless oil resulted which did not crystallise for some days, but ultimately solidified almost completely. The mass was rapidly washed with formic acid (sp. gr. 1.22) and recrystallised from this solvent, from which the dibromo-acid separates in small, glistening crystals.

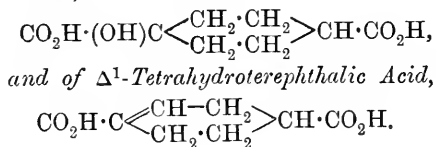

0.1444 gave 0.1888 AgBr. Br = 55.6.

$C_7H_{10}O_2Br_2$  requires Br = 55.9 per cent.

*$\gamma\delta$ -Dibromohexahydrobenzoic acid* melts at  $84-86^\circ$ , and is sparingly soluble in cold formic acid and light petroleum, but readily so in alcohol, ether, or chloroform. It dissolves readily in sodium carbonate, and, if the solution is boiled for 5 minutes and then acidified, nothing separates, but ether extracts a very readily soluble syrupy acid which, when kept, shows signs of crystallising.

Since this acid reduces ammoniacal silver solution, but does not decolorise permanganate, it is probably  $\gamma\delta$ -dihydroxyhexahydrobenzoic acid produced from the dibromo-acid by hydrolysis.

*Action of Hydrogen Cyanide on  $\delta$ -Keto-hexahydrobenzoic Acid. Formation of the cis- and trans-Modifications of  $\alpha$ -Hydroxyhexahydro-terephthalic Acid,*

In the first experiments on the action of hydrogen cyanide on  $\delta$ -keto-hexahydrobenzoic acid, the conditions recommended by Baeyer and Tutein (*Ber.*, 1889, 22, 2186) in the similar case of  $\gamma$ -keto-hexahydrobenzoic acid were employed, that is to say, the acid was mixed with potassium cyanide and the mixture treated with hydrochloric acid. The addition did not take place satisfactorily under these conditions, and, after several experiments, the following process, based on the observations of Lapworth (*Trans.*, 1903, 83, 995), was employed with excellent results. The pure acid (4 grams) was dissolved in a little warm water, cooled until crystallisation just commenced, and then mixed with pure potassium cyanide (5 grams) and 10 c.c. of a 15 per cent. solution of hydrocyanic acid. The liquid gradually darkened, and after 24 hours had become nearly black; it was mixed with a little hydrochloric acid and extracted 6 times with ether. After drying over calcium chloride and evaporating, a light brown syrup (5 grams) was obtained, which, on rubbing with a glass rod, rapidly became semi-solid. The mass was left in contact with porous porcelain until quite dry; the residue was dissolved in ether, the solution digested with animal charcoal, filtered, and concentrated. An equal volume of chloroform was then added and the ether distilled off, when a sandy, crystalline precipitate was soon deposited, which melted at  $180^\circ$ , and was easily identified as aminomalononitrile,  $\text{NH}_2 \cdot \text{CH}(\text{CN})_2$ , produced by the polymerisation of some of the hydrogen cyanide employed. The filtrate from this substance deposited, on spontaneous evaporation, a mass of crystals, which were collected and purified by re-dissolving in ether, adding chloroform, and distilling off the ether as before.

The glistening, pale yellow plates thus obtained consist of the nitrile of *trans- $\alpha$ -hydroxyhexahydroterephthalic acid*.

0.1805 gave 12.6 c.c. nitrogen at  $14^\circ$  and 774 mm.  $\text{N} = 8.4$ .

$\text{C}_8\text{H}_{11}\text{O}_3\text{N}$  requires  $\text{N} = 8.3$  per cent.

The melting point of this nitrile is not sharp; it begins to shrink together at  $125^\circ$  and is completely melted at  $140^\circ$ . It is readily

soluble in water or methyl alcohol, but sparingly so in chloroform, benzene, or light petroleum. When heated in a test-tube, water is eliminated and an oil distils which does not solidify on cooling, and, since the solution of this oil in sodium carbonate does not decolorise permanganate, it may very probably be the corresponding cyano-lactone. When the nitrile is hydrolysed under the conditions stated below, it yields *trans*- $\alpha$ -hydroxyhexahydroterephthalic acid.

The chloroform mother liquors of this *trans*-nitrile contain the *cis*-modification, but, as this did not appear to crystallise readily, no attempt was made to isolate it in a condition suitable for analysis.

In preparing the *cis*- and *trans*-modifications of hydroxyhexahydroterephthalic acid in quantity, 20 grams of ketohexahydrobenzoic acid were converted into the mixed nitriles, and after extracting with ether, the oil was dissolved in 100 c.c. of concentrated hydrochloric acid and heated, first on the water-bath for three hours and then to boiling for one hour. The whole was evaporated to dryness, the crystalline cake was then ground up and digested with absolute alcohol, and after filtering from the ammonium chloride the alcoholic solution was evaporated almost to dryness. The residue, which still contained ammonium chloride, was dissolved in excess of dilute barium hydroxide and boiled until the evolution of ammonia had completely ceased, the barium was then exactly removed by sulphuric acid, and the filtrate from the barium sulphate evaporated almost to dryness.

After remaining for 24 hours, the crystalline crust was left in contact with porous porcelain until quite dry, dissolved in water, digested with animal charcoal, and evaporated considerably, when a mass of white, nodular crystals of the *trans*-hydroxy-acid gradually separated. These were collected and purified by crystallising twice from water, when the substance was obtained in hard crystals containing one molecule of water of crystallisation.

After being exposed to the air for 6 days, the following results were obtained on analysis:

0.1654 gave 0.2822  $\text{CO}_2$  and 0.1023  $\text{H}_2\text{O}$ .  $\text{C} = 46.5$ ;  $\text{H} = 6.9$ .

$\text{C}_8\text{H}_{12}\text{O}_5 \cdot \text{H}_2\text{O}$  requires  $\text{C} = 46.6$ ;  $\text{H} = 6.8$  per cent.

0.2416 gram, heated at  $90^\circ$  until constant, lost 0.0221 gram or 9.1 per cent., whereas  $\text{C}_8\text{H}_{12}\text{O}_5 \cdot \text{H}_2\text{O}$  contains 8.8 per cent. of water. The anhydrous acid was also analysed.

0.1852 gave 0.3488  $\text{CO}_2$  and 0.1064  $\text{H}_2\text{O}$ .  $\text{C} = 51.3$ ;  $\text{H} = 6.4$ .

$\text{C}_8\text{H}_{12}\text{O}_5$  requires  $\text{C} = 51.1$ ;  $\text{H} = 6.4$  per cent.

On titration with decinormal caustic soda, 0.0956 gram required for

neutralisation 0.0408 NaOH, whereas this amount of a dibasic acid,  $C_8H_{12}O_5$ , should neutralise 0.0407 NaOH.

*trans- $\alpha$ -Hydroxyhexahydroterephthalic acid* melts at 228—230° with decomposition, and when heated in small quantities in a test-tube, water is eliminated and a crystalline sublimate of  $\Delta^1$ -tetrahydroterephthalic acid is obtained (p. 437). It is readily soluble in water or alcohol, but sparingly so in cold ether, chloroform, benzene, or concentrated hydrochloric acid. The neutral solution of the ammonium salt gives no precipitate with barium or calcium chloride, but a heavy caseous precipitate with lead acetate; with copper sulphate, a turbidity is produced, and, on warming, a pale blue, amorphous precipitate separates.

*cis- $\alpha$ -Hydroxyhexahydroterephthalic Acid*.—The aqueous mother liquors of the *trans*-acid yielded, on further concentration, first an additional small crop of the same acid, and afterwards the *cis*-hydroxy-acid separated in masses of irregularly shaped crystals. These were collected and purified by repeated crystallisation from water, the substance being dried at 100° before analysis.

0.1594 gave 0.2958  $CO_2$  and 0.0912  $H_2O$ .  $C=50.6$ ;  $H=6.4$ .

The substance was then recrystallised from ether and again analysed.

0.1832 gave 0.3428  $CO_2$  and 0.1052  $H_2O$ .  $C=51.0$ ;  $H=6.4$ .

$C_8H_{12}O_5$  requires  $C=51.1$ ;  $H=6.4$  per cent.

On titration, 0.1220 gram neutralised 0.051 gram NaOH, whereas this amount of a dibasic acid,  $C_8H_{12}O_5$ , should neutralise 0.052 NaOH.

*cis- $\alpha$ -Hydroxyhexahydroterephthalic acid* melts at 168—170°, and is readily soluble in water and alcohol, but sparingly so in chloroform, benzene, or ether. If, however, the finely-powdered substance is digested in a reflux apparatus with a large quantity of ether, it dissolves, and, after concentrating considerably, the pure acid gradually separates in hard, crystalline crusts. When crystallised from water, the hard nodules obtained do not, like the *trans*-acid, contain water of crystallisation, since the air-dried substance loses only very slightly in weight on drying at 90°.

If a small quantity of the dry acid is heated in a test-tube, it first melts and then gives off water, and a sublimate of  $\Delta^1$ -tetrahydroterephthalic acid forms on the cooler portions of the tube.

When the *cis*-hydroxy-acid is mixed with concentrated sulphuric acid and warmed to about 60°, carbon monoxide is evolved in quantity, and if, when the evolution has ceased, the pale yellow liquid is poured into water, a white, crystalline precipitate separates.

This was collected and found to consist of pure  $\Delta^1$ -tetrahydro-

terephthalic acid, and from the filtrate a quantity of  $\delta$ -keto-hexahydrobenzoic acid was obtained by extraction with ether and identified by conversion into the semicarbazone.

The *cis*-hydroxy-acid shows a curious behaviour when heated with fuming hydrobromic acid (saturated at  $0^\circ$ ) in a sealed tube in a boiling water-bath. The acid dissolves, and then a gas (presumably carbon dioxide) is slowly given off and, on diluting the yellow solution with water, a quantity of a very voluminous, white, amorphous precipitate separates. This substance, which contains bromine, seems to be formed quantitatively; it is practically insoluble in water, but dissolves in sodium carbonate. It separates from dilute formic acid apparently as a microcrystalline precipitate; this shrinks together at  $160$ — $165^\circ$  and has no definite melting point. This substance was not further investigated, but it was noticed that the *trans*-hydroxy-acid also appeared to show the same behaviour on heating with hydrobromic acid.

The amount of the mixed hydroxyhexahydroterephthalic acids obtained by the addition of hydrogen cyanide to  $\delta$ -keto-hexahydrobenzoic acid and subsequent hydrolysis was upwards of 70 per cent. of the theoretical, and it is interesting to note that in this way a very much larger amount of the *cis* acid is produced than of the *trans*-acid.

$\Delta^1$ -Tetrahydroterephthalic Acid.—As explained above, this acid is produced when either the *cis*- or *trans*-modification of  $\alpha$ -hydroxyhexahydroterephthalic acid is heated. In investigating this decomposition, 5 grams of the pure *cis*-acid was distilled under 10 mm. pressure, the sublimate was dissolved in hot sodium carbonate, the solution decolorised with animal charcoal, concentrated, and acidified, when the tetrahydro-acid separated as a microcrystalline deposit.

This was collected and recrystallised from much water.

0.1406 gave 0.2894  $\text{CO}_2$  and 0.0764  $\text{H}_2\text{O}$ .  $\text{C}=56.2$ ;  $\text{H}=6.0$ .

$\text{C}_8\text{H}_{10}\text{O}_4$  requires  $\text{C}=56.4$ ;  $\text{H}=5.9$  per cent.

This acid melted above  $300^\circ$  and reduced permanganate, and was evidently identical with the  $\Delta^1$ -tetrahydroterephthalic acid described by Baeyer (*Annalen*, 1888, 245, 160). In order that there should be no doubt as to its identity, the acid was converted into its methyl ester by digesting with a five per cent. solution of hydrogen chloride in methyl alcohol. The methyl ester, thus obtained, crystallised from dilute methyl alcohol in needles and melted at  $38$ — $39^\circ$ , whereas Baeyer gives  $39^\circ$  as the melting point of methyl  $\Delta^1$ -tetrahydroterephthalate.

The author wishes to express his thanks to Mr. S. S. Pickles, B.Sc.,

for valuable assistance in carrying out these experiments, and to state that much of the heavy expense entailed has been met by a grant from the Government Grant Committee of the Royal Society.

MANCHESTER.

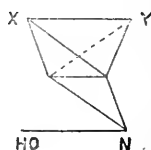

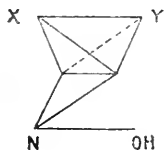

## XLIX.—*The Arrangement in Space of the Groups Combined with the Tervalent Nitrogen Atom.*

By FREDERIC STANLEY KIPPING and ARTHUR HENRY SALWAY.

THE discussion as to the cause of the existence of isomeric oximes and of that of certain other derivatives of tervalent nitrogen, which for so many years occupied a prominent place in current chemical literature, apparently came to an end some time ago; at any rate, the occurrence of such isomerides now excites but little interest, and is, in fact, taken as a matter of course, and the usual "*syn*" and "*anti*" configurations having been respectively assigned to the two isomerides, the matter is dismissed from further consideration.

It is far from our intention to attempt to make any review of the literature of this subject, as it would occupy far too much space even were we merely to refer in the briefest manner to the views of the principal workers in this field, or to recapitulate quite cursorily the various arguments which have led to the adoption of the "*syn*" and "*anti*" configurational formulæ for isomeric derivatives of tervalent nitrogen; it is necessary, however, in order to explain one of the objects of this investigation, to briefly recall the meaning and consequences of such stereochemical representations.

According to Hantzsch and Werner (*Ber.*, 1890, 23, 11), the existence of this type of isomerides is to be explained by assuming that the groups around a tervalent nitrogen atom are situated at the corners of a regular tetrahedron, of which the nitrogen atom itself occupies the fourth corner; the "*syn*" and "*anti*" configurations are thus respectively represented by the following symbols:

Now this hypothesis, which seems to be generally accepted by chemists as a means of explaining the phenomenon in question, involves, or seems to involve, certain consequences which are by no means confirmed by experimental evidence.

In the first place, this conception premises the existence of isomerides in the case of a great number of compounds which hitherto have been obtained in only one form (compare Hantzsch and Werner, *loc. cit.*). Azobenzene, for example, as far as is known, does not exhibit stereoisomerism, and yet the existence of *syn*- and *anti*-forms of this and of azo- and azoxy-compounds generally would be in accordance with theory; as a matter of fact, the only cases of isomerism in such compounds which have yet been described are those of *p*-azoxy-toluene and trinitrazotoluene (Janovski and Reimann, *Ber.*, 1889, 22, 40, and Janovski, *Ber.*, 1889, 22, 1172), and it would appear that even these may be capable of some other explanation. Many other examples of a similar absence of conceivable isomerides might be quoted, but it is unnecessary to do so; Hantzsch, himself, has tried to obtain isomeric compounds containing doubly-linked nitrogen in many cases where their existence seemed a probable consequence of his and Werner's theory (compare *Ber.*, 1893, 26, 926).

The question which more immediately concerns our work, however, is that of the possibility of existence of isomerism in compounds of the type  $\text{NR}_1\text{R}_2\text{R}_3$ ; if the three atoms or groups combined with trivalent nitrogen are situated at the angles of a regular tetrahedron, secondary and tertiary nitrogen bases which are of the above type, that is to say, in which the three atoms or groups are all different from one another, should exist in enantiomorphously related forms, and the latter in all probability would be optically active; such forms would be represented respectively by the configurational formulæ:

The possibility of the existence of such isomerides has been previously considered, and, in fact, experiments have already been made in order to try and obtain such optically active compounds. Kraft (*Ber.*, 1890, 23, 2780), at the suggestion of Hantzsch, attempted to resolve benzylethylamine and *p*-tolylhydrazine by fractionally crystallising their hydrogen tartrates, whereas Behrend and König (*Annalen*, 1891, 263, 175; *Ber.*, 1891, 24, 447c) carried out similar and additional

experiments with  $\beta$ -benzylhydroxylamine, whilst Ladenburg (*Ber.*, 1893, 26, 864) investigated methylaniline, tetrahydroquinoline, and tetrahydropyridine; all these investigations, and likewise some experiments of Le Bel (*Compt. rend.*, 1891, 112, 11), were, however, uniformly unsuccessful.

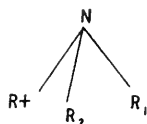

Now it may be observed in connection with the investigations just referred to that the point actually put to the test of experiment was not so much the existence of isomeric tervalent as that of quinquevalent derivatives of nitrogen containing two identical groups or atoms. Even had isomeric salts been obtained, the latter might not have afforded enantiomorphously related bases when decomposed with alkalis, because in passing from the quinquevalent to the tervalent state a complete rearrangement in space of the nitrogen "valencies" might occur, and both the isomeric salts might give the same compound or the same mixture of isomerides.

These considerations led us to undertake the present work in the hope of adding to our knowledge of the configuration of tervalent nitrogen. Our first experiments were directed towards an investigation of the products obtained by the action of an externally compensated acid chloride on certain primary and secondary amines. A *dl*-acid chloride, such as *dl*-phenylchloroacetyl chloride, gives with a *dl*-base, such as *dl*-hydrindamine, a mixture of two isomeric phenylchloroacetohydrindamides, which can be separated by fractional crystallisation (Kipping and Hall, *Trans.*, 1901, 79, 444); this is due, of course, to the formation of the four compounds,

which are enantiomorphously related in pairs, and which crystallise together, forming two different *dl*-isomerides. An externally compensated acid chloride may therefore be employed for the detection of asymmetry in bases, a fact which in the first place we confirmed by proving that *dl*-benzylmethylacetyl chloride gives with *dl*-hydrindamine a mixture of isomeric *dl*-substituted amides from which the two compounds may be isolated without much difficulty.

Now if instead of a base such as *dl*-hydrindamine, which owes its asymmetry to a carbon group, some primary or secondary base, such as *p*-toluidine or methylaniline, were treated with a *dl*-acid chloride, it seems reasonable to suppose that two isomeric substituted amides should be obtained, provided that the three nitrogen valencies are not arranged in one plane, but, as surmised by Hantzsch and Werner in the case of the oximes; the *d*-component of the acid chloride would give equal or approximately equal quantities of the two compounds,

which are not enantiomorphously related, whilst the *l*-component would give rise to two analogous isomerides; these would then crystallise in pairs, just as in the case of the hydrindamides, giving two different *dl*-substituted amides.

The experiments were tried with methylaniline, *p*-toluidine, phenylhydrazine, and benzylaniline, the acid chloride being *dl*-benzylmethylacetyl chloride; in no case, however, could we observe the least indication of the formation of isomerides.

In all these examples, if non-enantiomorphously related isomerides were produced at all, each of the four compounds which might conceivably have been formed would contain one group enantiomorphously related to that in one of its isomerides; thus, although *dBdA* and *dBIA* are not enantiomorphously related, a portion of the molecule of the one does bear such a relationship to a portion of that of the other; similarly with *lBIA* and *lBdA*. This might condition the formation of a double racemic salt  $\left\{ \begin{array}{l} \textit{dBdA}, \textit{dBIA} \\ \textit{lBIA}, \textit{lBdA} \end{array} \right\}$  such as is possibly produced from *dl*-hydrindamine and *dl*-mandelic acid (Kipping and Hall, *Trans.*, 1901, 79, 442), and thus account for the failure of our attempts to separate isomerides.

In order to limit such a possibility to some extent, we next made experiments on the behaviour of some primary and secondary bases towards optically active benzylmethylacetyl chloride, and examined the substituted amides derived from *p*-toluidine and benzylaniline; no evidence of the formation of isomerides *dBdA* and *lBdA*, however, could be obtained.

Our last and most conclusive experiments on these lines were made with optically active bases and optically active benzylmethylacetyl chloride. If, in the case of asymmetric carbon groups, the two enantiomorphously related compounds are generally separable as soon as an asymmetric radicle is substituted for one of the atoms or radicles in each of the groups, it would seem highly probable that the introduction of a second centre of asymmetry would greatly enhance the difference between the two isomerides as regards their solubility, &c., and thus greatly facilitate their separation by fractional crystallisation.

Now when an optically active base such as *l*-menthylamine is treated with *d*-benzylmethylacetyl chloride, the resulting substituted amide contains two centres of asymmetry due to carbon; if, in addition,

the three nitrogen valencies are so arranged as to condition a third centre of asymmetry, two very different isomerides, represented respectively by the following configurational formulæ, should be obtained:

The bases examined in this way were *d*-hydrindamine, *l*-methylhydrindamine, *l*-menthylamine, and *l*-phenylethylamine; in all cases, however, the product seemed to consist of one substance only, and when crystallised fractionally from various solvents retained its uniform character.

We conclude from these results that the three radicles, together with the tervalent nitrogen atom itself, are situated in one plane; that two of the radicles are symmetrically grouped with respect to the third, and that in all probability this is true of any two, that is to say, the whole arrangement is the most symmetrically possible one.

*Examination of Oximes.*—Having failed to detect any indication of isomerism in the case of saturated tervalent nitrogen compounds which would be in accordance with the theory of Hantzsch and Werner, we next turned our attention to the oximes themselves.

Assuming that the isomerism of the *syn*- and *anti*-forms is structural and that the two compounds are represented by the formulæ

an asymmetric carbon group, would exist in enantiomorphously related forms. If, then, an optically active acyl group were substituted for the hydrogen atom, two non-enantiomorphously related optically active isomerides should be obtained, whereas by employing a *dl*-acyl chloride two different *dl*-compounds should be produced.

Intending, subsequently, to investigate the benzaldoximes, we first studied the action of the *dl*-acid chloride on benzoinoxime, a substance which crystallises well, and the derivatives of which, it was thought, would show a similar behaviour. The reaction, however, proceeded in a manner altogether abnormal; instead of obtaining an acyl derivative by the simple displacement of the oximic hydrogen atom, we got a number of other products, namely, benzil, benzoin, benzaldehyde, benzonitrile, ammonium chloride, hydrogen chloride, benzylmethylacetic acid, and a compound melting at 126°; this decomposition of the oxime made it impossible, of course, to accomplish the objects in view, but the result is not without interest as showing how easily the

benzoin molecule—which is generally so stable—may undergo decomposition.

In order to try and throw some light on this extraordinary reaction, we next studied the action of benzoyl chloride on benzoinoxime, but found that interaction proceeded in a normal manner, giving a benzoinoxime benzoate in which the benzoyl group had displaced the oximic hydrogen atom; the constitution of the product was established by preparing the oxime of the benzoylbenzoin described by Zinin (*Annalen*, 1857, 104, 117); the latter, which would necessarily have the constitution  $C_6H_5 \cdot CH(Obz) \cdot CPh : N \cdot OH$ , is not identical with the benzoyl derivative of benzoinoxime, so that our compound must be represented by the formula  $C_6H_5 \cdot CH(OH) \cdot CPh : N \cdot Obz$ .

Failing to obtain the desired results with benzoinoxime, we made a few experiments with  $\alpha$ -benzaldoxime, but were unable to prepare the benzylmethylacetyl derivative owing to the decomposition of the aldoxime into benzonitrile.

*The Resolution of dl-Bases with the aid of d-Benzylmethylacetyl Chloride.*

The resolution of a *dl*-base by fractionally crystallising the salt obtained by combining it with an optically active acid is very often unsuccessful owing to the fact that the two salts *dBdA* and *lBdA* or *dBIA* and *lBIA* may differ so slightly in solubility that no appreciable separation occurs, or, again, they may unite to form a partially racemic compound. Judging from the many cases which have been examined in this laboratory, it would seem that it is rather the exception than the rule for a resolution to take place, and were all the negative results of investigators on record, this conclusion would probably be amply substantiated; contrary to the views sometimes held, the use, in such experiments, of a relatively weak acid also seems to be just as likely to give satisfactory results as that of a relatively strong one, since hydrolytic dissociation seldom plays any important part, the difference in solubility of the salts being practically the only factor of importance.

The investigations carried out during the last few years on the behaviour of *dl*-hydrindamine have shown that the resolution of this base presents more than the usual difficulties, and that ordinary fractional crystallisation of its salts with *d*-bromocamphorsulphonic, *d*-chlorocamphorsulphonic, Reyhler's *d*-camphorsulphonic, *l*-mandelic, and *d*-tartaric acids fails to effect a separation of the two isomerides. In these circumstances, it occurred to one of us that a resolution might be accomplished by using an optically active acid chloride which would probably give isomeric substituted amides differing considerably in solubility; this expectation proved to be well-founded, inasmuch as

the product of interaction of *dl*-hydrindamine and *d*-benzylmethylacetyl chloride was easily separated into two isomerides having different specific rotations.

*d*-Benzylmethylacetyl chloride was also employed for the resolution of *dl*-phenylethylamine, and in this case also the two isomeric amides corresponding with the *d*- and *l*-bases respectively are separated without much difficulty.

Judging from these examples, an optically active acid chloride may be employed with success when the use of an acid gives unsatisfactory results, but it will be necessary to wait until a greater number of cases have been tried before concluding that such a method is universally applicable. One great drawback to the use of the acid chloride is that it may be impossible to obtain the optically active bases themselves, either because the substituted amides are so stable that they cannot be hydrolysed, or because so high a temperature is required to bring about hydrolysis that the bases undergo racemisation. Thus, in the case of the benzylmethylacetohydrindamide, all attempts to regenerate the base were unsuccessful; the amides are exceedingly stable towards ordinary hydrolysing agents at moderate temperatures, and although change occurs at high temperatures, it results in the formation of indene and ammonia.

The application of an optically active acid chloride for the resolution of *dl*-alcohols or other *dl*-hydroxy-compounds has not yet been tried.

#### EXPERIMENTAL.

##### *dl Hydrindamine and dl-Benzylmethylacetyl Chloride. Isolation of Two Isomerides.*

In order to satisfy ourselves that *dl*-benzylmethylacetyl chloride would prove serviceable in detecting asymmetry, we first tried its action on *dl*-hydrindamine, a base which is very prone to form partially racemic salts, and which is resolved into its enantiomorphously related components only with great difficulty.

On adding the *dl*-benzylmethylacetyl chloride to the *dl*-base, both in ethereal solution, a development of heat occurred, and the hydrochloride of the base separated in crystals; after filtering, washing with water, and evaporating the ethereal solution, the substituted amide was obtained as an oil which rapidly solidified.

When crystallised fractionally from methyl alcohol, ether, and other solvents, this product, which at first melts indefinitely at about 70°, is finally resolved into two isomerides. One of these crystallises in thick, transparent prisms melting at 110—111°, but when the partially melted substance is allowed to cool it immediately solidifies, and when heated again melts at about 126°; it is therefore dimorphous.

This amide is very readily soluble in cold methyl alcohol, moderately so in ether, but dissolves very sparingly in light petroleum (b. p. 40—60°).

0.1615 gave 0.4857 CO<sub>2</sub> and 0.1090 H<sub>2</sub>O. C = 82.0; H = 7.5.

C<sub>19</sub>H<sub>21</sub>ON requires C = 81.7; H = 7.5 per cent.

The second isomeride crystallised from aqueous methyl alcohol in felted masses of needles melting sharply at 119.5°; it seems to be far less soluble in cold ether than the preceding compound.

0.1497 gave 0.4484 CO<sub>2</sub> and 0.0996 H<sub>2</sub>O. C = 81.7; H = 7.4.

C<sub>19</sub>H<sub>21</sub>ON requires C = 81.7; H = 7.5 per cent.

*Products from dl-Benzylmethylacetyl Chloride and Primary or Secondary Bases.*

Having proved that evidence of asymmetry due to a carbon group is easily obtained with the aid of *dl*-benzylmethylacetyl chloride, we studied the products of the action of this compound on some primary and secondary bases.

Methylaniline and the *dl*-chloride interact readily in ethereal solution. The resulting substituted amide remained in an oily condition for a long time, but ultimately solidified completely; it was fractionally crystallised from warm light petroleum (b. p. 30—40°) in which it was readily soluble, and was thus obtained in lustrous, transparent prisms melting sharply at 54—55°; all the fractions had the same appearance, and except the last, which melted a few degrees below 54°, liquefied at the same temperature. *Benzylmethylacetomethylanilide* exists, therefore, in only one form; it is readily soluble in all ordinary organic solvents.

*p*-Toluidine and *dl*-benzylmethylacetyl chloride interact vigorously in ethereal solution; the *benzylmethylaceto-p-toluidide*, which is thus formed, solidified readily, and was fractionally crystallised from aqueous alcohol; it separated in concentrically grouped needles melting at 130°. The very last mother liquors gave traces of a product melting about 2° lower than the rest, but there was no evidence of the existence of isomerides. *Benzylmethylaceto-p-toluidide* is readily soluble in all ordinary organic solvents with the exception of light petroleum (b. p. 30—40°), in which it dissolves somewhat sparingly.

Benzylaniline and *dl*-benzylmethylacetyl chloride give a product which is at first rather difficult to obtain in a crystalline condition, but which afterwards crystallises easily from aqueous alcohol in ill-defined prisms; the compound was separated into a number of fractions, but the latter were all identical in appearance and melting point.

*Benzylmethylacetobenzylanilide* is readily soluble in most organic solvents and melts at 69—70°.

0.1452 gave 0.4457 CO<sub>2</sub> and 0.0921 H<sub>2</sub>O. C = 83.7; H = 7.05.  
 C<sub>6</sub>H<sub>5</sub>·CH<sub>2</sub>·CH(CH<sub>3</sub>)·CO·N(C<sub>7</sub>H<sub>7</sub>)·C<sub>6</sub>H<sub>5</sub> requires C = 83.9; H = 7.0 per cent.

Phenylhydrazine, when treated with the *dl*-chloride in ethereal solution, readily yielded *benzylmethylacetophenylhydrazide*, which crystallised from methyl alcohol in large, transparent, lustrous prisms melting at 116—117° and readily soluble in ethyl acetate; fractional crystallisation failed to indicate the presence of an isomeride.

*Products from d-Benzylmethylacetyl Chloride and Primary or Secondary Bases.*

For the reasons already stated, we next examined the products obtained with the aid of the optically active chloride; in doing so, it was found that even when the acid chloride had the highest specific rotation previously observed, namely,  $[\alpha]_D + 18^\circ$  in ethereal solution (Kipping and Hunter, *Trans.*, 1903, 83, 1005), it still contained a small quantity of the *l*-isomeride, owing, doubtless, to the occurrence of racemisation during its preparation, and gave rise to some of the *dl*-substituted amide; the presence of the latter was a serious disadvantage because, although the main portions of the active and inactive amides could be separated without much difficulty, there still remained a considerable quantity of mixed products in which the required isomeric active compound might conceivably be concealed. In the later and more important experiments, therefore, the active acid chloride was prepared from very carefully purified acid by a method which should exclude the possibility of racemisation (p. 447).

*p*-Toluidine and *d*-benzylmethylacetyl chloride gave a product which, when repeatedly fractionally crystallised from aqueous alcohol, was resolved into two compounds, one of which, however, was present in relatively small proportions; this was the amide of the *dl*-acid and melted at 130° (p. 445). The main component, namely, *d*-benzylmethylaceto-*p*-toluidide, crystallised in large, flat, transparent, well-defined prisms melting at 115—116°; it was readily soluble in cold alcohol and in ethyl acetate.

0.2364, dissolved in alcohol and the solution diluted to 25 c.c., gave, in a 200 mm. tube,  $\alpha + 3.17^\circ$ , whence  $[\alpha]_D + 167.6^\circ$ .

0.5150, dissolved in chloroform and the solution diluted to 20 c.c., gave, in a 200 mm. tube,  $\alpha + 5.67^\circ$ , whence  $[\alpha]_D + 110.1^\circ$ .

During the fractional crystallisation, no compound other than the

two already mentioned was obtained, and we concluded that optically active isomerides were not produced. The experiment was subsequently repeated, using a sample of *d*-chloride free from the *l*-isomeride, and in this case only one compound, namely, that melting at 115—116°, was obtained.

Benzylaniline and *d*-benzylmethylacetyl chloride gave a product which was very difficult to crystallise even when the acid chloride had been prepared by the special method to be described later. This was due to the fact that the product retained benzylaniline very tenaciously, and repeated washing with warm hydrochloric acid was required before the whole of this base was removed. Finally, however, the amide solidified to a crystalline mass, which was fractionally crystallised from light petroleum and from aqueous alcohol. The several fractions of *d*-benzylmethylacetobenzylanilide,

thus obtained melted at the same temperature (69—70°), which is also the melting point of the inactive amide already described (p. 446); moreover, a mixture of the crystals of the active and inactive amides also melted at 69—70°.

The specific rotation of the *d*-anilide was determined in chloroform solution: 0.3079, dissolved in chloroform, the solution diluted to 20 c.c. and examined in a 200 mm. tube, gave  $\alpha + 0.27^\circ$  whence  $[\alpha]_D + 8.8^\circ$ ; in methyl-alcoholic solution the specific rotation was  $[\alpha]_D + 16^\circ$ .

Although only one active compound was isolated, and although there was no evidence of the formation of an isomeride in the above experiment, we are unable to state positively that only one substance was produced, as a portion of the product from the last mother liquors crystallised badly and had a brown colour, doubtless owing to atmospheric oxidation.

#### *Preparation of d-Benzylmethylacetyl Chloride.*

Owing to the readiness with which the *d*-acid chloride is racemised under the influence of heat (Kipping and Hunter, *Trans.*, *loc. cit.*), the compound prepared in the usual manner is almost invariably mixed with more or less of the *l*-isomeride, the presence of which is very objectionable in such experiments as those already described, where it is a question of the existence of isomeric amides. In order to prepare the active compound in an optically pure condition, it is necessary to keep the temperature as low as possible and then to remove the phosphorus oxychloride from the product without the application of heat. This can be accomplished by passing a current of dry air through the mixture under greatly reduced pressure, but the operation requires a considerable time before the last portions of phosphorus oxychloride

are removed. The *d*-chloride thus prepared has a specific rotation in light petroleum  $[\alpha]_D + 26.2$ , a value which is a trifle higher than that previously obtained (*loc. cit.*).

This method of preparation does not remove every trace of phosphorus compounds, for the acid chloride still gives a slight reaction with ammonium molybdate, probably due to the presence of phosphoric acid; this impurity, however, is of little consequence, as it is easily eliminated by washing with water, when the acid chloride is used for the preparation of a substituted amide.

*Products from d-Benzylmethylacetyl Chloride and Optically Active Bases.*

1. *1-Phenylethylamine*.—The active base, prepared by the method recently described (Kipping and Hunter, *Trans.*, 1903, 83, 1147), was dissolved in dry ether and the active acid chloride added gradually, when a reaction immediately occurred, and the hydrochloride separated in crystals. This salt was removed by filtration, and the ethereal solution washed successively with dilute hydrochloric acid, water, sodium carbonate, and water, by which treatment any remaining hydrochloride, free base, or free acid is removed. After evaporating off the ether, the crude product, which immediately solidified, was then fractionally crystallised from benzene and thus separated into at least nine fractions, but one and the same compound melting at  $122^\circ$  was obtained throughout, and no indication whatever of the presence of isomerides was observed. *d-Benzylmethylaceto-1-phenylethylamide*,  $C_6H_5 \cdot CH_2 \cdot CH(CH_3) \cdot CO \cdot NH \cdot CH(CH_3) \cdot C_6H_5$ , crystallises from benzene in beautiful, long, silky needles melting at  $122.5^\circ$ . It is readily soluble in ethyl acetate, chloroform, methyl alcohol, ether, or alcohol, but only sparingly so in light petroleum.

0.4315, dissolved in ether and diluted to 20 c.c., gave, in a 200 mm. tube,  $\alpha + 0.37^\circ$ , whence  $[\alpha]_D + 8.6^\circ$ .

2. *1-Methylhydrindamine*.—The reaction was conducted in dry ethereal solution, and since the product was not readily soluble in ether the solvent was allowed to evaporate and the residue washed at the pump with dilute hydrochloric acid, hot water, dilute sodium carbonate, and hot water successively. The substance, which then melted at  $150$ — $152^\circ$ , was now subjected to fractional crystallisation from benzene and separated into at least eight portions, but in this case, as before, only one compound was found to be present, although the last fractions had their melting point lowered slightly through the presence of a trace of unavoidable impurity.

*d-Benzylmethylaceto-1-methylhydrindamide* crystallises from benzene and alcohol in long, silky needles very similar to those of the acid

amide of *l*-phenylethylamine and melting at  $152^{\circ}$ ; it is readily soluble in hot benzene, alcohol, chloroform, or ether.

0.4071, dissolved in chloroform and diluted to 20 c.c., gave, in a 200 mm. tube,  $\alpha - 1.08^{\circ}$ , whence  $[\alpha]_D - 26.5^{\circ}$ .

3. *l*-Menthylamine.—The optically pure base, prepared from its *d*-bromocamphorsulphonate (Tutin and Kipping, *Trans.*, 1904, 85, 65) dissolved in ether, was added to an ethereal solution of *d*-benzylmethylacetyl chloride, when a vigorous reaction occurred; the deposited menthylamine hydrochloride was separated by filtration and the ethereal solution washed with dilute hydrochloric acid, sodium carbonate, and water successively. The product was fractionally crystallised from benzene and separated into at least six fractions, but the first and last fractions were identical in crystalline form and melting point.

*d*-Benzylmethylaceto-*l*-menthylamide crystallises from benzene in long needles melting at  $140^{\circ}$ ; it is readily soluble in all the ordinary organic solvents.

0.7704, dissolved in chloroform and diluted to 20 c.c. in a 200 mm. tube, gave  $\alpha + 0.58^{\circ}$ , whence  $[\alpha]_D + 7.5^{\circ}$ .

4. *d*-Hydrindamine.—The reaction was conducted as in the case of the former active bases and the product fractionated from benzene. Six fractions were thus obtained, but no difference in appearance or melting point could be observed on comparing the first and last deposits.

*d*-Benzylmethylaceto-*d*-hydrindamide crystallises from benzene in long, colourless needles melting at  $148-149^{\circ}$ ; it is readily soluble in methyl alcohol, chloroform, acetone or ethyl acetate; moderately so in ether, and dissolves sparingly in light petroleum.

0.8580, dissolved in methyl alcohol and the solution diluted to 20 c.c., gave, in a 200 mm. tube,  $\alpha - 1.33^{\circ}$ , whence  $[\alpha]_D - 15.5^{\circ}$ .

1.2482, dissolved in chloroform and the solution diluted to 20 c.c., gave, in a 200 mm. tube,  $\alpha + 0.76^{\circ}$ , whence  $[\alpha]_D + 6.1^{\circ}$ .

#### *Action of dl-Benzylmethylacetyl Chloride on Benzoinoxime.*

*dl*-Benzoinoxime was covered with dry ether or light petroleum and slowly treated with one molecular proportion of *dl*-benzylmethylacetyl chloride. No appreciable development of heat was observed, but the gradual progress of the reaction was indicated both by the conglomeration of the benzoinoxime into a united whole, and also by the slow evolution of hydrogen chloride. If the mixture is warmed to the boiling point of the solvent, the reaction is considerably accelerated, the

whole of the oxime dissolves, and a crystalline product is deposited in small quantities.

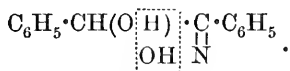

The crystalline product was fractionally crystallised from alcohol; the first deposit consisted of beautiful, long, lemon-yellow crystals which were evidently pure and melted at  $95^{\circ}$ , being thus identified as benzil. The second deposit of crystals consisted of a mixture of small, colourless needles and of a white, fluffy, crystalline substance. The latter, which was immediately dissolved on washing with water, consisted of ammonium chloride. The residue, when crystallised, yielded colourless needles identified as benzoin (m. p.  $134^{\circ}$ ). The alcoholic mother liquors yielded further quantities of these three products only.

The ethereal solution gave, on evaporation, a yellow oil, which was washed with dilute aqueous sodium carbonate until the extracts were found to be free from acid. The substance thus removed was precipitated from the alkaline solution by the addition of dilute sulphuric acid, extracted with ether, and distilled under reduced pressure (18 mm.). It consisted almost entirely of benzylmethylacetic acid, boiling at  $164^{\circ}$ . The ethereal solution, which had been extracted with sodium carbonate, gave, on evaporation, an oil, which had a strong odour of bitter almonds and which was distilled under atmospheric pressure, the fractions being collected at  $179\text{--}190^{\circ}$  and  $190\text{--}200^{\circ}$ . The residue was then distilled under reduced pressure (17 mm.) and the distillate solidified to a yellow mass, which, when crystallised from alcohol, melted at  $95^{\circ}$ , and proved to be benzil, the presence of which among the products of the reaction had been previously observed. The two fractions, boiling at  $179\text{--}190^{\circ}$  and  $190\text{--}200^{\circ}$  respectively, were too small for further fractional distillation, but as the former had the strong odour and boiling point of benzaldehyde, it was treated with phenylhydrazine in acetic acid solution, when benzaldehydephenylhydrazone (m. p.  $154^{\circ}$ ) was obtained. The second fraction, boiling at  $190\text{--}200^{\circ}$ , was found to be hydrolysed by prolonged boiling with an aqueous solution of sodium hydroxide, a copious evolution of ammonia taking place; the alkaline solution, when neutralised, yielded a crystalline precipitate, which was identified as benzoic acid. This fraction therefore consisted chiefly of benzonitrile.

We have thus shown that the products of the interaction of benzoin-oxime and benzylmethylacetyl chloride are: (1) benzylmethylacetic acid; (2) benzaldehyde; (3) benzonitrile; (4) benzoin; (5) benzil; (6) ammonium chloride; and (7) hydrogen chloride.

This decomposition of the molecule of benzoinoxime by the acid chloride is somewhat obscure, but apparently decomposition occurs in two different directions simultaneously. In the first instance, the molecule is severed between the two central carbon atoms with the

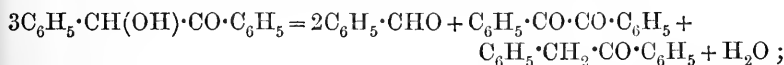

formation of benzaldehyde and its oxime, the latter of which by dehydration is converted into benzonitrile. This decomposition may be indicated thus :

In the second place, the decomposition of the benzoinoxime takes place by the elimination of ammonia and the formation of benzil according to the equation :

In any case, the above decomposition of benzoinoxime at the ordinary temperature is a reaction of some interest, inasmuch as it affords one of the few known examples whereby the benzoincondensation of benzaldehyde is reversed. Zinin (*Ber.*, 6, 1207), by repeated distillation of benzoin, obtained a decomposition into benzaldehyde, benzil, deoxybenzoin, and water according to the equation :

whilst the same products were obtained by passing benzoin vapour through a red-hot tube (compare also Knoevenagel and Tomaszewski (*Ber.*, 1903, 36, 2829).

Thinking that the decomposition of the benzoinoxime might be due to the action of the hydrogen chloride which is liberated, experiments were made in which an excess of dry quinoline was previously mixed with the oxime; the presence of this base, however, seemed to have little effect on the course of the reaction. It may be added that in many of the experiments the various products already enumerated were accompanied by very small quantities of a crystalline compound melting at 126°; this substance was not identified, but from its composition and reactions it seemed to be the substituted amide,

produced by intramolecular change.

In order to ascertain whether other acid chlorides would react normally with benzoinoxime giving acyl derivatives, or whether, like benzylmethylacetyl chloride, they would bring about a decomposition of the molecule, molecular proportions of benzoyl chloride and benzoinoxime were allowed to interact in ethereal solution. A gradual

evolution of hydrogen chloride occurred, but the reaction was not vigorous. After keeping for several hours at the ordinary temperature, the ethereal liquid was separated from the solid by filtration. The filtrate contained unchanged benzoyl chloride together with approximately equal proportions of benzoin and benzil. The solid product consisted chiefly of benzoinoxime benzoate, but it also contained a moderate quantity of benzoin and hydroxylamine hydrochloride. The presence of the latter was shown, after the removal of the benzoate by crystallisation, by evaporating the alcoholic mother liquors and washing the residue with water. The aqueous extract immediately reduced Fehling's solution and also gave the reactions of a chloride.

Benzoinoxime benzoate is easily purified by crystallisation from alcohol, in which it is only slightly soluble (approximately 1 part in 30 parts of boiling alcohol); it is thus obtained in leaf-like plates melting at 165—166°.

0.1540 gave 0.4301  $\text{CO}_2$  and 0.0729  $\text{H}_2\text{O}$ .  $\text{C} = 76.17$ ;  $\text{H} = 5.26$ .

0.4795 „ 19.4 c.c. moist nitrogen at 21° and 750.3 mm.  $\text{N} = 4.6$ .

$\text{C}_{21}\text{H}_{17}\text{O}_3\text{N}$  requires  $\text{C} = 76.13$ ;  $\text{H} = 5.14$ ;  $\text{N} = 4.2$  per cent.

Benzoinoxime benzoate is hydrolysed by acids and alkalis giving benzoin, benzoic acid, and hydroxylamine. It is moderately soluble in chloroform and ethyl acetate; only slightly so in benzene.

The foregoing method of preparing the benzoyl derivative leaves open several possibilities with regard to its constitution. Since benzoinoxime contains two hydroxyl groups, it is uncertain whether the benzoyl group has entered the alcoholic or the oximic hydroxyl, or whether the benzoinoxime has undergone the Beckmann transformation prior to benzoylation. The latter possibility, however, is shown to be untenable by a study of the reactions of the product. Since, on hydrolysis, it yields benzoin and hydroxylamine, it cannot have the constitution  $\text{C}_6\text{H}_5 \cdot \text{CH}(\text{OH}) \cdot \text{CO} \cdot \text{NBz} \cdot \text{C}_6\text{H}_5$  or

but may be either

A decision between these two formulæ has been rendered possible by the fact that we have prepared the compound having the latter constitution by benzoylating benzoin prior to the introduction of the oxime group, a process which ensures the substitution of the hydrogen of the alcoholic hydroxyl group by the benzoyl radicle. In order to distinguish between the two isomerides, we have described them as benzoinoxime benzoate and benzoylbenzoinoxime respectively.

Benzoylbenzoin was prepared by heating molecular proportions of benzoin and benzoyl chloride at  $150^\circ$  for an hour (Zinin, *loc. cit.*); the reaction was always accompanied by oxidation with the formation of benzil (about 10 per cent.). The benzoylbenzoin was boiled in aqueous alcoholic solution with twice the theoretical quantities of sodium acetate and hydroxylamine hydrochloride, the heating being continued during 6—12 hours; when the greater portion of the alcohol was then distilled off and the residue poured into water, the semi-solid product, on crystallisation from alcohol, deposited globular clusters of crystals melting at  $148^\circ$ .

0.2400 gave 0.1122  $\text{H}_2\text{O}$  and 0.6704  $\text{CO}_2$ .  $\text{C} = 76.18$ ;  $\text{H} = 5.19$ .

0.5295 „ 20.3 c.c. moist nitrogen at  $17.5^\circ$  and 763.5 mm.  $\text{N} = 4.5$ .

$\text{C}_{21}\text{H}_{17}\text{O}_3\text{N}$  requires  $\text{C} = 76.13$ ;  $\text{H} = 5.14$ ;  $\text{N} = 4.2$  per cent.

Benzoylbenzoinoxime is readily soluble in the ordinary organic solvents.

#### *Action of Benzylmethylacetyl Chloride on $\alpha$ -Benzaldoxime.*

When  $\alpha$ -benzaldoxime, covered with light petroleum, is treated with benzylmethylacetyl chloride, the mixture becomes warm and hydrogen chloride is slowly evolved, while the transparent crystals of the oxime are converted into a fine, white powder. After leaving the mixture at the ordinary temperature for several hours, the solid is separated by filtration and identified as benzamide. On evaporation, the light petroleum solution gave an oil which had a strong odour of bitter almonds; on distilling in steam, a portion passed over and was identified as benzonitrile. The residue consisted of benzylmethylacetic acid.

In one experiment, 10.7 grams of acid chloride and 7.1 grams of benzaldoxime were used, from which 5 grams of benzonitrile, 2 grams of benzamide, and 9 grams of benzylmethylacetic acid were obtained.

In a second experiment, only 0.5 gram of benzamide was produced from 8.3 grams of benzaldoxime, with a corresponding increase in the quantity of benzonitrile.

#### *The Resolution of dl-Bases with the Aid of an Active Acid Chloride.*

##### *Action of d-Benzylmethylacetyl Chloride on dl-Hydrindamine.*

On slowly adding a dry ethereal solution of hydrindamine (2 mols.) to an ethereal solution of benzylmethylacetyl chloride (1 mol.), pre-

pared from the *d*-acid in the ordinary way, a vigorous reaction ensues with development of heat and precipitation of hydrindamine hydrochloride, but after about half the base has been run in, the reaction moderates considerably. The solution, left overnight to ensure complete interaction, is then washed with water, the ether allowed to evaporate, and the crystalline product separated by filtration and washed with water until free from hydrochloride. On repeatedly crystallising the crude hydrindamide from methyl alcohol, the most sparingly soluble isomeride is obtained without much trouble; this compound crystallises from methyl alcohol in colourless needles or prisms melting at 148—149°; it is readily soluble in cold methyl alcohol, ethyl acetate, ether, and acetone, but practically insoluble, even in boiling water. This compound is laevorotatory in methyl-alcoholic solution, and is a derivative of *d*-hydrindamine, as is proved by the fact that it is identical with the *d*-benzylmethylaceto-*d*-hydrindamide already described (p. 449); its specific rotation was determined with the following results:

0.5766, in 25 c.c. methyl alcohol and in a 200 mm. tube, gave  $\alpha - 0.74^\circ$ , whence  $[\alpha]_D - 16^\circ$ .

0.1411 gave 0.4232 CO<sub>2</sub> and 0.0952 H<sub>2</sub>O. C = 81.79; H = 7.5.

0.1419 „ 0.4266 CO<sub>2</sub> „ 0.1016 H<sub>2</sub>O. C = 82.0; H = 7.9.

C<sub>19</sub>H<sub>21</sub>ON requires C = 81.7; H = 7.5 per cent.

The various mother liquors remaining after the isolation of the *d*-benzylmethylaceto-*d*-hydrindamide gave crystalline deposits, which, when submitted to fractional crystallisation, gave long, ill-defined needles melting at 119—120°; this substance is one of the externally compensated compounds identical with that prepared from *dl*-hydrindamine and the *dl*-acid chloride (p. 444). The later crystalline deposits yielded a compound which crystallised from methyl alcohol in well-defined prisms melting at 110—111°; this is the isomeric externally compensated compound previously described. The mother liquors which then remained gave crystalline deposits of very indefinite melting point, and from which, owing to their very great solubility, it seemed impossible to isolate the last component of the original product, namely, the derivative of the other active base. In these circumstances, the several most soluble deposits were collected, recrystallised until colourless, and then examined polarimetrically in methyl alcohol solution, when it was proved that these fractions contain a compound which was *dextro*-rotatory, and which therefore represents the derivative of the other active base, namely, the *l*-isomeride.

The acid chloride used in the above experiments had been distilled under reduced pressure, and contained a considerable quantity of the *l*-compound; the experiment was repeated, using the *d*-chloride pre-

pared as described in this paper (p. 447). In this case, the active amide melting at 148—149° was very easily isolated by two or three crystallisations from benzene, but again it was found almost impossible to obtain any quantity of a pure preparation of the isomeride from the mother liquors, although a few crystals were obtained melting at 113°. Attempts to hydrolyse the amide melting at 148—149° were unsuccessful; it seems to be quite stable towards boiling concentrated aqueous or alcoholic potash or aqueous baryta, and is only very slowly hydrolysed by boiling hydrochloric or dilute sulphuric acids, giving mere traces of ammonia and of indene; more concentrated sulphuric acid at 150° is much more rapid in its action, but ammonia is the only basic product; the liberated *d*-benzylmethylacetic acid is still optically active, thus indicating the stability of the asymmetric carbon group in this compound. The active hydrindamide, when heated in sealed tubes with alcoholic potash, hydrochloric acid, or sulphuric acid, or other hydrolysing agents, was decomposed into indene and ammonia.

*Action of d-Benzylmethylacetyl Chloride on dl-α-Phenylethylamine.*

The optically pure chloride of the *d*-acid was treated in dry ethereal solution with excess of freshly distilled base in the same solvent; a vigorous reaction took place, heat being developed, and a bulky precipitate of the hydrochloride being formed. The ether was allowed to evaporate, and the residue heated with a little water to dissolve the salt formed, when a white, slightly viscid solid remained, which melted at 95—100°. The product was first crystallised from methyl alcohol; the sparingly soluble fraction, which separated in thick prisms, melted at 118—119°; this portion was first crystallised from light petroleum (b. p. 60—80°), in which it was very sparingly soluble, and then from benzene; the fine, long needles thus obtained melted at 119°, and were identical with those of the *d*-benzylmethylaceto-*l*-phenylethylamide previously described (p. 448).

0.2925, dissolved in 25 c.c. ether gave, in a 200 mm. tube,  $\alpha + 0.24^\circ$ , whence  $[\alpha]_D + 10.3^\circ$ .

The isomeric derivative of *d*-phenylethylamine was not isolated from the mother liquors, since it was found impossible to regain the active bases by the hydrolysis of their amides.

A part of the expense incurred in this investigation has been met by a grant kindly awarded by the Government Grant Committee of the Royal Society.

UNIVERSITY COLLEGE,  
NOTTINGHAM.

# L.—Contributions to the Knowledge of the $\beta$ -Diketones.

By SIEGFRIED RUHEMANN and EDWIN ROY WATSON.

SOME years ago, J. Wislicenus (*Annalen*, 1899, 308, 219) published the results of the work undertaken by him in conjunction with Löwenheim, Schmidt, and Wells on the interaction of alcoholic potash with benzylideneacetophenone dibromide. They found that the compound thus formed had the formula  $C_{15}H_{12}O_2$ , and they regarded it as the tautomeride of dibenzoylmethane, which had been first obtained by v. Baeyer and Perkin (*Ber.*, 1883, 16, 2134) by boiling ethyl dibenzoylacetate with water, and afterwards by Claisen (*Annalen*, 1896, 291, 52) by the action of sodium ethoxide or metallic sodium on a mixture of ethyl benzoate and acetophenone. The two tautomeric forms of dibenzoylmethane could be represented by the following formulæ:  $C_6H_5 \cdot C(OH) : CH \cdot CO \cdot C_6H_5$  and  $C_6H_5 \cdot CO \cdot CH_2 \cdot CO \cdot C_6H_5$ .

Wislicenus is inclined to regard his compound as the diketonic form, and the old dibenzoylmethane as the enol-ketonic form, because, whilst the latter dissolves in alkali with the greatest ease and yields with ferric chloride a violet-red coloration and a greyish-green precipitate with alcoholic copper acetate solution, the former is insoluble in alkali and neither gives at once a coloration with ferric chloride, nor is precipitated by copper acetate.

That Wislicenus's compound was a tautomeride of the long-known dibenzoylmethane seemed to follow from the fact that it gave the same compounds on treatment with bromine, hydroxylamine, phenylhydrazine, hydrazine, or semicarbazide. Wislicenus further showed that, although his compound remained unchanged on distillation or on boiling with acetic acid, it was transformed into the old dibenzoylmethane under the influence of mineral acids. He therefore succeeded in effecting a transformation of his compound into the other, although the reverse change could not be accomplished.

That the transformation of the one form into the other is not brought about either by boiling or under the influence of alkali seems to be incompatible with our present knowledge of tautomeric compounds. These difficulties seem to have been recognised by Wislicenus himself, for he suggested the possibility of representing his compound as benzoylphenylethylene oxide,  $C_6H_5 \cdot CO \cdot CH \cdot CH \cdot C_6H_5$ .

These discrepancies and the desire to prepare ketones of the acetylene series in order to examine whether they are transformed by the action of bases into heterocyclic compounds, similar to those formed

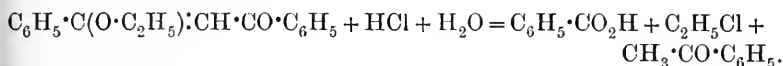

from the esters of the acetylene series (Ruhemann and Stapleton, *Trans.*, 1900, 67, 239), have induced us to repeat Wislicenus's experiments.

Such ketones of the acetylene series have indeed been obtained by Nef (*Annalen*, 1899, 308, 264) from the sodium compounds of the hydrocarbons of the acetylene series under the influence of acid chlorides; yet it seemed to us possible to prepare them from the olefinic ketones, just as Claisen has prepared acetylenic aldehydes from their olefinic analogues (*Ber.*, 1903, 36, 3664).

In following Wislicenus's directions, we obtained by the action of alcoholic potash on benzylideneacetophenone dibromide a compound with precisely the same properties as those recorded by this author for his dibenzoylmethane, but our analytical results differed considerably from the numbers given by Wislicenus, and agree, not with the formula  $C_{15}H_{12}O_2$  for dibenzoylmethane, but with  $C_{17}H_{16}O_2$ . This formula, which was, moreover, verified by a molecular weight determination, would correspond with the following constitution,

according to which the substance appears to be the ethyl ether of dibenzoylmethane, and would therefore be analogous to the corresponding esters which have lately been obtained by Lees (*Trans.*, 1903, 83, 145). This constitution is supported by the fact that the compound  $C_{17}H_{16}O_2$ , on heating with hydrochloric acid, is decomposed, giving acetophenone, benzoic acid, and ethyl chloride. This reaction, therefore, takes place in accordance with the following equation:

Löwenheim, who effected the decomposition of the compound by means of concentrated caustic potash and obtained acetophenone and benzoic acid, did not observe the formation of alcohol.

The correctness of the formula,  $C_{17}H_{16}O_2$ , for this compound is, moreover, supported by the fact that *p*-nitrobenzylideneacetophenone dibromide, on treatment with alcoholic potash, yields the corresponding nitro-derivative,  $C_{17}H_{15}(NO_2)O_2$ , which, therefore, is to be regarded as the ethyl ether of *p*-nitrodibenzoylmethane,

As regards the formation of the ethyl ether of dibenzoylmethane from benzylideneacetophenone dibromide, there cannot be any doubt that the first action of the alcoholic potash is to remove 1 mol. of hydrogen bromide and to yield the bromobenzylideneacetophenone,

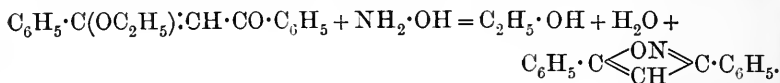

a compound obtained by Schmidt (Wislicenus, *loc. cit.*) by the action of potassium acetate on the dibromide. We have obtained a similar compound, namely, bromobenzylideneacetone,

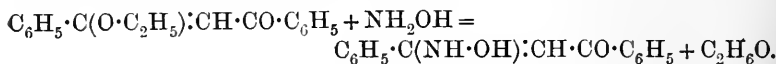

by the action of alcoholic potash in the cold on the benzylideneacetone dibromide. The bromobenzylideneacetophenone is subsequently transformed into the ethyl ether of dibenzoylmethane, either by the further removal of hydrogen bromide and subsequent union of alcohol with the first formed benzoylphenylacetylene, or by the direct replacement of the bromine atom by the ethoxyl group.

This constitution shows why the compound is insoluble in aqueous caustic potash and does not give a coloration with ferric chloride or a precipitate with copper acetate. It further explains why the compound can be readily transformed into dibenzoylmethane, and why the reverse change cannot be directly effected. Moreover, all the reactions of this compound, as described by Wislicenus, can be readily explained on this view of its constitution.

For example, an  $\alpha\gamma$ -diphenylisooxazole is formed with hydroxylamine,

The formation of  $\alpha\gamma$ -diphenylisooxazole, as shown by Wislicenus (*loc. cit.*), is preceded by that of a compound which he regarded as an oxime of dibenzoylmethane. The fact, however, that this substance, which is produced also from v. Baeyer and Perkin's dibenzoylmethane, does not yield a coloration with ferric chloride, is not in harmony with the formula  $\text{C}_6\text{H}_5\cdot\text{C}(\text{OH}):\text{CH}\cdot\text{C}(\text{C}_6\text{H}_5):\text{NOH}$ . After having proved that Wislicenus's dibenzoylmethane is ethoxybenzylideneacetophenone, its reaction with hydroxylamine may be expressed as follows:

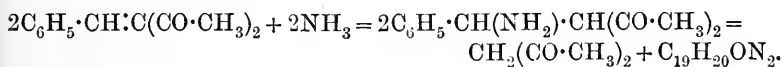

The compound would thus appear to be a hydroxylamine derivative and not an oxime. This constitution agrees with the fact that the compound does not give a coloration with ferric chloride; it explains, also, why the substance, although unchanged by neutral solvents, is readily transformed into  $\alpha\gamma$ -diphenylisooxazole under the influence of alkalis. It is thus isomerised to  $\text{C}_6\text{H}_5\cdot\text{C}(:\text{NOH})\cdot\text{CH}_2\cdot\text{CO}\cdot\text{C}_6\text{H}_5$ , which subsequently loses water to form the isooxazole derivative.

A ready explanation is also afforded of the action of bromine in forming the monobromo- and dibromo-benzoylmethane compounds, previously

prepared by Neufville and v. Pechmann (*Ber.*, 1890, 23, 3377) from dibenzoylmethane,

In connection with this investigation, we record the result of our experiments on the behaviour of bases towards olefinic diketones, an account of the action of benzamidine on these diketones having been lately given (*Trans.*, 1903, 83, 1371). The results obtained induced us to examine also the action of other bases on these diketones. We find that ammonia readily reacts with benzylideneacetylacetone, yielding a compound having the formula  $\text{C}_{19}\text{H}_{20}\text{ON}_2$ , the formation of which may be thus represented :

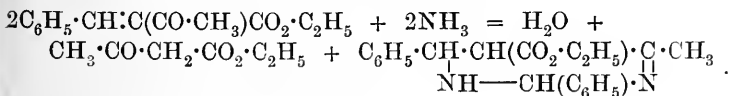

The constitution of the product should probably be expressed as follows :

according to which it is to be regarded as acetyldiphenylmethyltetrahydropyrimidine. This constitution is in agreement with the fact that the compound, although readily decomposed by dilute mineral acids with the formation of benzaldehyde, is yet comparatively stable towards alkalis. On heating with alkali, no ammonia is evolved, but on removing the acetyl group a compound is formed which is probably the corresponding diphenylmethyltetrahydropyrimidine.

One of us (Ruhemann, *Trans.*, 1903, 83, 378) has shown that by the action of ammonia on ethyl benzylideneacetoacetate, a compound was formed which was regarded as benzylideneaminoacetone,  $\text{C}_{10}\text{H}_{11}\text{ON}$ . On account of the ease with which this substance is decomposed, the above formula could not be verified by a molecular weight determination. The behaviour of this compound is analogous to that of the substance obtained from benzylideneacetylacetone, and this makes it necessary to assign to the two compounds similar constitutions. Such considerations lead us to double the molecular weight of the compound obtained from ethyl benzylideneacetoacetate, and to regard it as ethyl diphenylmethyltetrahydropyrimidinecarboxylate. Its formation may then be expressed by the following equation :

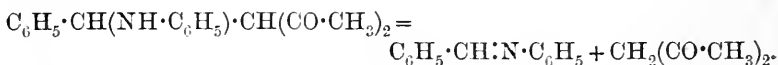

These compounds are still under examination.

The assumption that the first step in the reaction of ammonia on benzylideneacetylacetone leads to the formation of an additive product, as indicated in the above equation, is rendered probable by the action of aniline on benzylideneacetylacetone.

These compounds interact at the ordinary temperature to form the additive product,  $\alpha$ -anilino- $\beta\beta$ -diacetyl- $\alpha$ -phenylethane,

This compound, however, on heating at  $100^\circ$ , decomposes with the formation of benzylideneaniline and acetylacetone according to the equation:

Phenylhydrazine reacts with benzylideneacetylacetone as well as with benzylidenebenzoylacetone with development of heat, but the additive products, which may be assumed to be first formed, cannot be isolated, since, in both cases, they at once decompose forming benzaldehydephenylhydrazone.

The action of semicarbazide on benzylideneacetylacetone and benzylidenebenzoylacetone is of especial interest; in both cases, the reaction takes place between 1 mol. of the olefinic diketone and 1 mol. of the semicarbazide; water (1 mol.) is eliminated, and compounds are obtained having the formulæ  $\text{C}_{13}\text{H}_{15}\text{O}_2\text{N}_3$  and  $\text{C}_{18}\text{H}_{17}\text{O}_2\text{N}_3$  respectively. These compounds might be regarded as semicarbazones,

but taking into consideration the behaviour of other bases towards the olefinic diketones, there remains the alternative view that, in these cases also, additive products are first formed, which subsequently lose water to form cyclic compounds, for example:

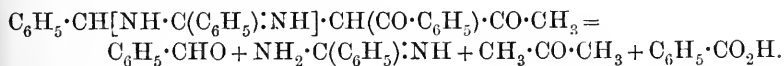

One of us has recently shown (*loc. cit.*) that benzamidine also reacts with benzylidenebenzoylacetone forming an additive product. The fact that this compound, on heating with hydrochloric acid, decomposes and yields dibenzamide led to the view that the constitution of this compound should be represented by the formula:

This constitution, however, would not be in harmony with the results recorded in this paper, according to which the bases react additively with the olefinic diketones in such a way as to destroy the double linking. In the light of these researches, the above compound must be represented thus :

and this formula would also readily explain the formation of dibenzamide. Under the influence of hydrochloric acid, decomposition takes place, as indicated by the equation :

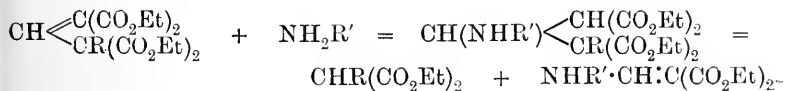

The benzamidine and benzoic acid in turn react in the presence of mineral acid to yield dibenzamide, thus :

The reaction of benzamidine on benzylideneacetylacetone, which, as has been shown lately (*loc. cit.*), yields diphenylmethyl dihydropyrimidine, may well be explained in a similar manner by assuming that first the additive product,  $\text{C}_6\text{H}_5 \cdot \text{CH}[\text{NH} \cdot \text{C}(\text{C}_6\text{H}_5) : \text{NH}] \text{CH}(\text{CO} \cdot \text{CH}_3)_2$ , is formed, which then condenses to the dihydropyrimidine.

The constitution of the products formed by the interaction of benzylideneacetylacetone and benzylidenebenzoylacetone with semicarbazide has not yet been definitely fixed, but without considering this problem the general hypothesis may be deduced that, in the first place, ammonia and organic bases, on reacting with the olefinic diketones, destroy the ethylene linking to form additive compounds.

This assumption may be extended to explain the behaviour of bases towards ethyl dicarboxyglutaconate and its derivatives. As shown by one of us and his pupils, ethyl benzyl dicarboxyglutaconate, on treatment with ammonia, yields ethyl benzyl malonate and ethyl aminomethylenemalonate. In these cases, also, it may be supposed that the decomposition is preceded by the formation of additive products, which subsequently break up in the manner indicated by the following equation :

## EXPERIMENTAL.

*Action of Alcoholic Potash on Benzylideneacetophenone Dibromide.*

Benzylideneacetophenone is readily prepared by Claisen's method (*Ber.*, 1887, 20, 657) by the action of sodium methoxide in methyl-alcoholic solution on a mixture of benzaldehyde and acetophenone. Its transformation into the dibromide,  $C_6H_5 \cdot CHBr \cdot CHBr \cdot CO \cdot C_6H_5$ , is best effected by dissolving the olefinic ketone in carbon disulphide instead of chloroform, as recommended by Wislicenus (*loc. cit.*), when almost the total quantity of the dibromide separates out; it dissolves in boiling alcohol with difficulty and, on cooling, crystallises in colourless needles which melt at  $158^\circ$  (according to Wislicenus at  $156.5-157.5^\circ$ ).

0.2078 gave 0.3711  $CO_2$  and 0.0642  $H_2O$ . C = 48.70; H = 3.43.

0.2017 „ 0.3618  $CO_2$  „ 0.0624  $H_2O$ . C = 48.92; H = 3.43.

0.2371 „ 0.2406 AgBr. Br = 43.18.

$C_{15}H_{12}OBr_2$  requires C = 48.91; H = 3.26; Br = 43.47 per cent.

We have pointed out in the introduction that the dibromide reacts with alcoholic potash to yield the ethyl ether of dibenzoylmethane,  $C_6H_5 \cdot C(O \cdot C_2H_5) : CH \cdot CO \cdot C_6H_5$ , instead of dibenzoylmethane,

as stated by Wislicenus. Our mode of procedure is practically the same as employed by this author: caustic potash (2 mols.) dissolved in absolute alcohol is gradually added to the hot solution of the dibromide (1 mol.) in absolute alcohol, and the reaction is completed by digesting the mixture at  $100^\circ$  for about an hour. The alcohol is then distilled from the water-bath as far as possible, the residue treated with water and extracted with ether. After drying the ethereal solution with calcium chloride and evaporating off the ether, an oil is left which distils at  $212^\circ$  under 10 mm. pressure. The yellowish, oily distillate, when left for a short time, solidifies almost completely. The solid is only sparingly soluble in cold light petroleum (b. p.  $50-80^\circ$ ), but readily dissolves in the hot solvent. It is readily soluble in hot alcohol and crystallises from either solvent in colourless prisms which melt at  $77-78^\circ$  and have all the properties recorded by Wislicenus for his "dibenzoylmethane."

0.2037 gave 0.6020  $CO_2$  and 0.1190  $H_2O$ . C = 80.60; H = 6.49.

0.1925 „ 0.5695  $CO_2$  „ 0.1120  $H_2O$ . C = 80.68; H = 6.46.

0.1818 „ 0.5397  $CO_2$  „ 0.1052  $H_2O$ . C = 80.96; H = 6.42.

$C_{17}H_{16}O_2$  requires C = 80.95; H = 6.35 per cent.

These numbers differ considerably from those given by J. Wislicenus, which show a close agreement with the percentage results required for dibenzoylmethane,  $C_{15}H_{12}O_2$ , namely, C = 80.36 ; H = 5.36 per cent.

The formula  $C_{17}H_{16}O_2$  agrees also with the result of the molecular weight determination of the compound by the freezing point method.

0.405 in 22.49 benzene gave  $\Delta t = 0.405^\circ$ . M. W. = 256.

$C_{17}H_{16}O_2$  requires M. W. = 252.

The constitution  $C_6H_5 \cdot C(O \cdot C_2H_5) : CH \cdot CO \cdot C_6H_5$  follows from the decomposition which the compound undergoes when heated with concentrated hydrochloric acid in a closed tube at  $150-160^\circ$  for two hours. It thus furnishes ethyl chloride, acetophenone, and benzoic acid. The formation of ethyl chloride is sufficiently proved by the fact that on opening the cold tube hardly any pressure is noticed, but on warming, a gas escapes which burns with a green flame. The other products of decomposition have been isolated and identified as acetophenone and benzoic acid by their properties and by analysis.

*Action of Alcoholic Potash on p-Nitrobenzylideneacetophenone Dibromide.*

The action of alcoholic potash on benzylideneacetophenone dibromide is analogous to the behaviour of the same reagent towards the *p*-nitrobenzylideneacetophenone dibromide, the latter reaction giving rise to the ethyl ether of *p*-nitrodibenzoylmethane :

*p*-Nitrobenzylideneacetophenone is formed by adding dilute caustic soda to an alcoholic solution of *p*-nitrobenzaldehyde and acetophenone. It was thus prepared by Sorge (*Ber.*, 1902, 35, 1068), who also transformed it into the dibromide. We find that the union of bromine with the olefinic ketone takes place more readily than stated by this investigator, and that it is completed when the solution of both reagents in chloroform has been left overnight. The dibromide, which separates out on concentrating the solution, has been once recrystallised from chloroform, when it is obtained in yellow needles. On gradually adding the exact quantity of alcoholic potash (2 mols.) dissolved in absolute alcohol to the hot alcoholic solution of *p*-nitrobenzylideneacetophenone dibromide (1 mol.), potassium bromide separates out and the solution turns deep red. After digesting the mixture for an hour at  $100^\circ$ , the alcohol is distilled from the water-bath and the residue extracted with ether. On evaporating off the ether, a dark oil is left behind which partially solidifies in the course of 2—3 days ; the solid is collected at the pump and dissolved in hot dilute alcohol, from which solvent it separates in yellow needles which,

after two crystallisations from the same solvent, melt constantly at 89—90°.

0.1993 gave 0.5018 CO<sub>2</sub> and 0.0923 H<sub>2</sub>O. C = 68.62; H = 5.14.

0.1965 „ 8.4 c.c. moist nitrogen at 17° and 744.5 mm. N = 4.85.

0.1959 „ 8.4 c.c. „ at 19° and 755.5 mm. N = 4.89.

C<sub>17</sub>H<sub>15</sub>O<sub>4</sub>N requires C = 68.68; H = 5.05; N = 4.71 per cent.

*p*-Nitrodibenzoylmethane is readily soluble in alcohol, chloroform, or ether and insoluble in cold potash, but on warming with the alkali, however, decomposition takes place, and the odour of acetophenone is perceptible.

*Action of Alcoholic Potash on the Benzylideneacetone Dibromide.*

In preparing benzylideneacetone, we have followed the directions given by Claisen and Ponder (*Annalen*, 1884, 223, 139). This compound readily takes up bromine and yields the dibromide, C<sub>6</sub>H<sub>5</sub>·CHBr·CHBr·CO·CH<sub>3</sub>, but for this purpose we find it advisable to employ carbon disulphide rather than chloroform as a solvent (compare Claisen and Claparède, *Ber.*, 1881, 14, 2461), since the yield is better and the product is at once obtained in a pure state. On adding caustic potash (2 mols.), dissolved in absolute alcohol, to the warm alcoholic solution of the dibromide (1 mol.), potassium bromide separates, and the solution turns red without further heating. The alcohol was not distilled off, as in the previous cases, but the solution was diluted with water and extracted with ether. After removing the ether, a yellow oil was obtained boiling at 150—151° and 169—170° under 10 and 20 mm. pressure respectively.

This compound was bromobenzylideneacetone, C<sub>6</sub>H<sub>5</sub>·CBr:CH·CO·CH<sub>3</sub>, which, however, as indicated by the analysis, was not quite pure, but probably contained a little of the ethyl ether of benzoylacetyl-methane.

0.2063 gave 0.4023 CO<sub>2</sub> and 0.0839 H<sub>2</sub>O. C = 53.18; H = 4.51.

0.2264 „ 0.1775 AgBr. Br = 33.39.

C<sub>10</sub>H<sub>9</sub>OBr requires C = 53.33; H = 4.0; Br = 35.55 per cent.

On adding phenylhydrazine to the alcoholic solution of bromobenzylideneacetone and slightly warming, a crystalline precipitate slowly separates, consisting of the phenylhydrazone,

This substance crystallises from alcohol in yellow, glistening plates which melt and decompose at 97°.

0.1831 gave 14.2 c.c. moist nitrogen at 20° and 763 mm. N = 8.90.

C<sub>16</sub>H<sub>15</sub>N<sub>2</sub>Br requires N = 8.89 per cent.

Bromobenzylideneacetone is analogous to the bromobenzylideneacetophenone,  $C_6H_5 \cdot CBr \cdot CH \cdot CO \cdot C_6H_5$ , which Schmidt (*loc. cit.*) obtained by the action of potassium acetate on benzylideneacetophenone dibromide. We have as yet not heated the bromobenzylideneacetone with alcoholic potash, but we propose to carry out this experiment with the view of examining whether in this case the corresponding ethyl ether,  $C_6H_5 \cdot C(O \cdot C_2H_5) \cdot CH \cdot CO \cdot CH_3$ , of acetylbenzoylmethane is produced.

*Action of Ammonia and Organic Bases on Olefinic Diketones.*

One of us has shown lately (Trans., 1903, 83, 1371) that, in the first place additive products are formed by the action of benzamidine on these diketones, and such a product has been isolated on treating benzamidine with benzylidenebenzoylacetone. We have already stated (p. 459) that other bases form with these diketones similar additive products, which, however, are unstable and readily give rise to other compounds.

*Action of Ammonia on Benzylideneacetylacetone and Benzylidenebenzoylacetone.*

The solution of benzylideneacetylacetone in excess of alcoholic ammonia, when left overnight, deposits colourless plates. These are insoluble in ether, but readily dissolve in hot alcohol and melt somewhat indefinitely at  $147^\circ$ .

0.2010 gave 0.5739  $CO_2$  and 0.1248  $H_2O$ .  $C = 77.87$ ;  $H = 6.89$ .

0.1844 „ 15.4 c.c. moist nitrogen at  $12^\circ$  and 749 mm.  $N = 9.71$ .

0.1865 „ 15.4 c.c. „ „ „  $15^\circ$  and 755 mm.  $N = 9.66$ .

$C_{19}H_{20}ON_2$  requires  $C = 78.08$ ;  $H = 6.85$ ;  $N = 9.59$  per cent.

With regard to the constitution of this compound, we have already (p. 459) expressed the view that it is acetyldiphenylmethyltetrahydropyrimidine. It dissolves in cold dilute mineral acids, but on warming the solution, decomposition takes place, which is indicated by the formation of benzaldehyde. The compound is more stable towards alkalis for, on boiling with alcoholic potash, no odour of benzaldehyde is perceptible, but it loses the acetyl group and yields a substance which is most probably diphenylmethyltetrahydropyrimidine. This product is isolated by distilling off the alcohol from the water-bath and adding water to the residue; a yellow oil is thus precipitated, whilst the aqueous solution contains acetic acid, which has been identified by its general reactions. The oil, which rapidly solidifies and crystallises from dilute alcohol in yellow leaflets, is still under examination.

The action of alcoholic ammonia on benzylidenebenzoylacetone differs from the preceding condensation. In this case, the solution turned yellow, but did not deposit a solid, even after a long time. On adding water to the solution, a viscous product was precipitated which could not be induced to crystallise.

*Action of Aniline on Benzylideneacetylacetone.*

A mixture of equal quantities of benzylideneacetylacetone and aniline, when left for a short time, develops heat and becomes solid. After washing with a little alcohol, the product is dissolved in hot dilute alcohol; the solution, on cooling, deposits colourless needles which melt at  $113^{\circ}$ .

0.2010 gave 0.5646  $\text{CO}_2$  and 0.1248  $\text{H}_2\text{O}$ .  $\text{C} = 76.60$ .  $\text{H} = 6.89$ .

0.2367 „ 11 c.c. moist nitrogen at  $22^{\circ}$  and 732 mm.  $\text{N} = 5.04$ .

0.2384 „ 11 c.c. „ „ „  $21^{\circ}$  and 733 mm.  $\text{N} = 5.03$ .

$\text{C}_{18}\text{H}_{19}\text{O}_2\text{N}$  requires  $\text{C} = 76.86$ ;  $\text{H} = 6.76$ ;  $\text{N} = 4.98$  per cent.

This additive compound,  $\text{C}_6\text{H}_5 \cdot \text{CH}(\text{NH} \cdot \text{C}_6\text{H}_5) \cdot \text{CH}(\text{CO} \cdot \text{CH}_3)_2$ , is somewhat unstable, and when heated on the water-bath it readily decomposes into acetylacetone and benzylideneaniline. This mixture, on cooling, partially solidifies; the adhering oil is pressed out from the solid, and the latter dissolved in hot dilute alcohol. On cooling, a white emulsion is produced in the solution, which gradually deposits a compound crystallising in colourless plates melting at  $50$ — $51^{\circ}$ . This compound was identified as benzylideneaniline by the foregoing properties and by analysis.

The additive compound is also formed on heating the mixture of aniline and benzylideneacetylacetone at  $100^{\circ}$ .

*Action of Phenylhydrazine on Benzylideneacetylacetone and Benzylidenebenzoylacetone.*

On mixing benzylideneacetylacetone (3 grams) and phenylhydrazine (2 grams), heat was developed and a semi-solid product results, which crystallised from dilute alcohol in almost colourless needles melting at  $155$ — $156^{\circ}$ , and was identified by these properties and by analysis as benzaldehydephenylhydrazone.

Benzylidenebenzoylacetone reacts with phenylhydrazine in a similar manner; an alcoholic solution of these reagents, when boiled and subsequently cooled, deposits needles melting at  $155$ — $156^{\circ}$ .

0.2069 gave 0.6010  $\text{CO}_2$  and 0.1165  $\text{H}_2\text{O}$ .  $\text{C} = 79.26$ ;  $\text{H} = 6.25$ .

0.2032 „ 25.5 c.c. moist nitrogen at  $16^{\circ}$  and 743 mm.  $\text{N} = 14.29$ .

$\text{C}_{13}\text{H}_{12}\text{N}_2$  requires  $\text{C} = 79.59$ ;  $\text{H} = 6.12$ ;  $\text{N} = 14.28$  per cent.

*Action of Semicarbazide on Benzylideneacetylacetone and on Benzylidenebenzoylacetone.*

Semicarbazide hydrochloride (1 mol.), dissolved in water, is mixed with a solution of sodium (1 atom) in alcohol, and then treated with benzylideneacetylacetone (1 mol.); heat is developed, and after a short time a precipitate is formed which dissolves in alcohol with difficulty and, on cooling, crystallises in yellow plates, which melt at  $210^{\circ}$  with evolution of gas.

0.2030 gave 0.4728  $\text{CO}_2$  and 0.1147  $\text{H}_2\text{O}$ .  $\text{C} = 63.52$ ;  $\text{H} = 6.27$ .

0.1604 „ 24.5 c.c. moist nitrogen at  $18^{\circ}$  and 746.5 mm.  $\text{N} = 17.31$ .

$\text{C}_{13}\text{H}_{15}\text{O}_2\text{N}_3$  requires  $\text{C} = 63.67$ ;  $\text{H} = 6.12$ ;  $\text{N} = 17.14$  per cent.

Benzylidenebenzoylacetone reacts with semicarbazide under the same conditions. The white, crystalline precipitate which separates is insoluble in water, sparingly soluble in boiling alcohol, and melts at  $230^{\circ}$  with evolution of gas. For analysis, the compound was washed successively with water and alcohol.

0.2013 gave 0.5174  $\text{CO}_2$  and 0.1034  $\text{H}_2\text{O}$ .  $\text{C} = 70.10$ ;  $\text{H} = 5.70$ .

0.1679 „ 19.5 c.c. moist nitrogen at  $9^{\circ}$  and 744.5 mm.  $\text{N} = 13.68$ .

$\text{C}_{18}\text{H}_{17}\text{O}_2\text{N}_3$  requires  $\text{C} = 70.35$ ;  $\text{H} = 5.53$ ;  $\text{N} = 13.68$  per cent.

Further experiments are required in order to decide whether these substances are cyclic compounds, as indicated in the introduction, or whether they are mono-semicarbazones of benzylideneacetylacetone and benzylidenebenzoylacetone, but at present we are inclined to hold the latter view.

GONVILLE AND CAIUS' COLLEGE,  
CAMBRIDGE.

## LI.—*The Formation of Periodides in Organic Solvents.*

By HARRY MEDFORTH DAWSON.

THE results of an investigation on the nature of nitrobenzene solutions containing iodine and potassium iodide have been already communicated to the Society (Dawson and Gawler, *Trans.*, 1902, 81, 524). It was found that solutions containing small quantities of iodine, when saturated with potassium iodide, dissolve approximately one molecular proportion of the latter for each molecule of iodine present. With more concentrated iodine solutions, the proportion of potassium iodide dissolved is smaller. On the other hand, solutions saturated with iodine contain four molecules of iodine for each molecule of iodide present, and this relationship holds for a very

extended series of concentrations. The existence in solution of complex periodides represented by  $KI_3$  and  $KI_5$  was deduced from these experiments.

The considerable solvent action thus exhibited by nitrobenzene for these periodides, taken in conjunction with the fact that potassium iodide alone is practically insoluble and iodine only moderately soluble (0.2 gram-mol. per litre) in nitrobenzene, seemed to justify a closer inquiry into the cause of this phenomenon. The nitro-group is possibly a factor in promoting the formation of the dissolved periodides for the free hydrocarbon and many substituted benzene derivatives do not dissolve any appreciable amount of potassium iodide even in the presence of iodine. With this idea as a working hypothesis, several other nitro-compounds have been examined, but since the great majority of these derivatives are solid at the ordinary temperature the number available for direct investigation is somewhat limited.

Nitrobenzene was replaced by the liquid nitro-compounds, *o*-nitrotoluene, *m*-nitrotoluene, *o*-nitroanisole, nitromethane, nitropentane, and trichloronitromethane. In none of these solvents is potassium iodide sensibly soluble, whilst iodine only dissolves to a comparatively small extent.

In the first series of solubility measurements, the results of which are recorded in the following table, the quantities of potassium iodide dissolved by solutions containing varying amounts of iodine were determined; in the second series, the solubility of iodine in solutions containing potassium iodide in varying amounts was measured:

*Composition of Solutions saturated with Potassium Iodide.*

Exactly similar relationships are observable on comparing the experimental data for the three aromatic nitro-compounds now investigated with the results previously obtained for nitrobenzene. For solutions saturated with potassium iodide, the molecular ratio  $I_2/KI$  increases rapidly with increasing concentration, and on this account no definite conclusions can be drawn with regard to the components of the solution. The observations accord, however, with the view that increasing concentration favours the formation of periodides of greater complexity. From solubility measurements alone, the presence of any particular iodide and its concentration in any one of these saturated solutions cannot be determined, but it is probable that with gradually increasing concentration the equilibrium changes are such that the tri-iodide, penta-iodide, hepta-iodide, and enneaiodide in turn become the predominant components of the solution.

Solutions saturated with iodine, on the other hand, all contain approximately four molecules of iodine for each molecule of iodide. In *o*- and *m*-nitrotoluenes and in *o*-nitroanisole, as in nitrobenzene, conditions favourable for the formation of the highest periodide lead therefore to the production of the enneaiodide,  $KI_9$ , the existence of which in solution is clearly characterised by the constancy of the molecular ratio  $I_2/KI = 4$  over a large range of concentrations.

The data obtained for nitromethane differ considerably from those for the aromatic solvents. The difference in behaviour is very clearly seen by a graphic representation of the experimental results. Nitromethane solutions saturated with potassium iodide contain approximately one molecule for each molecule of iodine, and although the molecular ratio  $I_2/KI$  increases with increasing concentration, yet the alteration is much smaller than in the case of the

aromatic nitro-compounds. Furthermore, solutions saturated with iodine do not contain four molecules for each molecule of iodide; for the range of concentrations investigated, the molecular ratio slowly increases with the concentration from 2.5—3. There is therefore little evidence of the existence of the highest periodide,  $\text{KI}_9$ , in the nitromethane solutions under conditions comparable with those where it appears to be the principal component in the aromatic nitro-compounds.

The solubility data for nitropentane are insufficient to justify any very definite conclusions, yet the two experiments carried out indicate that by substituting the amyl for the methyl group, the solubility relationships approximate to those observed for the benzene derivatives and therefore in all probability the nature of the predominant dissolved periodide at any given concentration is the same. Periodides are not formed in trichloronitromethane, the solubility of potassium iodide in presence of iodine being very small.

The solid nitro-compounds were examined either by dissolving them in an inactive solvent and studying the behaviour of the resulting solution towards iodine, or by investigating the solvent capacity of their solutions in nitrobenzene. Of the two methods, the former is *a priori* to be preferred, for with an active nitro-derivative dissolved in an inert solvent the experimental data should give a more or less direct expression of the behaviour of the active constituent. In the second method, the influence of the solid nitro-compound can only be deduced by taking into account the solvent capacity of the admixed nitrobenzene. As will be seen later, this process alone can be applied in the case of the majority of the nitro-compounds investigated.

In order to carry out the further investigation in the manner indicated, a preliminary inquiry into the way in which the solvent capacity of nitrobenzene is altered by admixture with other liquids was necessary. The substances employed for this purpose were carbon tetrachloride, carbon disulphide, chloroform, benzene, toluene, *p*-chlorotoluene, ethyl alcohol, ethyl acetate, and methyl alcohol. Nitrobenzene was mixed with each of these in equal volumes (10 c.c. of each), and the mixed solvents thus obtained were shaken for several hours with iodine and excess of potassium iodide. The experiments were carried out in such a way that the concentration of the iodine in the resulting solutions was in every case approximately the same, and each solution was saturated with potassium iodide. In the following table, the liquid mixed with the nitrobenzene is indicated in the first column, the iodine concentration is given in the second and third columns, and the quantities of dissolved potassium iodide are tabulated in the fourth and fifth columns.

A glance at the experimental data shows that the effect of mixing the nitrobenzene with an equal volume of carbon tetrachloride, carbon disulphide, chloroform, benzene, toluene, or *p*-chlorotoluene is in every case the same. The amount of potassium iodide which the mixed solvent can take up for one and the same amount of iodine is constant within the limits of experimental error. These admixed substances, therefore, simply dilute the nitrobenzene, and the solvent capacity of the latter is not in any way affected by the specific character of the inert liquid. This result is of some interest in view of the different densities of the liquids, which vary from 0.90 in the case of benzene to 1.63 for carbon tetrachloride. The relative proportions by weight of benzene and carbon tetrachloride added to the same weight of nitrobenzene in the above experiments are as 10 : 18, and yet these very different quantities by weight (representing, however, equal volumes) have the same effect. These results lead to the conclusion that in the investigation of the problem in hand the proportions by volume, and not by weight, must be made the basis of comparison. The conclusion drawn has probably a general significance, and may prove of considerable service in similar investigations. That the foregoing six liquids merely act as diluents is in accord with the fact that none of them takes up potassium iodide, even in presence of large quantities of iodine.

Mixtures of nitrobenzene with ethyl alcohol, ethyl acetate, and methyl alcohol dissolve more potassium iodide than pure nitrobenzene. This is due to the fact that these liquids themselves dissolve considerable quantities of potassium iodide and still larger amounts in the presence of iodine, and hence these are also to be regarded as solvents which promote the formation and solution of periodides.

In the previous experiments, the volumes of the two component

liquids were in every case equal. To obtain further data for the purpose of elucidating the behaviour of solid nitro-compounds towards iodine and potassium iodide, the effect of mixing one and the same quantity of nitrobenzene with different quantities of an inert substance has been determined. Of the inactive liquids, carbon tetrachloride and benzene were chosen for this purpose, and as might almost be expected from the preceding results, the effects produced by these two diluents at corresponding concentrations (volume proportions) are the same. In the table, the proportions by volume (before mixing) are given in the first column, and opposite are numbers representing the iodine and potassium iodide concentrations, all the solutions, as before, being saturated with iodide, and having approximately the same iodine concentration. The last column gives the potassium iodide concentration reduced to a uniform iodine concentration of 144 grams per litre.

Composition of solvent.				Iodine concentration.		KI concentration.		KI concentration (reduced).
				Gram-mols. per litre.		Gram-mols. per litre.		Grams per litre.
$C_6H_5NO_2$ .				Grams.		Grams.		
100	per cent.			144.3	0.569	80.4	0.484	80.3

50	„	50	„ $C_6H_6$	144.6	0.570	53.6	0.323	53.3
33	„	67	„ $CCl_4$	143.9	0.567	44.3	0.267	44.3
33	„	67	„ $C_6H_6$	144.4	0.569	43.2	0.260	43.1
15	„	85	„ $CCl_4$	9.3	0.075	—	—	—

If the numbers in the last column are represented graphically, it is found that the decrease in the amount of potassium iodide dissolved is almost exactly proportional to the increase in the proportion of the carbon tetrachloride or benzene in the mixture.

This relationship holds, at any rate, for solvents ranging from pure nitrobenzene on the one hand to a mixture containing more than 60 per cent. of the inactive component on the other. When the relative proportion of the nitrobenzene is further decreased, precipitation of the nitro-compound from solution takes place, and, as is evident from the last experiment recorded in the table, the quantities of iodine and potassium iodide in the resulting solution are very small. A similar phenomenon has been observed on shaking benzene solutions of several other nitro-compounds with iodine and potassium iodide, and on this

account it has not been possible to employ the first method of investigation suggested on p. 224.

From the data in the previous tables, the amount of potassium iodide dissolved by nitrobenzene when mixed with any given volume proportion of an inactive substance can be directly ascertained for a concentration of iodine of 144 grams per litre. If the amount of iodide dissolved when the inert substance is replaced by an equal volume of some other nitro-compound is greater than this, it would appear justifiable to conclude that this nitro-compound is not inert, but promotes the formation and solution of periodides. In the following table are given the experimental data relating to the solubility of potassium iodide in mixtures of nitrobenzene with other aromatic nitro-compounds, the iodine concentration being in all cases approximately the same. The first three columns give respectively the volume composition of the mixed solvent, the iodine and iodide concentrations; in the fourth, the potassium iodide concentrations are reduced to a uniform iodine concentration (144 grams per litre), and in the fifth column the corresponding numbers which would be obtained for the solubility of the iodide if the nitrobenzene were mixed with the same volume proportion of an inert substance. The figures in the last column are obtained by interpolation from the data in the previous table.

Composition of solvent.			KI concentration from curve for nitrobenzene		
100 per cent.	nitrobenzene	Iodine concentration.	KI concentration.	KI concentration reduced.	+ inactive substance.
100	per cent. nitrobenzene	144.3	80.4	80.2	—
66	„ nitrobenzene	143.2	74.6	75.0	61
34	„ <i>o</i> -chloronitrobenzene				
67	„ nitrobenzene	139.8	75.4	77.5	62
33	„ $\alpha$ -nitronaphthalene				
77	„ nitrobenzene	142.5	78.8	79.5	67
23	„ <i>m</i> -dinitrobenzene				
77	„ nitrobenzene	139.5	76.8	79.1	67
23	„ 2 : 4-dinitrotoluene				
67	„ nitrobenzene	143.5	79.5	79.8	62
33	„ 2 : 4 : 6-trinitrotoluene				
76	„ nitrobenzene	141.9	59.8	60.8	67
24	„ <i>p</i> -nitrobenzyl chloride				

A comparison of the numbers in the last two columns shows that

the solubility of potassium iodide in nitrobenzene when this is mixed with *o*-chloronitrobenzene,  $\alpha$ -nitronaphthalene, *m*-dinitrobenzene, di- or tri-nitrotoluene is considerably greater than when the nitrobenzene is mixed in the same volume proportion with an inactive substance such as benzene or carbon tetrachloride. The solubility numbers in the fourth column for the mixed solvents approximate, indeed, closely to that found for nitrobenzene itself, and the conclusion may be drawn that the above-mentioned nitro-compounds act very similarly to nitrobenzene with regard to the formation of periodides. This appears to be the case whether one or several nitro-groups are present in the molecule, for, according to the table, *m*-dinitrobenzene, 2:4-dinitrotoluene, and 2:4:6-trinitrotoluene agree almost completely with nitrobenzene. The solubility number obtained for the mixture of *o*-chloronitrobenzene and nitrobenzene is undoubtedly somewhat lower than that for pure nitrobenzene and the value found for the mixture of nitrobenzene and *p*-nitrobenzyl chloride is quite different from that obtained in the other cases investigated, and no adequate explanation of the fact is evident.

The composite solutions, the nature of which has been discussed, are characterised by the same iodine concentration and saturation with regard to potassium iodide. It is important to remember, however, that in the case of the liquid aromatic nitro-solvents investigated, the solutions saturated with iodine are much more definitely characterised. Over a considerable range of concentration, the molecular ratio  $I_2/KI$  in these solutions is equal to four, and it was thought possible that the examination of the composition of such solutions, when mixed solvents are used, might give more definite information with regard to the behaviour of those (solid) substances not available for direct investigation. Preliminary experiments with solvents composed of nitrobenzene and an inactive substance showed, however, that the amount of iodine dissolved per molecule of potassium iodide is practically the same as in the case of pure nitrobenzene. In these experiments, carbon tetrachloride was used on account of its small solvent power for iodine (one litre dissolves about 1/10 gram-molecule).

The following numbers show this sufficiently:

Composition of solvent.	Iodine concentration.	KI concentration.	Mol. ratio $I_2/KI$ .
33 per cent. $C_6H_5 \cdot NO_2$ , 67 per cent. $CCl_4$	1.10 gr.-mols.	0.268 gr.-mols.	4.1
67 „ $C_6H_5 \cdot NO_2$ , 33 „ $CCl_4$	1.83 „	0.447 „	4.1

Since the admixed inert liquid exerts apparently no appreciable influence on the proportion of dissolved iodine, the free nitrobenzene, and the mixture of this with nearly 70 per cent. of inert carbon tetrachloride both giving the value 4 for the molecular ratio, it is evident that the examination of such solutions saturated with iodine

and containing nitrobenzene as one component cannot furnish much information with regard to the behaviour of other nitro-compounds.

A consideration of the experimental data obtained for the solubility of the iodide leads, however, to the conclusion that to this extent many aromatic nitro-compounds resemble nitrobenzene in their behaviour towards iodine and potassium iodide. It is by no means possible to ascribe a specific action to the nitro-group, for the formation of periodides of the types which have been discussed probably also takes place in many other solvents.

Of the liquids which have been examined, hexane, benzene, toluene, methyl iodide, chloroform, bromoform, carbon tetrachloride, carbon disulphide, ethyl iodide, bromobenzene, *p*-chlorotoluene, benzyl chloride, and ethyl ether do not dissolve potassium iodide to any appreciable extent in the presence of iodine. These organic liquids do not promote the formation of soluble periodides.

Ethyl alcohol, ethyl cyanide and ethyl acetate, on the other hand, give solutions which certainly contain periodides, but the interpretation of experimental data is in these cases attended with considerable difficulty, for potassium iodide itself is appreciably soluble in the first and the third, and in all three the solubility of iodine is far greater than in the aromatic nitro-compounds which have been investigated. In two other solvents investigated, namely, ethyl bromide and *isobutyl* alcohol, potassium iodide is almost insoluble and its ready solubility in these solvents in presence of iodine is indicative of periodide formation. The quantitative relationships in these two cases differ considerably from those found for ethyl alcohol, ethyl cyanide, and ethyl acetate, as is evident from the following table containing solubility data. The simple solubility of potassium iodide or of iodine in the various solvents is indicated in the second column of the table. The numbers in brackets in the last column of the first part of the table give the molecular ratio  $I_2/KI$  after subtracting the solubility value for potassium iodide from the total iodide concentration.

*Composition of Solutions Saturated with Potassium Iodide.*

Solvent.	Solubility of KI in grams per litre.	Iodine concentration.		KI concentration.		Mol. ratio $I_2/KI$ .
		Grams.	Gram-mols. per litre.	Grams.	Gram-mols. per litre.	
Ethyl alcohol	14.4	96.4	0.38	68.6	0.413	0.92 (1.16)
Ethyl cyanide	4	94.5	0.372	65.1	0.392	0.96 (1.01)
Ethyl acetate	12.8	97.9	0.386	65.8	0.396	0.98 (1.21)
Ethyl bromide	0	100	0.394	18.8	0.113	3.5
<i>isoButyl</i> alcohol	0	96.1	0.379	52.6	0.317	1.2

*Composition of Solutions saturated with Iodine*

Solvent.	Solubility of iodine in grams per litre.	Iodine concentration.		KI concentration.		Mol. ratio- I <sub>2</sub> /KI.
		Grams.	Gram-mols. per litre.	Grams.	Gram-mols. per litre.	
Ethyl alcohol	224	627	2.47	110	0.66	3.75
Ethyl cyanide	110	640	2.52	107	0.645	3.9
Ethyl acetate	141	801	3.16	134	0.81	3.9
Ethyl bromide	211	619	2.44	76.2	0.46	5.3
isoButyl alcohol	78	436	1.22	58.6	0.353	3.5

In the first series of saturated solutions, the iodine concentration is approximately the same in every case; in the second series, the potassium iodide concentrations are not so nearly equal, but the concentrations are such as to make it possible to compare the solutions with the corresponding solutions in aromatic nitro-compounds for which the existence of a simple molecular relationship between iodine and iodide has been experimentally established. The values of the molecular ratio in the ethyl alcohol, ethyl cyanide and ethyl acetate solutions approximate to those found in the case of the aromatic nitro-compounds. It is, however, not justifiable to conclude from this that the periodides present are the same, for the conditions which hold for the solutions in aromatic nitro-compounds, namely, small individual solubilities of iodine and potassium iodide, do not obtain in the last-mentioned solvents. The data in the last table can at the most be regarded as of an orientating character, for in order to compare satisfactorily the properties of these solvents with the nitro-compounds, a series of solubility determinations would be necessary in each case.

Some of the materials employed in this investigation have been purchased with the aid of a grant from the Research Fund of the Royal Society, and the author is much indebted to the Grants Committee for the assistance thus received.

THE YORKSHIRE COLLEGE,  
LEEDS.

# ANNUAL GENERAL MEETING,

MARCH 23RD, 1904.

Professor W. A. TILDEN, D.Sc., F.R.S., in the Chair.

THE PRESIDENT declared the ballot open for the election of Officers and Council for the ensuing year, Mr. G. BARGER and Dr. S. B. SCHRYVER being appointed Scrutators. He then presented the following Report on the state of the Society during the past twelve months :

## REPORT OF THE COUNCIL.

The Council are in the fortunate position of being able to report that the Society continues to increase and flourish. At the date of the Annual General Meeting last year, the number of Fellows was 2,631\* ; since that date, 170 Fellows have been elected and three reinstated, making a gross total of 2,804. Of these, 23 have been removed for non-payment of subscriptions, and the elections of 2 have become void, 28 have resigned, and 17 have died, leaving a net total of 2,734 Fellows on our list.

The names of the Fellows who have died are :

H. G. Adshead.	T. H. Dodd.	C. James.
J. O. Alexander.	T. W. Fletcher.	T. A. Lawson.
A. E. Barrows.	W. Francis.	J. Mactear.
Baron de Bush.	H. B. Fulton.	J. Reddrop.
Samuel Clift.	A. G. Hendry.	G. H. Robertson.
W. H. Corfield.	T. Isherwood.	

The following Fellows have withdrawn :

W. H. Barlow.	W. Grafton.	W. Round.
W. M. Brothers.	A. Hill.	W. J. C. Scrutton.
R. J. Brown.	T. Lemmey.	G. A. Shaw.
A. Collenette.	W. Lewins.	E. A. Smith.
W. Diamond.	H. Macan.	G. C. Thomson.
J. R. Don.	A. M. Martin.	A. L. Thornton.
D. Ferrier.	J. A. Mathews.	G. A. Waterhouse.
A. E. Garrod.	J. Morison.	W. J. Williams.
W. Goodall.	A. A. Ramsay.	A. W. Winterton.
	J. Robson.	

\* Last year this number was incorrectly stated to be 2,471 (*Proc.*, 1903, 19, 81 ; *TRANS.*, 1903, 83, 629).

As in future Reports the accounts and other statistics of the Society will be given for the calendar year, the following data for the year 1903 may be of interest for purposes of comparison. The number of Fellows on January 1st, 1903, was 2,607, and during the year 173 Fellows have been elected and 5 reinstated by the Council, making a gross total of 2,785. Of these, the Society has lost 16 by death, 46 from resignations, and 23 by removal for non-payment of subscriptions, giving the number of Fellows in the Society on December 31st, 1903, as 2,700.

The Society has to lament the death of a distinguished Foreign Fellow, Professor Wladimir Markownikoff, on February 11th, 1904.

The small number of Fellows still living, who were elected in the early days of the Society has been further reduced by the death of Dr. William Francis.

The scientific work of the Society during the past session gives evidence of continued activity. Since the last Annual General Meeting, 163 scientific communications have been made to the Society, 107 of which have already been published in the *Transactions*, and abstracts of all have appeared in the *Proceedings*.

During 1903, 181 scientific communications were made to the Society, 110 of which were published in the *Transactions* for that year, abstracts of all appearing in the *Proceedings* for 1903.

The volume of *Transactions* for 1903 contains 142 memoirs occupying 1,490 pages, whilst that for the preceding year contains 160 memoirs occupying 1,604 pages.

The *Journal* for 1903 contains also 3,882 abstracts which may be classified as follows:—

#### Part I.

	Pages.	No. of Abstracts.

In April last, Professor Emil Fischer was invited to give the Faraday Lecture in the autumn, and provisional arrangements were made for its delivery early in the present session. Much to the regret of the Council, continued ill-health has prevented Professor Fischer from fulfilling his intention, and for the present the hope of numbering him among the Faraday Lecturers has had to be abandoned. The Council are glad to be able to announce that Professor Ostwald will deliver the Faraday Lecture on Tuesday, April 19th, in the Lecture Theatre of the Royal Institution, kindly lent by the Managers for the occasion.

The Centenary of the Enunciation of the Atomic Theory by Dalton was celebrated by the Literary and Philosophical Society of Manchester in May last, and in company with Sir Henry Roscoe, Professor Thorpe, and Professor Frankland, Vice-Presidents, Dr. Scott, Secretary, and Sir William Ramsay, Foreign Secretary, the President attended the meeting, and presented an address in the name of the Chemical Society.

The triennial award of the Longstaff Medal to the Fellow of the Society who, in the opinion of the Council, has done the most to promote chemical science by research in the interval since the last presentation was made, on the recommendation of the Research Fund Committee, to Professor W. J. Pope, F.R.S., for his researches on the stereochemistry of compounds of elements other than carbon.

The Fifth International Congress of Applied Chemistry was held in Berlin in June last, and the President attended as the representative of the Society. An invitation to the Congress to hold its next meeting in London, given by the President of the Society of Chemical Industry, was supported by the President, but on a vote being taken Rome was chosen as the place of the meeting in 1905.

The Council welcomed the opportunity of sending a letter of congratulation to their distinguished Foreign Fellow, Professor Mendeléeff, on the occasion of his seventieth birthday, which occurred on February 9th last.

The increase in the use of the Library mentioned in last year's report has been maintained, as 975 books were borrowed from the Library, as against 925 during the previous year. The additions to the Library comprise 115 books, of which 49 were presented, 268 volumes of periodicals, and 48 pamphlets; as against 84 books, 338 volumes of periodicals, and 23 pamphlets last year. The corresponding numbers for the year ending December 31st, 1903, are 991 books borrowed, the additions to the Library being 126 books, of which 51 were presented, 271 volumes of periodicals, and 43 pamphlets.

The changes proposed in last year's report with regard to the Library have now been carried out, and cases have been erected in one

of the rooms in the basement for the storage of the less used books. These cases will accommodate about 3,500 volumes, and so provide room for the growth of the Library for about seven years. An equal number of cases can be added at any future period without cost beyond that of the cases themselves.

Mr. F. W. Clifford was appointed Librarian on July 1st.

The Council regret to have to record the death, on May 10th, of Mr. Josiah Hall, who for twenty-five years had been Collector to the Society, and who retired in 1895 with a pension of £130 a year. It was decided to grant to Mrs. Hall, his widow, an annuity of £30.

The Society has been the fortunate recipient of two handsome busts in bronze of distinguished chemists, that of Liebig (a copy of the one in Munich) having been presented by Dr. Messel, and that of Dalton, which has been modelled from all available sources by Miss Levick, by Professor Thorpe. Two interesting photographs of portraits have also been received, one of Roger Bacon, presented by Mr. Oscar Guttmann, and one of Dr. Wm. Prout, F.R.S., from his son, the Rev. T. J. Prout.

At an extraordinary General Meeting of the Society held on July 2nd, the proposal of the Council to alter Bye-Law I. so that the annual publications of the Society should not be sent to Fellows who are in arrear with their subscriptions was unanimously approved. To give effect to this change in the Bye-Law, the *Journal* is now issued to Fellows on the last day instead of the first day of the month. An extra number of the *Transactions* was issued on December 31st to provide for the publication of papers which would have appeared on January 1st, 1904, under the old arrangement, and now that the change has been made the net result is that Fellows receive the monthly parts of the *Journal* a day earlier than heretofore.

The first part (Authors' Index) of the Collective Index for the decade 1893—1902, promised provisionally for 1904, was issued in January to those Fellows who had made application for it in accordance with the printed notices circulated with the monthly parts of the *Journal* since last July, and it is hoped that the subject index for the same period may be ready before the end of next year. The rapid publication of the Author's Index is due to the untiring energy and devotion of the Indexer, Mrs. Dougal, and has in no way interfered with the issue of the Annual Index at the end of February, which has been customary since she undertook the work involved in its preparation.

The Second Report of the Joint International Committee on Atomic Weights, which now includes Professor Moissan as the representative of France, with its revised table of atomic weights, has been issued to Fellows both in the *Proceedings* and in the *Journal*.

The Council resolved that the rooms of the Society should be closed not later than 10.30 p.m. on those evenings on which meetings are held, and, as very few Fellows were found to use the Library on Saturday afternoon, it was further resolved that it should be closed at 2 p.m. on Saturdays from the beginning of the present year.

Grants amounting in all to £232 have been made during the year from the Research Fund, of which amount £15 has been returned.

The Council desires to record its deep sense of obligation to Dr. Horace T. Brown for the ability and patience with which he has discharged the duties of Treasurer during the past year. Finding on taking office that a complete reorganisation of the method of collecting the contributions of Fellows and of keeping the Accounts of the Society was immediately necessary, he did not shrink from the immense labour involved in establishing a new system and getting it into operation. The nature of the changes which have been made is explained below, and it is obvious that great sacrifices of time and of personal effort were involved in the process. It is, therefore, with the utmost regret that the Council has received from Dr. Brown an intimation that his engagements no longer permit him to retain office.

In March last it was found that certain subscriptions and admission fees of Fellows which had apparently been paid had not been entered in the Books of the Society. An examination of the Books was made by a firm of Chartered Accountants, and on April 22nd, the late Assistant Secretary, who at that time was acting as Librarian and Curator, was dismissed.

The Accountants subsequently reported that an investigation of the Society's Books, carried back to March, 1895, showed that there was an apparent deficiency amounting to £2306.

The late Assistant Secretary, whilst not admitting the accuracy of the amount of the deficiency, has, up to the present, repaid to the Society sums amounting to £250.

Hitherto, it has been customary for the Treasurer to close the Books of the Society a few days before the Annual General Meeting, and to make up the Accounts to a date as near to that of the Annual Meeting as possible. This arrangement has given rise to considerable inconvenience, owing in the first place to the short time allowed to complete the financial statements, and secondly to the impossibility of conforming strictly to that portion of Bye-Law VIII., which requires the Auditors to report to the Council at least one week before the Annual General Meeting. In future, therefore, the Treasurer will present his Accounts at the Annual Meeting made up to December 31st, instead of to some indeterminate day near the end of March, and these Accounts will be drawn up in a somewhat different form from that previously adopted. A statement of the financial

condition of the Society made up for the year ending December 31st last in this modified form accompanies this Report, including a Revenue and Expenditure Account and Balance Sheet, but the Treasurer has considered it advisable on this occasion to include for purposes of comparison another statement made out on exactly the old lines up to March 12th, and it is to this latter statement, which is comparable with the one of last year, that the following remarks apply.

The total income of the Society, from March 22nd, 1903, to March 12th, 1904, was £7276 16s. 5d., whilst the expenditure for the same period was £6060 17s. 4d., showing an excess of income over expenditure of £1215 19s. 1d., against a surplus last year of £817 7s. 1d. The comparison, however, is not a fair one, unless we adjust the figures in the respective years for the arrears of contributions in each case.

Owing to the alteration in July last of Bye-Law I., by which Fellows who are in arrear with their subscriptions do not receive the publications of the Society, the annual contributions, which become due in January, have been paid up more punctually this year than usual. On March 22nd, 1903, the arrears amounted to £2316, whilst on March 12th this year they were £2008, a difference in favour of this year of £308. When this adjustment is made, the surplus of this year becomes £907 19s. 1d. against £817 7s. 1d. last year, a result which may be regarded as highly satisfactory when we take into consideration certain large items of extraordinary expenditure which have been incurred this year, and which will be alluded to later.

The total amount received this year for Admission Fees, Life Compositions, and Subscriptions is £5809 against £4776 last year, a difference in favour of this year of £1033. This, however, includes £250 received on Account of Arrears of Subscriptions from the late Assistant Secretary, and, as already stated, the subscriptions this year are paid up more closely by £308. With these adjustments, the increased income this year from contributions of Fellows is £475, about half of which is due to the unusually large number of Life Composition Fees.

The sale of the Society's publications, and the proceeds of the advertisements in the Journal have brought in £40 9s. 4d. more than last year.

With regard to investments, the Treasurer has to report that since the last General Meeting he has, with the authority of the Council, purchased on behalf of the Society £1500 of Transvaal 3 per cent. Guaranteed Stock. The investments on the General Account now stand at £18,909 0s. 5d., whilst those of the Research Fund Account are valued at £6659 5s. 5d.

The total expenditure this year shows the large increase of

£665 19s. 4*d.*, which is due to certain large items of an exceptional nature.

The balance of the cost of the first volume of the Decennial Index, 1893—1902, amounting to £386 9s. 7*d.*, is chargeable against this year's revenue, being an increase of £254 5s. 3*d.* The completion of the Library Catalogue was announced in the Report of last year, but the main cost of £156 16s. 0*d.* has been borne by the present accounts. The additional accommodation for books referred to in an earlier part of this Report has been provided at a cost of £128 2s. 4*d.* Two other large items of expenditure of an exceptional nature amounting to £228 1s. 6*d.* are included under Accountants' and Legal charges, and are mainly attributable to the special investigation of the Society's Accounts to 1895, to which reference has already been made above.

It is satisfactory to notice that the expenses incidental to the publication of the Journal show a decrease this year of about £100.

The system of keeping the Treasurer's accounts has undergone revision during the past year, the old system having been found insufficient for the present needs of the Society.

At the request of the Council, Messrs. W. B. Keen and Co., Chartered Accountants, have opened up a new set of books, and have also undertaken to give the Treasurer a quarterly audit, and to assist in the preparation of the accounts for the Annual Statement.

This arrangement, which guarantees skilled professional assistance and a thorough checking of the accounts at frequent intervals, has now been in operation for some time, and will not entail any additional expense to the Society, as the appointment of a Treasurer's Assistant is thereby rendered unnecessary.

Arrangements have been made with Messrs. Coutts and Co., the Society's Bankers, by which in future they will receive the contributions of Fellows direct.

Kohn, Ph.D., B.Sc. ; A. Lapworth, D.Sc. ; J. E. Marsh, M.A. ; E. J. Mills, D.Sc., F.R.S. ; S. Ruhemann, M.A., Ph.D. ; J. M. Thomson, LL.D., F.R.S.

The proceedings then terminated.

## PRESIDENTIAL ADDRESS.

Delivered at the ANNUAL GENERAL MEETING, MARCH 23RD, 1904.

By WILLIAM AUGUSTUS TILDEN, D.Sc., F.R.S.

I CANNOT commence the Address which, in accordance with long-established custom, it is my privilege to offer on this occasion without expressing my most grateful thanks to the Society for the honour conferred in raising me to the office of President, and to my colleagues on the Council, and especially to the Secretaries, and to all the Fellows attending the ordinary meetings, for their unvarying kindness during my year of office.

The past year has been comparatively uneventful, but as a period of steady progress it may be regarded with satisfaction. Our numbers and income have increased, our Journal has been produced with unfailing punctuality, a fact which we owe to the care of our Editors, and its contents are fully equal in quality to those of any previous year. The Society has received several interesting gifts, enumerated in the Report of the Council, for which the thanks of the Society have been returned.

In May last, in company with several other officers of the Society, I attended the celebration in Manchester of the Centenary of the Enunciation of the Atomic Theory and presented an address to the Literary and Philosophical Society on behalf of the Chemical Society. On this occasion the Dalton Lecture was given by Professor F. W. Clarke, of Washington, and the meeting was attended by Professor van't Hoff, from Berlin.

In June, together with a considerable number of British chemists, I visited Berlin on the occasion of the Congress of Applied Chemistry, held in that city. Having been appointed by the Government to represent the Board of Education, and as the representative of the Chemical Society, I was elected a Vice-President of the Congress, and at the inaugural general meeting in the presence of H. R. H. Prince Friedrich Heinrich of Prussia, at the request of the English-speaking delegates, I gave a short address of congratulation. Later I seconded the resolution proposed by the President of the Society of Chemical Industry that the next Session of the Congress be held in London. That resolution was very warmly supported by many of the German members, although it was ultimately lost by a small majority in favour of Rome.

Happily death has been less busy among the more distinguished of our Fellows than has been the case for several years. We have to

mourn the loss of only one of our Foreign Members, Professor W. Markownikoff, of Moscow, who passed away on Feb. 11th, full of years and honours. The volume of Transactions for 1903 is distinguished from the volumes for many preceding years in containing no memorial lecture.

One of my predecessors in this Chair, in an address distinguished alike by intrinsic interest and charm of style, has given the history of the development of scientific chemistry in Great Britain from the beginning of the nineteenth century to the foundation of our Society. It is to be regretted that he did not find an opportunity for completing this survey of English chemistry by carrying the story on through the sixty years which have elapsed since that time. Although the history of the development of the Society has been embodied in the interesting contributions to the Jubilee volume which we owe to Professor Warington and Professor Armstrong respectively, it occurred to me that a review of the state of knowledge and of theory in chemistry during the early years of the Society and the influence of the Society on the progress of scientific chemistry in this country would be useful.

I confess that I often look back with mingled interest and curiosity to the time, now forty years ago, when Hofmann was President and Odling a very active Secretary.

The first meeting of the Society I ever attended was toward the end of 1862, in one of the small rooms on the ground floor of old Burlington House, and the first event I distinctly remember was the lecture by Berthelot on "Synthetic Methods in Organic Chemistry," which was given on June 4th, 1863. As a frequent attendant at the meetings of the Society since that distant day, I am in the position of a spectator who, during two-thirds of the life of the Society, has been a witness of the successive changes of language, of subjects, and of ideas involved in the various contributions to its proceedings.

The establishment of the Journal in 1841 could not fail to supply a stimulus to the prosecution of research, and the three volumes of "Memoirs of the Chemical Society" contain many papers of importance, including contributions from eminent foreign chemists. In the second annual report the Council state that "it is now sufficiently evident that ample materials exist in England for a Chemical Society." The second volume of Memoirs (1843-5) justifies this remark; at the same time the activity of the Giessen laboratory is made manifest in the contributions received from "Dr. August Wilhelm Hofmann, Assistant in the Giessen Laboratory," and from "Alexander W. Williamson, Esq." who acknowledges "the presence and counsel of Professor Liebig."

At the anniversary Meeting in 1847, however, the report of the

Council contains the following interesting passage: "Although an event not immediately connected with the Society, the Council has much pleasure in commemorating the late successful establishment in London of Chemical Laboratories expressly designed to further the prosecution of original research. The new laboratories of the College of Chemistry, and of the two older Colleges of the London University, now offer facilities for practical instruction and research not surpassed, we believe, in any foreign school. They already exhibit their efficiency and claim our grateful recognition in the persons of new and promising contributors to our Memoirs."

The anticipations here expressed were not to be disappointed, for in the succeeding years the pages of the Quarterly Journal then issued by the Society were constantly enriched with the results of researches chiefly from the College of Chemistry, including the famous work of Mansfield on Coal Tar (Oct., 1848), and the researches of Hofmann on the Volatile Organic Bases (April, 1848, *et seq.*). It is also interesting to those who remember our former able Editor, Henry Watts, to notice that the first contributions from the Birkbeck Laboratory, University College, were supplied by him.

During the early years of the existence of the Society the friendly co-operation of eminent foreign chemists is noticeable, and the names of Liebig, Redtenbacher, Bunsen, Fresenius, Schoenbein, Will, and Wöhler appear among the direct contributors to the pages of the Memoirs. With the increase in the number of members, a proportionate increase in the amount of research in pure chemistry does not appear to have been accomplished, and as time went on the number of papers directly contributed to the Journal was comparatively small. Taking a volume at random of the Quarterly Journal we find from the report of the Council a list of only eighteen papers read between March 30, 1855, and March 31, 1856. Seven discourses, however, were given in the same period.

In 1862 the quarterly issue was replaced by a monthly issue, and the number of papers rose to thirty-five, with three discourses. This activity was, however, not long maintained. The thin volumes of the new series contain a good many reprints from the *Philosophical Transactions* and the *Proceedings of the British Association* and other bodies, and not until some twenty years later was this number of papers approximately doubled, although the numerical strength of the Society had in the meantime risen from 360 (1862) to 1,034 (1880).

The number of communications to the Society is, however, not a full and true measure of the assistance which it affords to the progress of science. The opportunities for personal interchange of views among those Fellows who attend the meetings form one of the most

potent influences in helping the development of ideas, and the discussions, often more animated forty years ago than at present, did much at that time to crystallise the amorphous ideas floating in the minds of chemists. Unfortunately, the greater part of the discussions which were carried on at the meetings of the Society are irrecoverably lost.

An examination of the early volumes issued by the Chemical Society gives a clue to the problems which occupied attention in 1841 and onward.

The most notable contribution to Part I. of the Memoirs is a paper "On the Atomic Weight of Carbon," by Professors Redtenbacher of Prague, and Liebig of Giessen. The method used by these investigators did not lead to results of great accuracy, but their work reminds us of the enormous amount of skill and labour which was at this period absorbed in the endeavour to determine with precision the combining proportions of the chief elements. In 1842, Dumas published his work on the ratio of H to O in water, and about the same time Penny, Pelouze, and Marignac were working on the combining weight of chlorine. The labours of Berzelius in the same field were over, and those of Stas belong to a later time.

Part II. of the Memoirs is equally reminiscent, containing the paper "On the Radical of the Cacodyl Series of Compounds," by Professor Bunsen of Marburg. With reference to the discovery of cacodyl, the author elsewhere remarks (*B.A. Report*, July, 1841) that "the theory of compound radicals has received a confirmation scarcely to be gainsaid; for not only has the radical itself been insulated, but the whole cacodyl series has been formed from it directly."

The word "radical" has at different times received different applications, but at the time now referred to it had assumed a well-recognised connotation arising out of the discoveries of Liebig and Wöhler, then fresh in the minds of chemists. After the recognition of benzoyl in the bitter almond series, many investigations were directed toward the isolation of these quasi-elemental components of organic compounds, and one of the most famous of such attempts is embodied under the title, "The Isolation of the Organic Radicals," by E. Frankland, in the *Quarterly Journal of the Society* for 1850.

In 1841, Berzelius was still living, and his authority was predominant in respect to ideas of constitution, and it was not until many years later that the views expressed by Laurent and Gerhardt, the synthesis of organic bases by Wurtz and Hofmann, the discovery of the organo-metallic compounds by Frankland, the introduction of the water type by Williamson successively and conjointly shaped the course of chemical theory toward the ideas which have prevailed in the latter half of the Society's history.

The pages of the Journal from 1841 onwards give, however, little evidence of the process of change. One of the first references to the views of Laurent and Gerhardt is contained in a paper by Hofmann in the Quarterly Journal for July, 1850, in which the notion is brought forward that "the bodies described under the names of methyl and ethyl might with more probability be considered as homologues of marsh gas." The same view was discussed a few months later by Brodie, who proposed for the first time the constitution which we have now so long been accustomed to attribute to the molecule of hydrogen, and which is expressed by the formula  $H_2$ . The arguments used by Brodie were based on the views he had recently put forward, which involved the notion of polarity in the two assumed components of the elementary molecule. In a paper by Kolbe (1851) "On the Constitution and Nature of Organic Radicals," it is remarked that the principal support for the view extensively entertained that methyl, ethyl, butyl, amyl, and capryl in the isolated state possess double the atomic weight assigned to them, that therefore their composition should be expressed by the empirical formulæ  $C_4H_6$  (methyl), &c. . . is found in the circumstance to which attention was first called by Hofmann that the boiling points of butyl, amyl, and capryl differ from each other successively by  $40^\circ$ , on account of the difference in their composition of  $2C_2H_2$ , while if they were composed according to the formulæ  $C_8H_9$ ,  $C_{10}H_{11}$ ,  $C_{12}H_{13}$ , their boiling points would only differ successively by  $20^\circ$ ."

The same volume of the Quarterly Journal (1851) contains the famous paper by Williamson, "On Etherification," as well as a reprint of a characteristic paper from the same hand, "On the Constitution of Salts." The latter contains an exposition of the doctrine of types, an idea originally due to Dumas, but newly conceived by the author, in which his view is clearly distinguished from that of Gerhardt, whose types were never put forward except as synoptic formulæ for the purposes of classification. Williamson, however, declared his opinion that a name should be made to represent what we conceive a compound *to be*, and his formulæ were "used as an actual image of what we rationally suppose to be the arrangement of constituent atoms in a compound, as an orrery is an image of what we conclude to be the arrangement of our planetary system." It was, however, a good many years before views of this kind obtained general acceptance.

In 1852, Frankland announced the principle of "atomicity," and stated clearly for the first time that the combining capacity of each atom is definite and usually limited. About the same time, Gerhardt pointed out the necessity for choosing a unit for molecular magnitudes and for the construction of formulæ. For this purpose, he applied practically the generalisation put forth half a century earlier by

Avogadro, but up to this time neglected. How far the chemists of that day were from recognising all the consequences of assigning to the atoms of elements a definite capacity of combination is illustrated by the distinction maintained between marsh gas and methyl hydride, between methyl and ethyl hydride which were supposed, even by Frankland himself, to be isomeric and not identical, a distinction only partly cleared away in 1862—1863 by Schorlemmer (*Journ. Chem. Soc.*, 15, 419, 16, N.S. 1, 216, 425).

The years 1853—1854 were distinguished by the activity with which the views of Gerhardt and of Williamson were discussed, while the transition from binary formulæ to the unitary system and to ideas of constitution was slowly proceeding.

The *QUARTERLY JOURNAL* for 1855 contains a paper by "William Odling, M.B., F.C.S., Lecturer on Natural Philosophy and Demonstrator of Chemistry at Guy's Hospital" on the constitution of acids and salts, in which the dashes to which we have been so long accustomed were introduced for the first time to indicate the different substitution values of simple and compound "atoms." Further on in the same volume is to be found Dr. Kolbe's "Critical Observations on Williamson's Theory of Water, Ethers, and Acids," and the masterly and crushing rejoinder thereto by Williamson.

Other indications of the fermentation in chemical theory proceeding at this period are afforded by the subjects of the discourses delivered before the Society, of which two very notable examples occur in the volume for 1859. The first is on "The Atomic Weights of Oxygen and Water," by Odling, then one of the Secretaries; the second "On Ammonia and its Derivatives," by Hofmann.

From the former, one or two short extracts may be usefully taken to show what questions still remained unsettled, but the whole paper deserves to be read, by teachers especially, at the present day, affording as it does a perfect model of masterly reasoning and dexterous marshalling of facts. "Whether an atom of water contains the same quantity or double the quantity of hydrogen that is contained in an atom of hydrochloric acid, and whether the atomic weight of oxygen is 8 or 16, are concrete examples of the many disputed questions which lie at the very basis of scientific chemistry . . . . Apart from the absolute accuracy or falsity of any explanation, it is evidently most inconsequent to interpret, as many chemists do, a certain set of facts in one special manner and a precisely similar set of facts in an opposite manner . . . . The majority of English chemists represent the atomic weight of carbon by 6, that of oxygen by 8, and that of sulphur by 16. Dr. Frankland would double the atomic weight of carbon, but would retain the old atomic weights of oxygen and sulphur. Mr. Griffin, who lays claim to priority in doubling the

atomic weights of carbon and oxygen, ridicules the notion of doubling that of sulphur. Dr. Williamson, Mr. Brodie, and myself have for a long time past advocated the doubling of all three."

Hofmann's discourse is interesting as showing the fascination which the doctrine of types exercised over certain minds, arising doubtless from the facilities it afforded for bringing into order the rapidly increasing number of new substances which continued to pour forth from the laboratory. But of course its indiscriminate application led to many erroneous ideas.

How slowly new views are assimilated in such a branch of science as chemistry, influenced as it has so long been by the sort of formulæ which successively happened to be fashionable, is shown by the fact that the idea of limited valency put forward by Frankland in 1852 required further exposition in 1860, when he gave to the Chemical Society a discourse on "Organo-Metallic Bodies" (Quarterly Journal, 13, 177). The idea of polyatomic (multivalent) radicles had been introduced long before, in 1851, by Williamson in the paper already quoted (Quarterly Journal, 4, 350), but notwithstanding the accumulation of facts, the application of the idea was far from being generally adopted till much later. I distinctly remember the inconvenience to students during the period of transition, and when, in 1861, I attended some of Hofmann's lectures, the change of  $O=8$  to  $O=16$  and  $C=6$  to  $C=12$ , together with the transformation of  $KOCO_2$  into  $K_2CO_3$  occurred in the middle of the course, much to the dismay of beginners like myself.

The new volume of the monthly Journal for 1862 contains a beautiful discourse by Wurtz, "On Oxide of Ethylene considered as a Link between Organic and Mineral Chemistry," in which comparing with oxide of ethylene, the oxides of barium, and other metals, he urged the duplication of the atomic weights of these elements. He concludes with these words: "I shall think myself happy if I have succeeded in impressing more firmly on the minds of my auditors this truth, which everybody is ready to enunciate but which few have undertaken to establish by strict demonstration, namely, that *there is but one chemistry, and that the laws which regulate the constitution of organic bodies apply with equal force to the compounds of mineral chemistry and mineralogy.*"

At this period in the history of the Society a considerable stimulus to activity seems to have been derived from the International Exhibition of 1862, and no doubt the presence of many foreign chemists in London contributed to that familiar interchange of views which is so conducive to the removal of misunderstandings in regard to theoretical questions. As if suggestive of the operation known as turning over a new leaf, the Journal was renumbered, and 1863 saw the

issue of the first volume of a new series. The talk was, however, still in the language of types. There was only a little more disputation as to the meaning of type formulæ, and as the types of Gerhardt and Williamson and Kekulé were found to be insufficient, condensed types and mixed types were employed. Playfair's peroxide type, on which he lectured to the Society in 1863, came too late to have any effect whatever, and never reappeared. The system of types was doomed.

Much of the discussion of the time remained barren so long as there was no agreement as to atomic weights. Notwithstanding that Kekulé and Couper, in 1858, had already shown the tetradic character of the atom of carbon, and had used formulæ in which the atoms are linked together in the same way as in modern constitutional formulæ, it was not until 1865 that a definite exposition of the doctrine of valency or atomicity in its application to the determination of the structure of molecules appeared in the *Journal* (Crum Brown, "On the Theory of Isomeric Compounds," [ii], 3, 230).

In the next volume (1866), the paper by Frankland, entitled, "Contributions to the Notation of Organic and Inorganic Compounds," shows that the time had arrived for the general adoption of the new doctrines. In the course of this paper, the author states that he has used the new notation throughout his course of lectures at the Royal College of Chemistry in the preceding autumn, although something of the same kind had been used by Frankland and Duppa two years previously.

There can be no doubt that this paper produced a great impression, at any rate in England, and the new notation was very freely discussed at the meetings of the Society and elsewhere. But, as showing how slowly the notions involved in type formulæ were modified, a paper by Griess on his diazo-compounds in the next volume of the *Journal* (1867) has a footnote in which he refers to the alternative representation of amino-compounds like phenylamine to the ammonia type and to the same type as the nitro-compounds from which they are derived. Further on in the same volume is the well-known paper by Dr. Perkin on the basicity of tartaric acid, which ends with a long array of formulæ written in conformity with the water type.

The recognition of valency and atomic linking as the basis of a system of constitutional formulæ could not, however, have been accomplished without the co-operation of many contributory investigations and conventions.

A scheme of atomic weights founded on some generally applicable principle was, before all things, necessary, and up to the time referred to no principle had been generally accepted. Cannizzaro, in 1858, had drawn attention to the application of the law of Dulong and Petit, and the law of Avogadro had been utilised, by Gerhardt especially, as the

basis of his system of formulæ. There is, however, no record in our Journal of these important proposals, and the Fellows of the Chemical Society were indebted at this period for the clarification of their ideas more to the writings and oral expositions of their then Junior Secretary, Odling, than to any other source of enlightenment.

The next great step in advance, the formulation of the theory of asymmetric carbon and the foundation of stereochemistry is represented in our Journal by two abstracts, to be found in the volume for 1875, the one entitled "Structural Formulæ," by J. H. van't Hoff, the other, "Relations between the Formulæ of Organic Bodies and the Rotatory Power of their Solutions," by J. A. Le Bel. I need not enter into the course of events which ultimately led to the complete triumph of the theory, but I recall with satisfaction the award of the Longstaff Medal last year to our colleague, Professor Pope, for a series of researches, in which he has successfully applied the fundamental ideas of stereochemistry to elements other than carbon, and has thus completed the justification of the hypothesis which we owe to the genius of Le Bel and van't Hoff.

I referred at the outset to the labours of those who, sixty years ago, were occupied in rectifying equivalents. In those days, the values assigned to many of the elements were grossly inaccurate. The work, however, still goes on, although in this our day the refinements of manipulation and the resources of our wider knowledge have reduced the errors to small dimensions. Save with regard to some of the rarer metals, it would appear that the practical limits have already been reached, if we may judge by the fact that the International Committee on Atomic Weights has during the past year found it necessary to suggest only two small corrections in the table of numbers.

The reduction of a mere list of equivalents to a harmonious system of atomic weights was not accomplished without a protracted struggle, the details of which are sufficiently well known to render unnecessary any attempt to repeat the history of it here. It can never fail to be a subject of regret, however, that the paper by J. A. R. Newlands, on "The Numerical Relations between the Atomic Weights of the Elements," read to the Society on March 1, 1866, was not printed in the Journal. In that paper Newlands clearly expressed for the first time the principle of periodicity which has since been developed and established by others.

Another event of the highest interest which immediately led to discoveries of great importance was the introduction of the spectroscope as an instrument of research. Animated by the success which had already in 1861 attended its use, every chemist of that time was more or less occupied in scrutinising all kinds of mineral matters, often with the

aid of a home-made instrument. No paper nor any formal discourse directed to an exposition of the subject, however, appeared in the Journal until the publication in that year of a translation of the Memoir by Kirchhoff and Bunsen. One of the earliest fruits of the new method was the discovery of thallium, which, observed in 1861, exhibited in the metallic state in 1862, was described for the first time in our Journal in 1864.

The settlement of molecular weights on a common foundation was another matter in which many difficulties were at first encountered. Even for those with the most definite leaning towards the doctrines of Avogadro, "anomalous" vapour densities provided a serious stumbling-block for a few years before and after 1860. It is to be regretted that no trace is to be found in the Journal of any paper or discourse relating to the general question, the difficulties of which everyone at that time recognised. A discourse was delivered by Deville in May, 1862, on Vapour Densities, but it is unreported in the Journal of the Society, and the brief notice in the *Chemical News* affords no clear idea of its scope. The same remark applies to Professor Dewar's lecture on Dissociation, given in 1874, of which no trace remains.

So large an amount of investigation carried on during recent years has been devoted to the study of the conditions which govern the rate and extent of chemical changes, that it is a source of gratification to recall the fact that one of our early volumes contains a discourse which will always rank as a classic in chemical literature, I mean Mr. Harcourt's account of his researches on the "Course of Chemical Change" (Journ. Chem. Soc., 1867, N.S. 5, 460). But even in this case it will be noticed that the first account of the work was communicated to the Royal Society, and appears in the *Philosophical Transactions* for 1866.

In 1871, at the instigation of Williamson, a very important change was introduced into the Journal by the publication of abstracts of papers appearing in foreign and other journals. This was not merely a revival of the practice, abandoned many years before, of printing abstracts of a few papers, culled rather at random from other periodicals, but a systematic attempt to present the whole of the results of world-wide research in the field of chemistry.

The Journal up to this time had been a sort of magazine containing the few original communications made directly to the Society, together with reprints from all kinds of sources. The *Philosophical Transactions* and the *Proceedings of the Royal Society* especially furnished important contributions, both as to quality and quantity. This was inevitable, so long as leaders like Hofmann, Frankland, Brodie, and others preferred to commit the results of their researches to the pages of journals of more assured position and long-established fame.

But it may also be accounted for partly by the paucity of systematic chemical research in the United Kingdom.

Frankland, in his Presidential Address in 1872, drew attention forcibly to this lack of progress. The decline in the number of papers offered to the Society having reached such a point that in the previous year only twenty-two papers had been presented seemed to justify the remonstrances of the President.

Whether Frankland was right in attributing this lethargic condition of the English chemical world wholly to the attitude of the Universities and the conditions under which degrees were granted, cannot now be discussed, but the severe remarks of another President, Dr. Perkin, in 1884, show that he was not alone in this opinion.

The question as to whether the Chemical Society provided the best medium of publication for the results of chemical research did not escape notice, and the remarks of Professor Odling, in the Presidential Address of 1875, seem to show that up to that time, at any rate, it seemed to be an accepted proposition that the Chemical Society could not expect to receive papers of the highest class representing the results of extended and laborious investigations by the most eminent workers, but must be content with discharging the useful, if somewhat humbler, function of publishing papers of more limited interest or more special character. It is otherwise now. For five and twenty years our Society has received direct communications from the most prominent and active workers, and with few exceptions the most important chemical memoirs have appeared in the Transactions, so that the Journal of the Chemical Society may now claim to be regarded as the organ of British chemistry.

Even at the present time, however, the number of papers, although large (163 from March, 1903, to March, 1904), is to the number of Fellows (2,734 in March, 1904) in about the same proportion as it has been for the last five and twenty years, namely, 1 to nearly 17.

During the sixty-two years of the life of the Society we have seen the discovery of new elements and the introduction of many new methods of experiment. Atomic and molecular weights have been distinguished, defined, and reduced to a common scale, the numerical relations among the atomic weights have been brought into a system in which the correlation of atomic mass and properties of the elements is clearly displayed. We have learnt that atoms exhibit definite and limited capacities of combination, and that certain phenomena are best explained by the assumption that atoms group themselves in definite geometrical order in space. The relation of physical properties to the constitution of compounds is now fully recognised, and to some extent traced out, while some steps have been taken toward clearer conceptions of the mechanism of chemical change. As one of the conse-

quences of the liquefaction of air and the other so-called "permanent" gases, the influence of low temperatures on the physical properties of many substances, and on the rate of chemical action, is much better understood.

What is to be the next step in advance? The subject which has occupied attention more than any other during the last two years is, of course, the phenomena presented by radioactive substances. For an account of the extraordinary properties of the substance known as radium, I cannot do better than refer to the thesis of Madame Curie, published in October and November last (*Ann. Chim. Phys.*, 1903, [vii], 30, 99—203, 289—326), which will always have great historical interest. But with regard to the hypotheses suggested by some physicists in connection with this subject, the only safe course is to reserve judgment until *the facts* have become better known. Chemists can hardly look without emotion on a scheme of the universe in which the atoms which have so long been the foundation of systematic chemistry are represented as undergoing spontaneous disintegration, although that process is supposed to be compensated by a reintegration which may result in a new order of things.

It is not possible in a breath to summarise the present state of knowledge and so to indicate the probable direction of future advance. I hope this will be done more completely and effectively by means to which I shall refer presently.

But it is interesting to compare the conditions under which scientific work is done nowadays with those which prevailed at the inauguration of this Society and for at least a quarter of a century later.

In 1841, there were practically no laboratories for instruction in this country. The teaching of chemistry was done wholly by lecture. In the University of Cambridge, the Professor of Chemistry was a country clergyman who usually visited the University once a year for a few weeks to deliver his course. The University of Oxford had a Professor of Chemistry who was also Professor of Botany. Graham was at University College, London, working actively but alone. There was neither Government Grant in those days nor Research Fund to give assistance.

At the present time, we may say even proudly that the chemical work done in this country is equal in quality and not greatly inferior in quantity to that of any other country, and that the number of universities, colleges, polytechnics, and schools is steadily increasing in which, not only is research carried on, but participation in this work is one of the avenues to degrees, scholarships, and other rewards which are open to the aspiring student. The endowment of research is always a difficult question, but the assistance afforded by our own Research Fund has undoubtedly been a means of facilitating systematic investigation by the chemists of this country. It is an object which

may fairly be commended to the notice of those who combine the possession of this world's goods with an interest in physical science. The fund is still small, and the amount distributed is annually less than the demand made upon it, chiefly for the cost of material.

In whatever direction we look, it is evident that each worker necessarily becomes more and more of a specialist with less time and power to follow the course of progress along lines other than those in which he is particularly occupied. This isolation of workers is, however, not good for anyone, and the question how each can most readily obtain information as to what is taking place in other divisions of his science is very important. In the early days of the Society some assistance was afforded by the lectures which were given rather frequently on subjects of general interest, and it was evidently considered that one of the functions of the Society was to provide this kind of instruction for its members. Special lectures have been much less frequent of late years and the only sources of general information, and that from the nature of the case, belonging chiefly to a bygone time, have been the Memorial Lectures in honour of eminent foreign Fellows deceased. I do not forget the addresses given by successive Presidents on the occasion of the Anniversary Meeting, but for a variety of reasons these have so often been directed towards other matters that it is evident the Presidential Address cannot be depended on for a review of progress or a summary of the existing state of chemical science. It is true that the Abstracts published monthly may be regarded as furnishing a tolerably complete *résumé* of chemical literature, but as each one usually deals with a detached portion of a research which is still in progress, the specialist cannot without great labour gather what he requires from any division of the subject not immediately his own. I venture therefore to make a suggestion.

It has been a growing custom with the British Association, for example, to publish reports on the present state of our knowledge in regard to selected subjects prepared by scientific men specially conversant with them. And I am encouraged by the expressions of approval in reference to such custom contained in the Address of my predecessor last year to suggest that the preparation of such reports is a matter to which the Chemical Society might advantageously give attention. Our abstracts are classified under seven heads, namely, organic, general and physical, inorganic, mineralogical, physiological, agricultural, and analytical chemistry. A report of progress during the year in each of these divisions of our science would, I believe, be very acceptable to the busy chemist, and would serve in an important degree to guide the historian of science. I propose to lay a scheme before the Council, and I hope it may be found practicable to carry this proposal into effect.

---

## FARADAY LECTURE.

(Delivered before the Fellows of the Chemical Society in the Theatre of the Royal Institution on Tuesday, April 19th, 1904.)

*Elements and Compounds.*

By WILHELM OSTWALD.

I have the honour of speaking to an audience of many men whom I have long venerated as my intellectual, although not my personal, teachers, and whom I admire as leaders in our common work for science. But however admirable the *present*, I am still more impressed by the thought of the *past* associated with this place. When, not long ago, I was engaged in electrochemical investigations and almost daily sought for information and enlightenment in Faraday's Researches, I did not dare to think in my boldest dreams that one day I should find myself standing on the very spot in which he was wont to give the first accounts of the innumerable results of his indefatigable labours, his indomitable zeal, and his inexorable love of truth.

All that the pupil can do in such a case is to imbue himself as completely as he can with the ideas of the master and to try to perform his modest work in the master's spirit. But here arises a new difficulty: what subject ought I to choose? When I look into my own humble efforts, I find everywhere traces of Faraday. So far as relates to electrochemistry, the thing is plain; I think there is no word that I have oftener spoken or written than the word "ion," that word which was uttered for the first time in its modern sense in this very spot. But in other fields in which I have also worked, I feel the influence of his skilful hands and his keen vision. Catalysis, which I have studied during the past ten years, likewise came under his hands; and in the parts of the subject he worked at, the charm of secrecy and inexplicableness has been exchanged for the better qualities of a problem capable of resolution by earnest workers. And in one subject which has engrossed a very great part of my scientific activity, in the question of energy, I find the venerated master again a leader. He was indeed the first scientific man to direct all his investigations in view of the idea of the conservation and the mutual transformation of the various forces, as he called them, or the various kinds of energy, as we call them now.

This is a side of Faraday's mind, to which perhaps not so much attention has been paid as it deserves. Although doubtless the greatest advance—the discovery of the quantitative proportionality

between the energy which disappears and that which originates—was due to Mayer and Joule at a later date, yet the practical perception of this relation was working in Faraday's mind long before. There is indeed a great difference between the intellectual development of a scientific truth to a degree sufficient for the discoverer's *own* work, and to the degree required for its successful transfer to the minds of *other* workers. Faraday contented himself in this case, as well as in others (for example, in his conception of lines of force), with the first step. But that he had reached this step and stood firmly on it, that he used this conception constantly and regularly in his work, is evident from his constant reference to it from the first year of his scientific work onwards. From a closer study of his lectures and papers we learn that in every case he put the question: how can I change a given force into another? This continued to the very end of his work; for the last experiments he made related to the direct conversion of gravity into electricity, and although he did not succeed in his attempt, he was nevertheless convinced of the possibility of the conversion.

Guided by these considerations, I directed my attention to the very earliest problems treated by the master. Even before Faraday held the Chair of Chemistry here in the Royal Institution, as a youth of twenty-five years of age he practised the art of a lecturer in a small club, the City Philosophical Society, and the first course which he delivered there was on chemistry. In the sixteenth lecture, after a description of the metals, he concluded with the following general remarks:

“To decompose the metals, then, to reform them, to change them from one to another, and to realise the once absurd notion of transmutation, are the problems now given to the chemist for solution. Let none start at the difficult task and think the means far beyond him; everything may be gained by energy and perseverance.” And after a description of how in the course of history the means necessary for the isolation of the metals from their combinations have grown ever more and more efficacious, he mentioned the recent great discoveries of his master Davy as follows:

“Lastly, glance but at the new, the extraordinary powers which the chemist of our own nation put in action so successfully for the reduction of the alkalies and the earths, and you will no longer doubt that powers still more progressive and advanced may exist and put at some favourable moment the bases of the metals in our hands.”

When I try to follow this hint and take for the object of our consideration the question of the nature of the elements and of their compounds, I am aware that I am not the first who has done so in this place. If I am not mistaken, the very first chemist who had the honour of addressing you as a Faraday lecturer, Jean-Bap-

tiste Dumas, lectured 35 years ago on the same subject. Nevertheless, I do not shrink from the repetition. Every generation of chemists must form its own views regarding this fundamental problem of our science. The progress of science shows itself in the way in which this is done. Faraday was at this time fully influenced by Humphry Davy's brilliant discoveries, and sought for the solution of the problem in Davy's way. For Dumas, the most important achievement of the science of his day was the systematising of organic chemistry, condensed into the concept of *homologous series*. He therefore regarded the elements as comparable with the hydrocarbon radicles, and tried to arrange them in similar series with constant differences in the numerical values of their atomic weights. It is well known that these ideas finally developed into the great generalisation we owe to Newlands, Lothar Meyer, and Mendeléeff. Although the problem of the decomposition of the elements was not solved in this way, these ideas proved to be most efficient factors in the general development of science.

From what store of ideas will a modern chemist derive the new materials for a new answer to the old question? A physicist will have a ready answer: he will construct the elements in a *mechanical* way, or, if he is of the most modern type, he will use *electricity* as timber. The chemist will look on these structures with due respect indeed, but with some reserve. Long experience has convinced chemists (or at least some of them) that every hypothesis taken from another science ultimately proves insufficient. They are adapted to express certain sides of his, the chemist's, facts, but on other not less important sides they fail, and the end is inadequacy. Learning by this experience, he makes a rule to use only chemical material for this work, and according to this rule I propose to proceed.

Hence, like Dumas, I put the question: what are the most important achievements of the chemistry of our day? I do not hesitate to answer: *chemical dynamics* or the theory of the progress of chemical reactions and the theory of chemical equilibrium. What answer can chemical dynamics give to the old question about the nature of the chemical elements?

The answer to this question sounds most remarkable; and to impress you with the importance I ascribe to this investigation, I will mention the result at once: *It is possible, to deduce from the principles of chemical dynamics all the stoichiometrical laws; the law of constant proportions, the law of multiple proportions and the law of combining weights.* You all know that up to the present time it has only been possible to deduce these laws by help of the atomic hypothesis. Chemical dynamics has, therefore, made the atomic hypothesis

unnecessary for this purpose and has put the theory of the stoichiometrical laws on more secure ground than that furnished by a mere hypothesis.

I am quite aware that in making this assertion I am stepping on somewhat volcanic ground. I may be permitted to guess that among this audience there are only very few who would not at once answer, that they are quite satisfied with the atoms as they are, and that they do not in the least want to change them for any other conception. Moreover, I know that this very country is the birthplace of the atomic hypothesis in its modern form, and that only a short time ago the celebration of the centenary of the atomic hypothesis has reminded you of the enormous advance which science has made in this field during the last hundred years. Therefore I have to make a great claim on your unbiassed scientific receptivity. But still I do not hesitate one moment to lay the results of my work before you. For I feel quite sure that I shall find this receptivity unrestricted; and, moreover, I shall reap another advantage. For I also feel assured that you will offer me the severest criticism which I shall be able to find anywhere. If my ideas should prove worthless, they will be put on the shelf here more quickly than anywhere else, before they can do harm. If, on the contrary, they should contain anything sound, they will be freed here in the most efficacious way from their inexact and inconsistent components, so as to take the shape fittest for lasting use in science. And now let us go into the matter.

The first concept we start from is *equilibrium*. In its original meaning, this word expresses the state of a balance when two loads are of the *same weight*. Later, the conception was transferred to forces of all kinds, and designates the state when the forces neutralise one another in such a way that *no motion* occurs. As the result of the so-called 'chemical forces does not show itself as a motion, the use of the word has to be extended still further to mean that *no variation* occurs in the properties of the system. In its most general sense, *equilibrium denotes a state independent of time*.

For the existence of such a state it is above all necessary that temperature and pressure shall remain constant; in consequence of this, volume and entropy remain constant too. Now it is a most general experimental law, that the possibility of such a state, independent of time, is dependent on the *homogeneity* of the system. In non-homogeneous bodies, as, for instance, in a solution of different concentrations in different places, or in a gaseous mixture of different composition in different places, equilibrium cannot exist, and the system will change spontaneously into a homogeneous state. We can therefore limit our consideration to this state, and we shall consider

only bodies or systems of bodies in equilibrium, and, consequently, homogeneous.

Perhaps the possibility of the existence of water in contact with water-vapour might be considered contradictory to this statement, because we have here two different states and no homogeneity. Here we meet with the new concept created by Willard Gibbs, namely, that of a *phase*.

Systems of this kind are formed of homogeneous bodies indeed, but of more than one. The water in our system is homogeneous in itself, and the vapour too, and equilibrium cannot exist until both are homogeneous. But there is a possibility that a finite number of different homogeneous bodies can exist together without disturbing one another. In such a system we must have the same temperature and the same pressure everywhere, but the specific volume and the specific entropy may change from one body to the other.

We call a *phase* every part of the system where these specific properties exhibit the same value. It is not necessary that a phase should be connected to one body only ; it may be distributed over any number of parts. In this way the millions of globules of butter in milk form only *one* phase, and the watery solution of casein and milk-sugar forms a second phase : milk is a two-phase system.

*Every system consisting of only one phase has two degrees of freedom.* This law involves only the assumption that the sole forms of energy involved in the system are heat and volume-energy ; we exclude from consideration any effects due to gravitation, electricity, surface-tension, &c. This law is connected with the famous phase rule of Willard Gibbs, but is not identical with it, for it contains no mention at all of the so-called components of the system. Indeed, the law is valid in the same way for any pure chemical element, for example, oxygen, or for any mixture, for example, a glass of whisky and water. If you allow to the latter only one phase, it is impossible to change it in more than two ways, namely, in pressure and temperature.

The existence of such a body in the shape of only one phase is generally limited. If the pressure be lowered at constant temperature, a liquid or a solid will change at last into a gas. Lowering of temperature will change a gas into a liquid and a liquid into a solid. For every one-phase system it is possible to determine a "sphere of existence." This sphere is not necessarily limited on all sides ; for gases we do not expect a limit on the side of low pressures and high temperatures, nor for solids on the side of high pressures and low temperatures. But on certain sides every phase has its limits, and most of these limits are experimentally accessible.

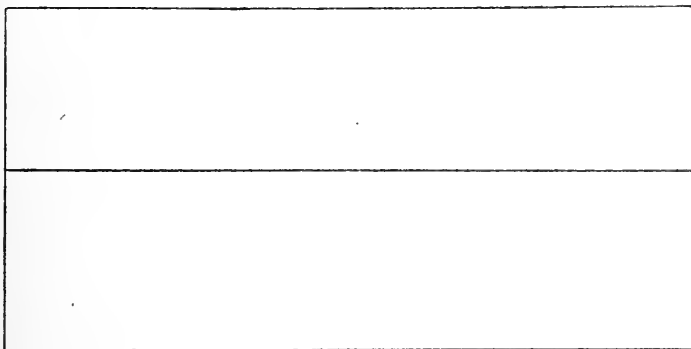

What will happen if we exceed the limit of existence of a phase?

The answer is most simple: *a new phase will be formed*. The spheres of existence of the different phases therefore limit one another, and the boundary-lines represent the interdependent values of temperature and pressure for the possibility of the co-existence of both phases.

By granting the co-existence of two phases we lose therefore one degree of freedom. At the same time a new variation has arisen from the ratio between the masses of the two phases. For we must not suppose that this ratio is without influence on the state; indeed we find here two radically different cases.

The most general case is, that during the transformation of one phase into another the properties of both are continually changing, and the state of every phase is therefore dependent on the ratio of the two masses. By evaporating sea-water at constant temperature the

FIG. 1.

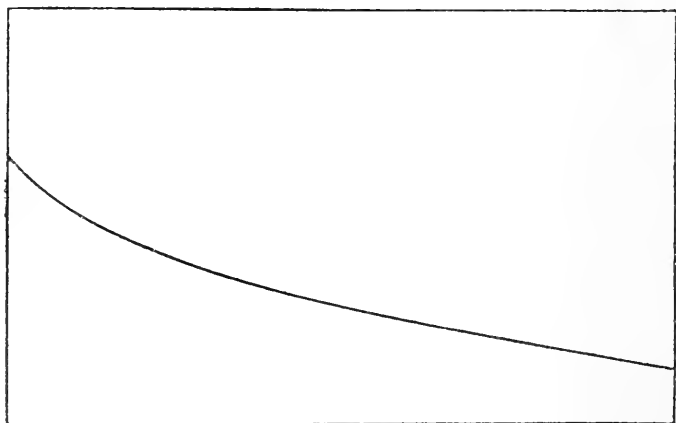

density of the residue grows continually higher, while the pressure, and therefore the density, of the vapour goes on decreasing. If, however, we evaporate distilled water, we do not find any change in the properties of the residue and of the vapour during the whole transmutation.

Bodies of the first description we will call *solutions*, and of the second, *hylotropic bodies*. You will be inclined to call the latter substances or chemical individuals, and indeed both concepts are most nearly related. However, the concept of a hylotropic body is somewhat broader than that of a substance. But the possibility of being changed from one phase into another without variation of the properties of the residue and of the new phase is indeed the most characteristic property of a substance or chemical individual, and all our methods of testing the purity of a substance or of preparing a pure one can be reduced to this one property; any one may readily convince him-

self of this by investigating any such method in the light of this description.

If we represent these cases by means of rectangular co-ordinates, taking as abscissæ the part of the first phase converted into the second, and as ordinates pressure or temperature, we get Fig. 1 (p. 6) for hylotropic bodies; they are represented by a horizontal straight line. With a solution we get a continuous line too, but not horizontal and generally not straight. If the ordinates are pressures at constant temperature, and the change is from liquid into vapour, the line will slope downwards as Fig. 2 shows. At other temperatures the lines will be of similar shape, only lying higher at higher temperatures and *vice versa*. With other changes we obtain similar lines, sloping upwards or downwards as the case may be. For simplicity's sake we

FIG. 2.

will consider in the future only vaporisation; this case gives the greatest possible variety, and we are sure not to omit anything by such a limitation.

What is the general process of change in a solution while it is being vaporised? The answer is quite distinct: *the residue is always less volatile* than the original solution, and *the distillate more volatile*. If there were an example of a solution behaving in the contrary way, then the process of vaporisation at constant temperature would be an explosive one. For the vapour begins to form at a given pressure; if by this the vapour-pressure of the residue were lowered, the vaporisation would continue of itself at a continually accelerated rate until all the liquid would be vaporised at once. It would be, in other words, a *labile* equilibrium. These equilibria are, however, only mathematical fictions, and have no experimental existence. If, on

the contrary, the residue has a lower vapour-pressure, then the process is self-limiting, and shows the characteristics of a *stable* equilibrium. With hylotropic bodies we have an *indifferent* equilibrium, because the state is independent of the progress of the transmutation.

This being granted, we can ask: if we continue the separation of a solution into a less and a more volatile part by repeated distillation, what will finally become of it? Generally considered, two cases may happen. First the residue may become less and less, and the distillate more and more volatile, and there is no end to the progress. This case we may exclude from experimental evidence of a most general character, for we may take it as a general law that it is impossible to enhance any property beyond all limits, even by the unlimited application of our methods. We must conclude, therefore, that we shall ultimately meet with a *limit of volatility on both sides*, that finally we shall have separated our solution into a least and a most volatile part, and that both parts will not change further by repeated distillation. This is a most interesting result, for it means that *every solution can be resolved into components, which are hylotropic bodies*. For simplicity's sake we have considered only the case that two hylotropic components are generated by the process of separation; generally more than two may be formed, but in every case only a limited number of such components is possible. We may formulate therefore as a general law:

*It is possible in every case, to separate solutions into a finite number of hylotropic bodies.*

From the components, we can compose the solution again with its former properties. This is also a general experimental law; if exceptions seem to exist, it is only because the case is not one of true equilibrium. Still we may limit our consideration to those cases where the law holds good. Then we have a relation between the properties of any solution, and the nature and relative quantity of its hylotropic components, which admits of only one interpretation. Every solution of distinct properties has also a distinct composition and *vice versa*.

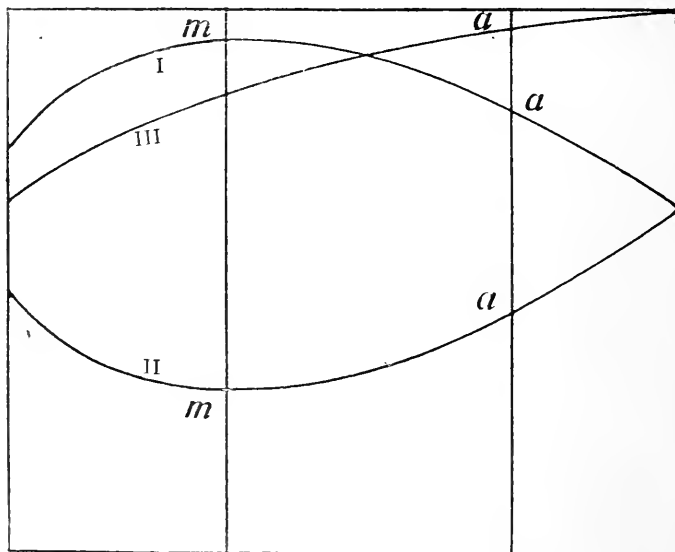

If we consider for simplicity's sake solutions of only *two* components, we may represent any property as depending upon the composition in a rectangular co-ordinate system, the abscissæ giving the composition and the ordinates the value of the property considered. In this way, we get a continuous line of a shape dependent on the particular case chosen.

If we consider the boiling points of all solutions formed by two hylotropic components, the most simple forms of curves (indeed the only experimental ones known) are given by the types I, II, and III, Fig. 3. For any solution, for example, the solution with the abscissa *a*, we can foretell its variation on distillation by the slope of the curve. For as

the residue must be less volatile, the residue will change to the ascending side of the curve. This is for I and III to the right, for II to the left side of the diagram. The change of the *distillate* is the opposite.

If we try to apply this criterion to the points *m* of the curve II and III, where there is a maximum and a minimum of the boiling point, we arrive at no decisive answer, for if the boiling point is already the highest possible it cannot rise, and if it is the lowest possible, it cannot fall. We are forced therefore to conclude that the boiling

FIG. 3.

point cannot change at all, that is, that this special solution must behave as a hylotropic body.

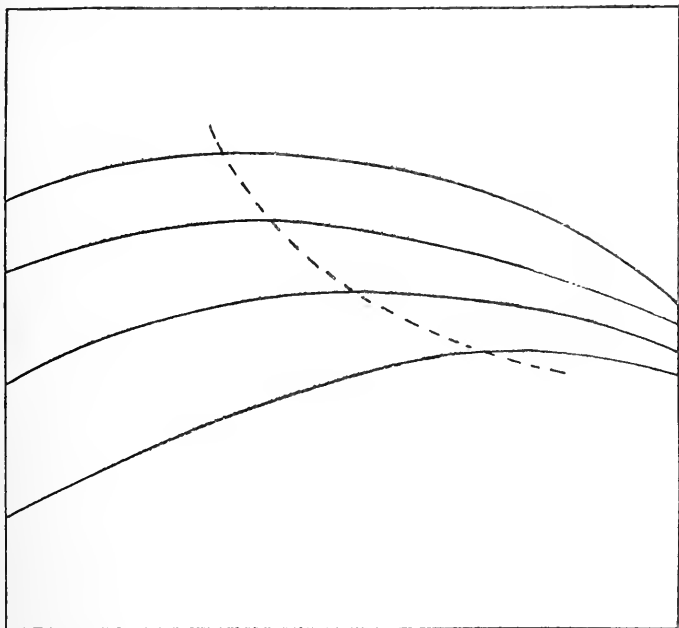

This is a well-known theorem of Gibbs and Konovaloff, to wit, that a maximum or a minimum, generally spoken of as a *distinguishing point* in the boiling-curve, is necessarily connected with the property of distilling without change in the composition of the solution. A similar law holds good for the transitions from liquid to solid and from solid to gas.

Now this looks like a contradiction; while a few minutes ago we placed solutions in a class exclusive of hylotropic bodies, we have here solutions, that is, mixtures, which behave like hylotropic substances. But the contradiction vanishes if we consider a series of boiling-point curves corresponding with various pressures. We then find that the composition at the distinguishing point does not remain constant under different pressures, but shifts to one side, with alteration of pressure. This fundamental fact was discovered and experimentally

developed in an admirable way by Sir Henry Roscoe, and has since proved itself a most important criterion in recognising a chemical individual.

By drawing curves corresponding with various pressures, we get therefore generally the diagram shown in Fig. 4, the loci of the distinguishing points forming one curve. Between the infinite possibilities of the shape of this curve we have a distinguishing case again, the case that the curve is a *vertical straight line*. This means that the composition

FIG. 4.

is independent of the pressure. When this is the case, we call this *hylotropic body a substance or a chemical individual*.

Therefore we conclude that a connection exists between solutions and chemical compounds or substances ; the latter being a distinguishing case of the former. On the other hand, we get an exact definition : *a substance or a chemical individual is a body, which can form hylotropic phases within a finite range of temperature and pressure*.

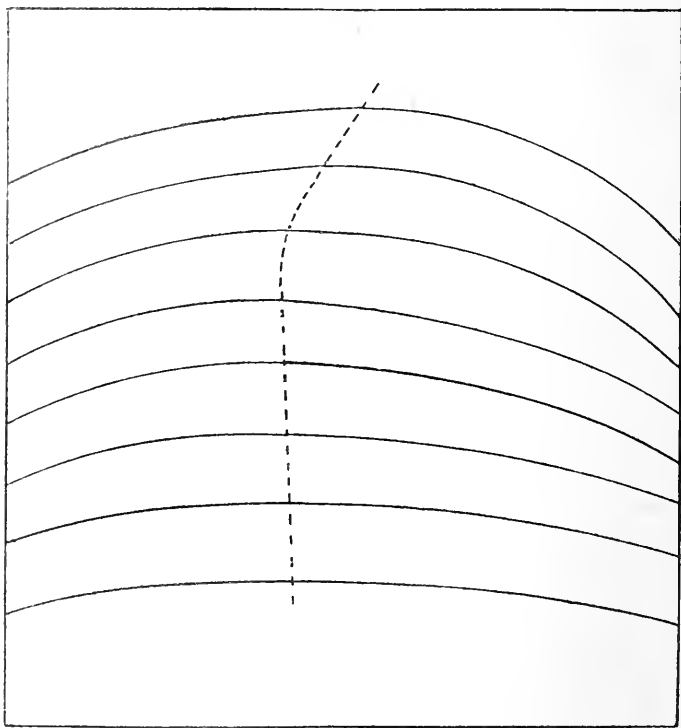

Such substances can often be produced from other substances in the same way as a solution is, namely, by putting them together. If that can be done, we may infer from our definition that there exists a definite ratio between the components, independent of temperature and pressure between certain limits.

Now, *this is essentially the law of definite proportions*, the first of the stoichiometrical laws. We have deduced, therefore, the law of constant proportions from the concept of the chemical individual.

As you have seen, this deduction is extremely simple; the constancy of composition is a natural consequence of the mode of preparation and purification of chemical substances.

If we exceed the limits of temperature and pressure, where the

FIG. 5.

body behaves as a hylotropic one, it assumes the properties of a solution, that is, its distinguishing point begins shifting in composition when the temperature is changed. Then it becomes possible to separate the body into its components, and we call this state the state of dissociation of the substance in question. In our graphic representation, the hitherto straight vertical line of distinguishing points turns sideways, Fig. 5.

Most substances behave in this way, but there are substances which have never been transformed into solutions or whose sphere of existence covers all accessible states of temperature and pressure. Such

substances we call elements. In other words, *elements are substances which never form other than hylotropic phases.*

From this we may conclude that every body is finally transformable into elements, and into only *one definite set of elements.* For the most general case is a solution. Every solution can be separated into a finite number of hylotropic components, and these again can generally be transferred into a state when they behave like solutions and can be separated further. Finally, the components remain hylotropic through the whole range of temperature and pressure, that is, they are elements.

From the fact that the relation between a compound substance and its elements admits of only one qualitative and quantitative interpretation, we derive the conclusion that the resolution of any substance into its elements must always lead to the same elements in the same proportion. Here we find the source of the law of the *conservation of the elements.* This law is not generally expressed as a special stoichiometrical law, because we tacitly infer it from the atomic hypothesis. But it is truly an empirical law, and we see that it is not only a consequence of the atomic hypothesis, but also a consequence of the experimental definition of an element and of our methods of obtaining elements.

Here I should like to pause for a moment for the purpose of quoting a couple of historical facts. Up to the present moment, the question whether it is possible to deduce the stoichiometrical laws without the help of the atomic hypothesis has only been raised by other investigators in order to deny the possibility. So far as I am aware, there exists only one man who has worked upon the question with the earnest hope of obtaining an affirmative answer. Very few know his name. The man is Franz Wald ; he is chief chemist at the iron works in Kladno, Bohemia. His papers on the subject are to be found in the *Zeitschrift für physikalische Chemie* and in the *Annalen der Naturphilosophie.*

In the foregoing considerations, Franz Wald has played a great part. To him I owe first the idea that the definition of substances and elements is in a certain sense arbitrary, although very helpful and convenient. This definition is a condensed expression of our methods of separating and purifying these bodies. While, generally speaking, every solution has the same claim to be investigated as these bodies, the latter soon distinguish themselves as standards to which all other cases may be referred. To Franz Wald I owe further the idea that the conception of a *phase* is a far more general one than that of a substance, and that the deduction of the idea of a substance, and, further, the deduction of the laws governing the nature of substances, must start from the conception of the phase. I do not know whether

Wald will agree with the way I have made use of his ideas, but I feel it imperatively necessary to express my deep respect for, and my thankful obligation to, this solitary philosopher, who has prosecuted his work during a long series of years almost wholly without encouragement or sympathy from others.

Now there are still two stoichiometrical laws to be deduced, namely, the law of multiple proportions and the law of combining weights. I prefer to invert the order, and first to deduce the second law. It expresses the fact that it is possible to ascribe to each element a certain relative weight in such a way that every combination between the elements can be expressed by these weights or their multiples.

We suppose three elements, A, B, and C, given, which may form binary combinations, AB, BC, and AC, and besides these a ternary combination, ABC; there shall be but one combination of every kind. Now we begin by forming the combination AB; for this purpose, we must take a certain invariable ratio between the weights of A and B, according to the already proved law of constant proportions. Now we combine AB with C and get the ternary compound, ABC. There will be a certain ratio, too, between AB and C, and we can, if we put A as unity, assign to B and C certain numbers describing their combining weights relatively to A.

Now we begin to combine A with C forming AC, and then we form the ternary combination, ACB from AC and B. According to our law of a relation between elements and compounds, which can be interpreted only in one way, ACB cannot be different from ABC, and, in particular, it must show the same ratio between the relative weights of its elements. Therefore, the ratio of the weights of A and C in forming the combination AC cannot be other than that expressed by the relative combining weights already found in the first way. In other words, it is possible to compute the composition of the hitherto unknown combination AC, from analyses of the combinations AB and ABC. In the same way, we can compute the composition of the unknown combination BC, by the help of the numbers obtained by the analyses of two other combinations of the same elements. To resume: the combining weights relatively to A regulate all other possible compounds between the elements concerned. But this is nothing else than the general stoichiometrical law of combining weights for we can extend our considerations without difficulty to any number of elements.

Lastly, it is easy to deduce the law of multiple proportions from the law of combining weights. If no compounds can be formed except according to their combining weights, then, if there are two different compounds between A and B, we can form the one containing more of B either directly from A and B, or indirectly, combining first A and B

to form the lower compound and then combining this with more of B. In applying the law of combining weights, we conceive that the weight of B in the higher compound must be twice its weight in the lower. The same consideration may be repeated, and finally we get the result, that instead of double the combining weight, *any multiple* of it may occur in combinations, but no other ratio.

If we cast a backward glance on the mental operations we have performed in the last two deductions, we recognise the method, the application of which has made the two laws of energetics so fruitful. In the same manner as the difference between the whole and the available energy is independent of the nature of the path between the same limiting points, the product of the chemical action between a number of given elements is independent of the way in which they are combined. If we compare two different ways, we get an equation between the characteristics of the two ways, and this is equivalent to a new law. In our case, this new law is the law of combining weights.

I will put the same idea into somewhat different words. By stating the equation between any two ways, we can get any number of different equations, each representing a new way as an experimental fact. Now, in order that all these equations shall be consistent, there must be some general law regulating the characteristics of the equations. For the consistency of the several equations in the case under discussion, the existence of specific combining weights, independent of the several combinations, is the necessary condition.

This is the main point of the considerations I wish to lay before you this evening. There are some secondary questions as to isomerides or allotropic states of substances, and there are other similar questions, but it would lead us too far to consider them one by one. I have investigated them on the same basis, and I can assure you that I have nowhere found an insurmountable difficulty or an impassable contradiction. All these facts find their proper place in the frame of the same general ideas.

Let me still add some words about the *nature of the elements*, as considered from my point of view. I wish to lay great stress on the fact that here, too, I find myself on the same ground as that on which Faraday has built his general concepts during his whole scientific career. There is only one difference, due to the development of science. Faraday ever held up the idea that we know matter only by its forces, and that if we take the forces away, there will remain no inert carrier, but really nothing at all. As Faraday still clung to the atomic hypothesis, he was forced to express this idea by the conception that the atoms are only mathematical points whence the forces emerge, or where the directions of the several forces intersect; here his view coincided with that of Boscovich.

In the language of modern science I express these ideas by stating: *what we call matter is only a complex of energies which we find together in the same place.* We are still perfectly free, if we like, to suppose either that the energy fills the space homogeneously, or in a periodic or grained way; the latter assumption would be a substitute for the atomic hypothesis. The decision between these possibilities is a purely experimental question. Evidently there exist a great number of facts—and I count the chemical facts among them—which can be completely described by a homogeneous or non-periodic distribution of energy in space. Whether there exist facts which cannot be described without the periodic assumption, I dare not decide for want of knowledge; only I am bound to say that I know of none.

Taking this general point of view, in what light do we regard the question of the elements? We will find the answer, if we remember that the only difference between elements and compounds consists in the supposed impossibility of proving the so-called elements to be compounds. We are therefore led to ask for the general energetic properties underlying the concept of a chemical individual, whether element or compound.

The answer is most simple. The reason why it is possible to isolate a substance from a solution is that the available energy of the substance *is a minimum*, compared with that of all adjacent bodies. I will not develop this thesis at length, for it is a well-known theorem in energetics or thermodynamics. I will only recall the fact that a minimum of vapour-pressure is always accompanied by a minimum of available energy; and we have already seen that a minimum of vapour-pressure or a maximum of boiling-point is the characteristic of a hylotropic body or chemical individual.

This granted, we proceed to the question regarding the differences between the several substances. Expressed in the most general way, we find these differences connected with differences in their *specific energy content*. Temperature and pressure are not specific, for we can change them at will. Specific volume and specific entropy, on the contrary, are not changeable at will; every substance has its own values of these. We may take therefore these values as the characteristics of the different substances. How many of such characteristics exist I cannot tell. Only for simplicity's sake I will assume that two of them are sufficient. As I will take care not to deduce any conclusions from this number, we shall not be led into error by accepting it.

We place these two characteristics in a system of planar co-ordinates; then the several elements will be represented by single points in the plane. We lay the plane horizontally and raise from these points ordinates, representing the available energy of each element. Between the points of the elements in the plane are situated the

points of all possible solutions, filling up the whole plane. Each of these solutions will also have its available energy, and all the corresponding points in space will form a continuous surface. The form of this surface can be described in a general way. For as each *element* has its point in a *relative minimum*, the surface as a whole will have a shape like the ceiling of a cavern full of hanging stalactites, the end of each stalactite representing an element.

How can we pass from one element to another? Evidently not otherwise than by going over the higher parts of the surface, or the passes separating each stalactite from its neighbours. This can only be done by accumulating an appropriate amount of available energy in the element to be changed. Now the concentration of energy is a task we cannot accomplish *ad libitum*, for the possibility very soon ends. Think, for example, of compressing a gas into a given space. Up to some ten thousand atmospheres the work of compression will go on smoothly, but after that every metal begins to flow like a liquid and you cannot proceed further. With the concentration of electric or any other energy the task is similar and so we come to the conclusion that the concentration of energy can be pushed to only a very limited extent. The application of this result to our question about elements is simple enough: we cannot get over the pass between two stalactites because we cannot attain the necessary concentration of energy.

From the history of science we learn that these considerations contain at least some truth, for the isolation of the elements has ever been dependent upon the power of concentrating energy available at that time. The most brilliant example is the application of the voltaic pile to the isolation of the alkali metals by Humphry Davy.

Still I must confess that these last considerations are in a very embryonic state, and I should not have brought them before you if an unexpected application had not lately made itself manifest. Some years ago I explained these views to my old friend Sir William Ramsay, when he asked me how the idea of elements fitted into my conceptions of energy. Then I forgot all about it until Sir William reminded me of it, saying that his perplexing discovery of the transmutation of radium into helium might conceivably find some explanation in this way. This I am convinced of, and the considerations may be pictured in the following manner.

In the corner of our cavern where the elements with the highest combining weight are assembled, the stalactites are very short; and at last they are not really stalactites, but rather regions of different slope in the sloping ceiling. In our cavern, a drop of water furnishes generally a picture of the stability of the elements. While hanging at the end of a true stalactite, more or less work must be done

to raise the drop over the pass until it flows down another stalactite. But in this corner it will flow of its own accord, and only delay for a short time on the nearly horizontal portions in the ceiling.

Such elements will have only a *temporary existence*. Now we are sure that for the transmutation of one element into another, enormous amounts of energy would be required, for the concentrations of energy as yet available have proved themselves insufficient for this purpose. We may expect, therefore, that enormous amounts of energy will be liberated if such an unstable element changes into a stable one. This accounts for the extraordinary quantity of energy developed by radium during its existence. The fact that radium changes into helium, an element with an exceptionally long stalactite (for it is impossible to get even any combination of helium) makes us expect indeed such an unusually great development of energy as is found to occur.\*

The heat from radium is surely only the last form of the energy developed in its transformation. There are a great many intermediate forms, termed rays or radiations, which have been studied by a band of eminent workers, whose ingenuity and ability have been displayed in the most brilliant way during these investigations. Perhaps I may venture the suggestion that first, other intermediate temporary elements are formed and that the energy liberated at this transmutation appears first in the shape of *new*, still imperfectly known forms. It is most likely that such forms are originated during the decay of the enormously concentrated energy of radium; at the same time it is probable that we have not yet the means of fixing these forms and so preventing their changing into other, more common forms. We should remember that, for example, the conservation of electric energy at a pressure of some thousand volts during some months or years is by no means an easy thing, and I have great doubt if it is possible at all.

But here I must conclude, for I have ventured to intrude on a field where I have not secured my own right of entry by personal work. I see among my audience men who are possessed of an incomparably more minute and comprehensive knowledge of these new realms of science than I. I must ask you, therefore, to take these suggestions in the same spirit as that in which Faraday took his own speculations. They are questions put to nature. If she says Yes, then we may follow the same path a little further. If she says No—well, then we must try another path.

\* Compare Soddy, "The Wilde Lecture," *Mem. and Proc. Manchester Lit. and Phil. Soc.*, 1904. I am very glad to find that I am in close agreement (except in so far as there is a difference in his accepting the atomistic, while I hold by the energetic point of view) with this most zealous worker; indeed, the above statements were written and printed before I saw Mr. Soddy's lecture.

### LII.—*Mercuric Nitrite and its Decomposition by Heat.*

By PRAFULLA CHANDRA RÂY, D.Sc. (Edin.).

It has been shown (Trans., 1897, 71, 340) that when mercurous nitrite is treated with water, it undergoes the following dissociation,  $\text{Hg}_2(\text{NO}_2)_2 = \text{Hg} + \text{Hg}(\text{NO}_2)_2$ , but only to the extent of about 78 per cent., the rest going into solution along with the mercuric nitrite to form a mercurioso-mercuric nitrite having the formula

When the mercurous mercury is removed from solution by sodium chloride, a sodium mercuric nitrite is formed, from which dimercur ammonium nitrite has been obtained (Trans., 1902, 81, 644). But all attempts to isolate mercuric nitrite itself in the solid state have hitherto been unsuccessful.

Lang tried to prepare mercuric nitrite by means of the double decomposition occurring between mercuric chloride and silver nitrite, but obtained, on evaporating, a basic salt to which he assigned the improbable formula  $3\text{HgO}, \text{N}_2\text{O}_3, \text{H}_2\text{O}$  (*Kongl. Svenska Vet. Akad. Handl.*, 1860; *J. pr. Ch.*, 1862, 86, 295). A repetition of Lang's experiment, with certain modifications, has now not only yielded the normal salt,  $\text{Hg}(\text{NO}_2)_2$ , but has also shown that the cause of Lang's failure was the interesting decomposition which mercuric nitrite undergoes when gently heated.

Silver nitrite being very sparingly soluble in the cold, and heat acting prejudicially on a solution of mercuric nitrite, the following method was found, after repeated trials, to be the best for preparing mercuric nitrite.

Silver nitrite, purified by recrystallisation, and pure mercuric chloride are weighed out in molecular proportions and rubbed together in a mortar to a fine paste with water, a little more water being gradually added with continued stirring. The mass is then washed into a stoppered bottle and violently agitated. It is well known that silver nitrate does not remove the whole of the chlorine from a solution of mercuric chloride; silver nitrite behaves in a like manner, and, therefore, the solution thus prepared contains unavoidably a very little silver nitrite, but not enough to be troublesome.

The pale yellow solution of mercuric nitrite, thus obtained, cannot be evaporated on a water-bath without the salt decomposing to a considerable extent, but on concentrating the solution *in vacuo* over sulphuric acid, the salt crystallises in tufts of fine needles. The salt thus obtained is contaminated only with traces of silver nitrite. By

the analysis of two distinct preparations, its composition was found to conform with the formula  $\text{Hg}(\text{NO}_2)_2$ .

	Found.		Calculated.
Mercury .....	67.81	69.13	68.49 per cent.
Nitrogen .....	9.35	9.46	9.59 ,,

Mercuric nitrite has a light yellow colour ; it dissolves only partially even in boiling water, the larger proportion decomposing into mercuric oxide and nitrous acid. When kept exposed in the air, it slowly liquefies, and gives off nitrous fumes. When treated with a solution of caustic alkali, the solid salt yields mercuric oxide, whilst the whole of its nitrogen is obtained in solution as nitrite. This is proved by the fact that the nitrogen in the filtrate, when estimated by the Crum-Frankland method, is the same in amount as when measured by the "urea" process. Mercuric nitrite is not stable in presence of air, even when preserved in a stoppered bottle inside a desiccator ; it slowly evolves nitrous fumes, and if the stopper is loosened so as to allow the fumes to pass out and be absorbed by the sulphuric acid, the salt is transformed, in course of time, into a white powder of basic mercuric nitrate. In this respect, mercuric nitrite affords a striking contrast with mercurous nitrite, since the latter keeps well for years in a dry atmosphere. When exposed in a vacuum over sulphuric acid, before it has begun to change, the salt shows, however, no tendency to decompose if left undisturbed, but decomposition, when once begun, cannot be arrested.

If the original solution of mercuric nitrite is kept for some time in a stoppered bottle which is opened from time to time, the salt undergoes, but only to a very limited extent, much the same change as that presently described, which happens to it when heated in the solid state. Thus, a solution of sp. gr. 1.065 in the course of three weeks gave the proportion of mercuric to mercurous mercury as 13.7 : 1. If, however, the solution is preserved in a tube which has been exhausted of air and then sealed up, the salt remains absolutely undecomposed.

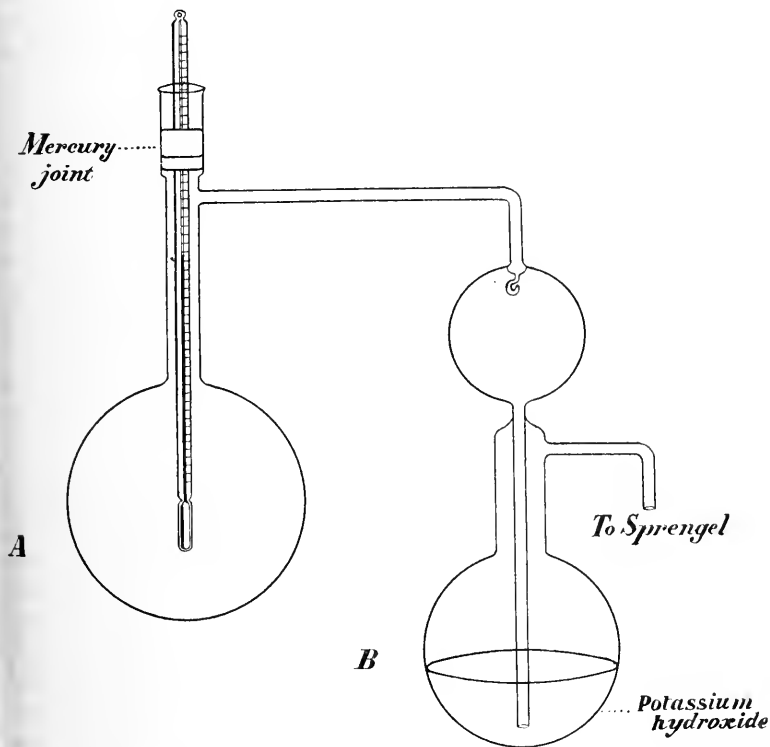

In its original solution, mercuric nitrite does not give any precipitate of oxymercuric sulphate with sodium sulphate, a fact which points to the "nitronic" constitution of the salt.

*Decomposition by Heat.*—A solution of mercuric nitrite, when evaporated on the water-bath, decomposes in two ways. The residue near the edge of the deposit consists almost wholly of crystalline, red mercuric oxide, whilst that in the middle of the deposit is a mixture of mercurous nitrate and undecomposed mercuric nitrite, with only traces of the oxide. It is probably this mixture which Lang took to be the basic nitrite he describes. For purposes of comparison, a solution of mercuric nitrate was similarly evaporated to dryness on the water-

bath ; this time the residue consisted of colourless crystals of mercuric nitrate interspersed with yellow streaks, indicating the partial formation of a basic salt. It will thus be seen that mercuric nitrite behaves in quite a different manner from the nitrate.

In order to study this decomposition more carefully, the following method and apparatus were devised.

The bulb, *A* (see fig.), contained from 5 to 10 c.c. of the solution of mercuric nitrite, whilst a dilute solution of potassium hydroxide was

placed in the bulb, *B*. The use of this alkali was necessary in order to protect the mercury in the pump from the action of the mixed gases, but it also served as a means of ascertaining whether any nitric oxide was being evolved other than that liberated by the decomposition of the nitrous anhydride produced. After the apparatus had been exhausted, the bulb, *A*, was gently heated, taking care that the temperature did not rise above  $60^{\circ}$ . Until the evaporation of the liquid was completed, very little gas was given off, in fact not more than 0.5 c.c. But the solid salt began to decompose rapidly, giving off

gas which was almost entirely absorbed by ferrous sulphate solution. The residue was found to consist of a mixture of mercurous nitrate and mercuric nitrite with only a small proportion of mercuric oxide, and no mercury whatever in the free state.

A similar result was obtained when solid mercuric nitrite was put into the apparatus and heated by keeping the bulb *A* immersed in water, the temperature of which was gradually raised to the boiling point. When the temperature had risen to 95°, the salt fused and intumescenced; then nitric oxide was for some time regularly evolved, but ultimately the gas in the bulb became reddish-brown. The gas, which was treated and collected as before, was found to be almost entirely soluble in ferrous sulphate solution, whilst the solid residue consisted mainly of mercurous nitrate. The ratio of the nitrogen as nitrate to that as nitrite was as 4.33 : 1.

It will thus be seen that when the solid salt is heated it decomposes chiefly into mercurous nitrate and nitric oxide, thus:  $2\text{Hg}(\text{NO}_2)_2 = 2\text{HgNO}_3 + 2\text{NO}$ , only a small quantity decomposing into mercuric oxide and nitrous anhydride.

It might be supposed, firstly, that mercuric nitrite in the solid state really decomposes at first into mercurous nitrite and nitric peroxide, thus:  $2\text{Hg}(\text{NO}_2)_2 = \text{Hg}_2(\text{NO}_2)_2 + 2\text{NO}_2$ , just as auric chloride breaks up into aurous chloride and chlorine; secondly, that the mercurous nitrite thus formed decomposes into free mercury and nitric peroxide; and, lastly, that these, by their interaction, give rise to the mercurous nitrate and nitric oxide actually obtained (Trans., 1903, 83, 491).

In order to settle this point satisfactorily, the earlier experiment with mercurous nitrite (*loc. cit.*) was repeated in the new apparatus. At 100° there was no appreciable amount of gas evolved. It was only when the bulb was directly heated by the flame and the temperature exceeded 200° that the decomposition took place. In this case the resulting mercurous nitrate was deposited in thin needles, interspersed with minute globules of mercury, on the bulb and stem of the thermometer, whilst, when the reaction is carried on in a short horizontal tube, the crystals of mercurous nitrate shoot forth from the upper side of the tube. In this case, as formerly pointed out, a portion of the vapour of the mercury acting on the nitrous fumes gives rise to mercurous nitrate, the remainder being deposited in globules. Heat thus acts on mercurous and mercuric nitrites in entirely different ways, the mercurous nitrate being produced as a pseudo-sublimate in the case of the former salt, whereas it is produced in the mass of the decomposing salt in the case of the latter compound.

The present investigation shows that when a solution of mercuric nitrite, obtained by double decomposition between mercuric chloride

and silver nitrite, is concentrated *in vacuo* over sulphuric acid, it yields the normal salt, mercuric nitrite; and that when this salt is heated at 100°, it breaks up in two ways as indicated by the equations,

### LIII.—*The Reduction of 2:6-Dinitrotoluene with Hydrogen Sulphide.*

By JULIUS BEREND COHEN and JOSEPH MARSHALL.

IN the course of an experiment in which 2:6-dinitrotoluene was reduced with hydrogen sulphide in alcoholic ammonia, a quantity of 6-nitro-2-amino-*m*-cresol was obtained together with 6-nitro-*o*-toluidine, these substances being separated in the following manner. The product, after reduction, was boiled with dilute hydrochloric acid and separated by filtration from sulphur. On adding ammonia in excess to the filtrate in order to precipitate the nitro-*o*-toluidine, a deep violet solution was obtained. The filtrate from the base was carefully neutralised, when a brown, crystalline precipitate was deposited, which was crystallised from alcohol. The new substance crystallises in dark, orange-coloured needles, which dissolve readily in dilute acids and alkalis and melt with decomposition at about 190°; it is completely precipitated by carbon dioxide from its solution in alkalis. With the mineral acids it forms well-crystallised, colourless salts; the hydrochloride crystallises in flat prisms with pointed ends, the sulphate, in fine needles, and the nitrate in clusters of acicular crystals. The compound is evidently an aminophenol and the analysis indicates a nitroamino-cresol.

0.1468 gave 22 c.c. moist nitrogen at 25° and 735 mm.  $N = 16.73$ .

$\text{C}_7\text{H}_8\text{O}_3\text{N}_2$  requires  $N = 16.56$  per cent.

In order to determine the relative positions of the amino- and hydroxyl-groups, the compound was dissolved in dilute sulphuric acid and oxidised with an excess of lead peroxide at a temperature of about 60°. The orange-coloured liquid was extracted with ether, and on removing the solvent a mass of dark red crystals remained which had the characteristic odour of quinone. On crystallisation from a mix-

ture of ether and light petroleum, the substance was deposited in the form of brilliant, ruby-red prisms which melted at 64—65°.

0.1801 gave 13.2 c.c. moist nitrogen at 17.5° and 747.5 mm.  $N = 8.54$ .

$C_7H_5O_4N$  requires  $N = 8.49$  per cent.

When sulphur dioxide is passed through the quinone suspended in water, it dissolves to a yellow solution from which ether extracts the corresponding quinol; on removing the solvent the quinol is deposited in the form of bright scarlet needles which may be crystallised from ether and light petroleum and melt at 117—118°.

The solution of the quinol in caustic soda has a deep violet colour which disappears on saturating with carbon dioxide, the quinol being regenerated. When the nitroaminocresol is dissolved in dilute hydrochloric acid and a solution of bleaching powder gradually added, a light brown precipitate is formed, which separates from a mixture of ether and light petroleum in clusters of pale yellow, spear-shaped crystals melting at 70—71°. The compound is a chloronitrotoluquinone,  $CH_3 \cdot C_6HO_2Cl \cdot NO_2$ .

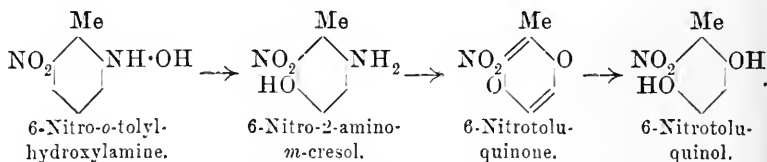

0.1352 gave 0.096 AgCl.  $Cl = 17.67$ .

$C_7H_4O_4NCl$  requires  $Cl = 17.61$  per cent.

The formation of nitroaminocresol from 2:6-dinitrotoluene is readily explained. Cohen and Dakin have shown (*Trans.*, 1902, 81, 26) that *s*-trinitrobenzene and 2:4:6-trinitrotoluene are readily reduced by hydrogen sulphide in faintly alkaline solution and yield the corresponding dinitrohydroxylamine compounds.

If the reduction of the 2:6-dinitrotoluene is not complete, 6-nitro-*o*-tolylhydroxylamine is formed and is converted by the boiling hydrochloric acid used in the extraction, into nitroaminocresol in the same way that phenylhydroxylamine yields *p*-aminophenol (Bamberger, *Ber.*, 1894, 27, 1349).

The series of changes which have been described may be represented by the following formulæ:

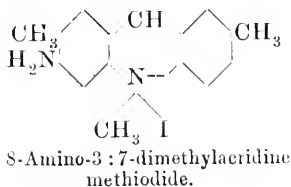

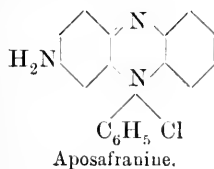

We propose to continue the investigation of the above compounds and to extend the study of the action of hydrogen sulphide to other nitro-compounds.

# LIV.—*Studies in the Acridine Series. Part I.*

By JOHN JACOB FOX and JOHN THEODORE HEWITT.

THIS paper is the first instalment of a series of communications describing the results of an examination of various acridine and azine compounds, which has been undertaken with the view of elucidating the constitution of the anhydrous bases obtained from quaternary ammonium compounds in which the quinquevalent nitrogen atom is a member of a ring attached to a benzene or naphthalene residue, this nucleus containing a substituent amino- or hydroxy-group in the meta- and para-positions relatively to the basic nitrogen atom and the remaining member of the heterocyclic ring respectively. The following substances have this configuration :

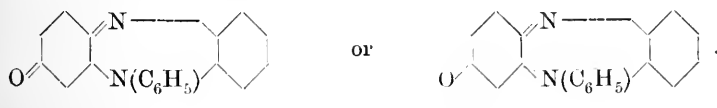

To the base obtained from the former salt the two following formulæ have been assigned,

the latter being remarkable in that a linking is supposed to occur between the substituent groups in the meta-position, whilst the ammonium nitrogen atom is represented as remaining quinquevalent after the removal of acid.

Corresponding with these formulæ for free aposafranin, aposafranone must be formulated either as

The question as to whether the ortho- or the para-quinonoid formula was the more correct aroused considerable discussion some six or seven

\* We have adopted the numbering given in Richter's *Lexikon*, whereas Ullmann describes the compound as 6-amino-2:7-dimethylacridine methiodide.

years ago, the para-quinonoid structure being defended by O. Fischer and E. Hepp (*Ber.*, 1895, 28, 2283, and 29, 361), and also by G. F. Jaubert (*Ber.*, 1896, 29, 414), whilst Nietzki regarded the safranine bases as being ortho-quinonoid, not merely in their salts, but also in the free state (*Ber.*, 1896, 29, 1445).

Kehrmann at first held an intermediate view, supposing that the aposafranine salts are ortho-quinonoid derivatives, whereas the para-quinonoid structure results when the acid is withdrawn (*Annalen*, 1896, 290, 257). Fischer and Hepp, who treated rosindone with phosphorus pentachloride, obtained phenylchloronaphthaphenazonium chloride and not a dichloride having the structure

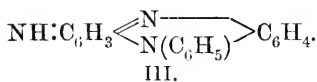

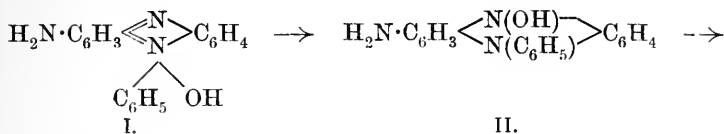

(*Ber.*, 1897, 30, 1827), but they pointed out at the same time that such an agent as phosphorus pentachloride might effect intramolecular change. Shortly afterwards, Kehrmann accepted Nietzki's view that aposafranone is an internal anhydride, but at the same time he showed that phenylphenazonium salts readily give aposafranone when treated with alkali in presence of air, or aposafranine when the alkali is replaced by ammonia (*Ber.*, 1897, 30, 2620). Fischer and Hepp subsequently (*Ber.*, 1898, 31, 299) concurred with the other investigators, with the exception of Jaubert, in accepting the ortho-quinonoid formula, and since this period aposafranone and the base, aposafranine, have generally been represented as meta-anhydrides.

One of the present authors has never accepted this view because aposafranone is practically insoluble in water and gives salts which are hydrolysed with great readiness. Were aposafranone really an internal anhydride of a phenol containing a powerful quaternary ammonium hydroxide group, then it should be comparable with the hydroxyphenyltrimethylammonium hydroxides which are readily soluble and very alkaline, and moreover give stable salts with acids.\*

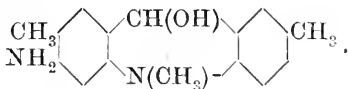

The conversion of an aposafranine salt into an anhydro-base of para-quinonoid structure is not only possible, but indeed probable, if the hydroxyl radicle of the ammonium group is assumed to migrate to the para-nitrogen atom. The product would, however, be a substituted hydroxylamine and would immediately lose the elements of water, so that the intermediate product (formula II.) in the following scheme might not be sufficiently stable to admit of isolation.

\* The examination of such hydroxides and the determination of their electrical conductivity is now being undertaken in the laboratory of the East London Technical College.—J. T. H.

If, however, the nitrogen atom of the ring were replaced by a methenyl group, the intermediate product, II., might be possible, especially since carbinol bases are produced by the action of alkalis on quaternary acridinium iodides (H. Decker, *J. pr. Chem.*, 1892, 45, 161; A. Bernthsen, *Ber.*, 1892, 25, 1746; A. Hantzsch, *Ber.*, 1899, 32, 275).

We consequently started with 3:7-dimethyl-8-acetaminoacridine (Ullmann, *Ber.*, 1903, 36, 1025), which was converted into a methiodide. By precipitating the iodide with ammonia, a carbinol base was obtained from which the acetyl group was removed by boiling with dilute sulphuric acid and reprecipitation with ammonia. The product of hydrolysis was a carbinol base,  $\text{C}_{16}\text{H}_{18}\text{ON}_2$ , which can only have the constitution

This base, when heated at about  $200^\circ$ , loses the elements of water; the resulting anhydro-base,  $\text{C}_{16}\text{H}_{16}\text{N}_2$ , redissolves in acids furnishing salts identical with those produced by the carbinol base, the hydrochloride, for example, being  $\text{C}_{16}\text{H}_{17}\text{N}_2\text{Cl}$ . It is noteworthy that the base, although containing two nitrogen atoms, is only monacidic, a property which it shares with aposafranine.

*8-Amino-3:7-dimethylacridine.*—This colouring matter has already been described by Ullmann (*Ber.*, 1903, 36, 1025), who obtained it by the action of *p*-toluidine on tetra-aminoditolylmethane. Our material was prepared by the method indicated by H. Terrisse and G. Darier (*D.R.*-P. 107,517).

The methylene derivative of *m*-tolylenediamine, obtained by the action of 40 per cent. formaldehyde solution on this diamine suspended in water, was dissolved in six parts by weight of fused *p*-toluidine, three parts of *p*-toluidine hydrochloride being then added and the mixture heated for 3 hours at  $160^\circ$ . The excess of *p*-toluidine was then removed in a current of steam, the residue was digested with hot water, the extract filtered after cooling, and the sparingly soluble nitrate of the base precipitated by the addition of potassium nitrate.

The base, which was liberated from this salt by ammonia, was dried and extracted with toluene. The residue usually melted above  $240^{\circ}$ , whilst the purified colouring matter, after recrystallising from alcohol, melted at  $245^{\circ}$  (compare Terrisse and Darier).

The acetylation was carried out according to Ullmann's method; but the melting point of our product was somewhat higher than that given by this investigator.

The acetylated base was heated in a sealed tube for 4 hours at  $110\text{--}120^{\circ}$  with five times its weight of methyl alcohol and one and a half molecular proportions of methyl iodide. The methyl-alcoholic solution was filtered and allowed to crystallise; the salt, which separated in small, very dark needles, was fairly soluble in water, the solubility being comparable with that of acridinium methiodide; it had no definite melting point.

0.1166 gave 0.0671 AgI.  $I = 31.1$ .

$C_{18}H_{19}ON_2I$  requires  $I = 31.3$  per cent.

*8-Amino-5-hydroxy-3:7:10-trimethyldihydroacridine*.—A solution of the foregoing methiodide, when left in contact with dilute ammonia, did not yield a carbinol base corresponding with the acetamino-compound owing to the ease with which the acetyl group was hydrolysed. The precipitate was therefore collected, washed, and boiled for 3 or 4 hours with 25 per cent. sulphuric acid to ensure the complete hydrolysis of the acetamino-group. The filtered dark-red solution was then poured into ammonia solution, the precipitate being dried in the air and extracted with dry acetone. After the addition of benzene, the extract was allowed to evaporate slowly, when pale reddish, microscopic needles were obtained; these appeared to melt at  $210^{\circ}$ , but in all probability the apparent melting was really nothing more than the removal of the elements of water.

0.0879 gave 0.2434  $CO_2$  and 0.0572  $H_2O$ .  $C = 75.5$ ;  $H = 7.3$ .

0.1209 „ 11.9 c.c. nitrogen at  $18.5^{\circ}$  and 763 mm.  $N = 11.3$ .

$C_{16}H_{18}ON_2$  requires  $C = 75.6$ ;  $H = 7.1$ ;  $N = 11.0$  per cent.

On keeping this substance, it darkens considerably; this change may be due either to a gradual oxidation resulting in an acridone, or possibly to the removal of the elements of water. The carbinol dissolves readily in acetone and the alcohols, is somewhat soluble in benzene, but practically insoluble in petroleum. The solutions of this substance darken very considerably on the addition of acids.

The first attempts to remove the elements of water were made by heating the dry substance in a bath of aniline vapour at  $184^{\circ}$ . The product, although much darker, did not give analytical numbers agreeing with those required for the formula  $C_{16}H_{16}N_2$ . We therefore

resorted to the following method, by means of which the desired result was obtained. A solution of this substance in nitrobenzene was heated for several hours just below the boiling point of the solvent. The liberation of water was rendered very evident by the crackling sound produced; eventually, the hot solution was filtered, and when cold treated with excess of light petroleum. The dark red precipitate produced was collected, washed with light petroleum, and dried.

Analysis of this substance proved conclusively that one molecule of water had been removed from the carbinol base.

0.1138 gave 0.3370  $\text{CO}_2$  and 0.0702  $\text{H}_2\text{O}$ .  $\text{C} = 80.8$ ;  $\text{H} = 6.9$ .

0.1062 „ 10.8 c.c. nitrogen at  $15^\circ$  and 769 mm.  $\text{N} = 12.0$ .

$\text{C}_{16}\text{H}_{16}\text{N}_2$  requires  $\text{C} = 81.3$ ;  $\text{H} = 6.8$ ;  $\text{N} = 11.9$  per cent.

The anhydro-base did not melt below  $250^\circ$ , and for this reason we think that the ill-defined melting point ( $210^\circ$ ) observed in the case of the carbinol base is not really caused by fusion, but rather by the removal of the elements of water.

This anhydro-base differs markedly from the carbinol in that it is practically insoluble in acetone or benzene, although its solutions in acids are identical in colour with those of the latter base.

A solution of the carbinol base in excess of hydrochloric acid was evaporated on the water-bath, the resulting crystals being recrystallised. The intensely dark red salt thus obtained showed that the base was apparently monacidic towards hydrochloric acid.

0.1150 gave 0.0609  $\text{AgCl}$ .  $\text{Cl} = 13.1$ .

0.1332 „ 0.0728  $\text{AgCl}$ .  $\text{Cl} = 13.5$ .

$\text{C}_{16}\text{H}_{17}\text{N}_2\text{Cl}$  requires  $\text{Cl} = 13.0$  per cent.

This salt is easily soluble in water to a dark red solution.

Our thanks are due to the Government Grant Committee of the Royal Society for financial assistance in carrying out this work.

EAST LONDON TECHNICAL COLLEGE.

# LV.—*The Acid Esters of Methyl Substituted Succinic Acids.*

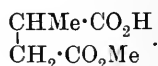

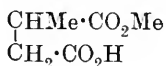

By WILLIAM ARTHUR BONE, JOHN JOSEPH SUDBOROUGH, and  
CHARLES HENRY GRAHAM SPRANKLING.

IN this communication are recorded the results of a systematic study of the methyl hydrogen esters of succinic acid and its methyl derivatives. Throughout the work, we have mainly concerned ourselves with the following questions, namely, (1) the methods of preparation, and, in the case of acids of unsymmetrical configuration, the isolation of the two possible acid esters, (2) the influence of successive methyl substitutions on the dissociation and esterification constants of the series, and (3) whether the ratio between the dissociation constants of an acid and its methyl hydrogen ester remains constant or changes in any regular manner throughout the series.

The three principal methods available for the preparation of the methyl hydrogen esters of a dibasic acid are: (1) digestion of the acidic anhydride with a slight excess of methyl alcohol, (2) partial hydrolysis of the dimethyl ester with the calculated quantity of methyl-alcoholic potash, and (3) partial esterification of the acid by the aid of a dilute solution of hydrogen chloride in methyl alcohol. Besides these three processes we also intended to employ a fourth method, namely, the action of methyl iodide on the silver hydrogen salts of the acids, but all attempts to obtain such salts entirely failed.

In the case of the symmetrical acids of the group, namely, succinic acid itself and its *s*-dimethyl and tetramethyl derivatives, we adopted the first of the three foregoing methods as the surest means of obtaining the acid ester in a state of purity. All these esters were solids at the ordinary temperature, and, except in the case of methyl hydrogen *cis*-*s*-dimethylsuccinate, we experienced no difficulty in purifying them by recrystallisation from suitable solvents.

Acids of unsymmetrical structure, for example, methyl-, *as*-dimethyl-, and trimethyl-succinic acids, should yield two isomeric methyl hydrogen esters, as represented by the following formulæ for the esters of the monomethyl acid:

In these cases, we employed all three methods of preparation with varying degrees of success, in so far as the isolation of distinct isomeric acid esters was concerned.

The study of the dissociation and esterification constants of the

oily esters obtained from methylsuccinic acid left no doubt as to the identity of the products yielded by the three methods, but whether each product was a single chemical substance and not a mixture of isomeric esters having almost identical physical properties is perhaps an open question. In this connection, we may recall the similar experience of Braunschweig (*J. pr. Chem.*, 1893, [ii], 47, 280, 286) with the liquid ethyl hydrogen methylsuccinates prepared respectively from the acid anhydride and by partial hydrolysis of the neutral ester. The two oils had almost identical boiling points, densities, and refractive indices, yet he did not feel justified in pronouncing either of them to be a single substance. The case of methylsuccinic acid is, in this respect, paralleled by that of *cis*- $\alpha$ -methyltricarballic acid, which yields identical methyl dihydrogen esters by the three general methods (Bone and Sprankling, *Trans.*, 1902, 81, 38).

We have succeeded in obtaining two distinct crystalline methyl hydrogen *as*-dimethylsuccinates. The  $\alpha^*$ -compound, prepared either from the acid anhydride or by the partial esterification of the acid, melts at  $52^\circ$ , and has a dissociation constant  $K = 0.00228$ ; its constitution is undoubtedly expressed by the formula

The  $b^*$ -isomeride, obtained by the partial hydrolysis of the normal ester, melts at  $40.5^\circ$ , has a dissociation constant  $K = 0.00256$ , and is esterified about six times as rapidly as the  $\alpha$ -compound, a circumstance which is in complete accord with the formula  $\text{CO}_2\text{Me} \cdot \text{CMe}_2 \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}$ .

In his numerous experiments on acid esters of unsymmetrical acids, Wegscheider has usually found that the product yielded by any one of the three methods we have employed is really a mixture of the two isomeric esters which is difficult to separate. In the preparation of these methyl hydrogen *as*-dimethylsuccinates, we have never been able to isolate two esters in any one of the processes described; the product was always an oil which gradually deposited crystals of either  $\alpha$ - or  $b$ -compound according to the method employed. It is true that the proportion of the oil which crystallised was usually small, but the dissociation and esterification constants of the

\* With regard to the nomenclature of such isomeric acid esters, we have, in this paper, followed the recent example of workers on the Continent in adopting Wegscheider's system (*Ber.*, 1902, 35, 4330), according to which the ester having the smaller electrical conductivity is called the  $\alpha$ -ester and the other the  $b$ -ester, rather from a desire to avoid confusion of terms than from a conviction that no better system can be devised. On the contrary, we would prefer the suggestion made by one of us (*Proc.*, 1901, 17, 43) that the nomenclature should be based on the esterification constants rather than on the electrical conductivities, since results already obtained in the acetic and benzoic series indicate that the esterification velocity of an acid is more simply related to its constitution than is the electrical conductivity.

residual oil were always only slightly different from the corresponding values obtained from the crystals which had separated.

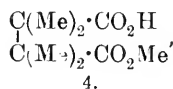

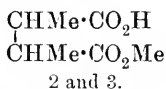

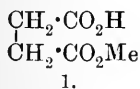

The methyl hydrogen esters of trimethylsuccinic acid have presented great difficulties; the products yielded by all three methods were oils which, on distillation under 20—30 mm. pressure, dissociated more or less completely into the acid anhydride and methyl alcohol. In order to purify these oils, they were dissolved in sodium carbonate and the neutral impurities extracted with ether. The alkaline liquid was subsequently acidified with a slight excess of hydrochloric acid, and the liberated methyl hydrogen ester extracted with light petroleum (b. p. 30—40°), a solvent which has no action on trimethylsuccinic acid itself. We never succeeded in obtaining crystals from any of the purified oils, but the values obtained for both dissociation and esterification constants indicated that, as in the case of *as*-dimethylsuccinic acid, the acid esters obtained from the anhydride and by the partial esterification of the acid are identical and different from the product of the partial hydrolysis of the normal ester.

A noteworthy property of all these methyl hydrogen succinates is their great stability in presence of water at the ordinary temperature. Thus, for example, methyl hydrogen succinate was not appreciably hydrolysed by cold water in 5 days, and methyl hydrogen methylsuccinate was not affected in 11 days.

The retarding influence produced by the introduction of various substituents on the rate of esterification of an organic acid has already been proved in several series of acids. Thus in the benzoic series a single ortho-substituent produces considerable retardation, and two ortho-substituents as a rule produce total inhibition (Meyer and Sudborough, *Ber.*, 1894, 27, 510, 1580, 3146; Lepsius, *ibid.*, 1635; V. Meyer, *Ber.*, 1895, 28, 182, 1254, 2773, 3196; 1896, 29, 830, 1397; van Loon and V. Meyer, *Ber.*, 1896, 29, 839; Goldschmidt, *Ber.*, 1895, 28, 3218; Kellas, *Zeit. physikal. Chem.*, 1897, 24, 221). The successive substitution of the three hydrogen atoms of acetic acid by other groups, no matter whether positive or negative in character, always produces retardation when the usual catalytic method of esterification is employed (Sudborough and Lloyd, *Trans.*, 1899, 75, 467). In the acrylic series, the retarding influences of  $\alpha$ -substituents, as well as the relative effects of *cis*- and *trans*-positions with respect to the carboxyl group, have been investigated (Sudborough and Lloyd, *Trans.*, 1898, 73, 81).

The catalytic method for the determination of esterification constants has already been fully described (*Trans.*, 1899, 75, 471), but since it is only applicable to monobasic acids it was necessary, when we wished to extend the observations to the succinic series, to examine the methyl hydrogen esters.

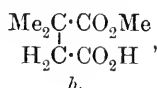

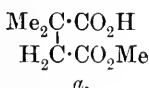

The results of experiments with the methyl hydrogen esters of the three symmetrical succinic acids afford another remarkable example of the retardation induced by the successive introduction of methyl groups. Thus, of the four compounds:

*cis*- and *trans*-Modifications.

the first is esterified very readily at 15°, when *N*/80 hydrogen chloride is employed as the catalytic agent, the process being almost completed in a few hours. With compound No. 4, the process is so very slow, even when *N*/40 hydrogen chloride is used, that no definite constant could be obtained. Compounds 2 and 3 are intermediate in this respect between 1 and 4, and the *cis*-compound is esterified more readily than its *trans*-isomeride.

Then, again, we find that methyl hydrogen succinate is esterified more than twice as rapidly as methyl hydrogen methylsuccinate; moreover, of the two methyl hydrogen *as*-dimethylsuccinates:

the *b*-compound is esterified about six times as rapidly as the *a*-ester, whilst the esterification velocity of the latter is considerably greater than that of either of the methyl hydrogen trimethylsuccinates.

A comparison of the values of  $E_{\text{MeOH}}^{15}$  (esterification constant) and  $K$  (dissociation constant) tabulated on page 540 shows that there is no connection between the two sets of numbers, or, in other words, that the esterification velocity, when the catalytic method is employed, is independent of the strength of the acidic group. A similar fact was observed in the acetic series (Sudborough and Lloyd, *Trans.*, 1899, 75, 480). But since the value for  $K$  depends on the degree of ionisation in aqueous solution, whereas the values of  $E_{\text{MeOH}}^{15}$  were deduced from observations on methyl-alcoholic solutions, the two sets of numbers are perhaps scarcely comparable.

The dissociation constants of a number of ethyl hydrogen esters of dicarboxylic acids were determined by J. Walker (*Trans.*, 1892, 61, 708), who summarised his results in the following empirical rule: "the constant of the dihydrogen salt is in general from 2 to 2.5 times as great as the constant of the corresponding ethyl hydrogen salt. The only exceptions to this rule are formed by dibasic acids, the constants of which are very high, greater than 0.1." Our results indicate that this rule is not obeyed in the succinic series; the ratio,

$K$  acid/ $K$  acid ester, appears to depend largely on the number of substituent alkyl groups present, increasing from 2.12 for succinic acid to 27.0 for tetramethylsuccinic acid.

Wegscheider (*Monatsh.*, 1895, 16, 153; 1902, 23, 346) represents the dissociation constant of an unsymmetrical dicarboxylic acid which does not show dibasic dissociation at moderate dilutions as a factor  $a$  of the sum of the constants of its  $\alpha$ - and  $\beta$ -methyl hydrogen esters ( $k_a$  and  $k_b$  respectively), thus:

$$aK = k_a + k_b.$$

In the special case of a symmetrical acid, the expression becomes

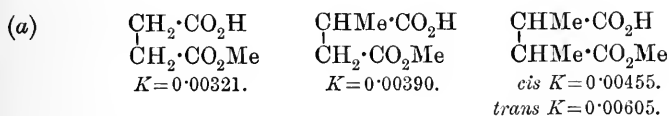

$$aK = 2k.$$

He finds that the value of  $a$  generally varies between 0.5 and 1.5, but is independent of the strength of the acid.

In a given series of dibasic acids, this factor will vary in inverse ratio to the mutual reinforcing effects of the two carboxyl groups, and it may be regarded as an index of the distances between them. In the methylsuccinate series, we find that  $a$  diminishes with successive substitutions, at first slowly, but afterwards very rapidly. Thus, whereas the value for succinic acid itself is 0.945, for the monomethyl acid it is 0.910. The second substitution lowers the factor to between 0.60 and 0.73, according to the position of the second methyl, the third substitution to 0.180, and the fourth to 0.074 (see table of properties on p. 540). Hence we may reasonably conclude that the distances between the two carboxyl groups of succinic acid diminish with successive alkyl substitutions, and that this diminution is most marked between the second and third replacements.

Further, since  $a$  for succinic acid nearly approaches unity, we may conclude that the negative character of the  $-\text{CO}_2\cdot\text{CH}_3$  group in this series of acids is not very marked. In a previous paper (Bone and Sprankling, *Trans.*, 1900, 77, 1307), it was pointed out that the magnitude of the dissociation constant in the succinic series depends on three factors, namely, (1) the number of substituent alkyl groups, (2) their mass and structure, and (3) the distances between the two carboxyl groups. The influence of the second factor was deduced from a comparison of the constants of a large number of alkylsuccinic acids. It was, however, impossible to distinguish between the effects of the first and third factors, or, in other words, between the direct and indirect effects of successive alkyl substitutions. Now, however, that the constants of the whole series of methyl hydrogen methylsuccinates have been determined, we are in a position to judge of the direct effects of methyl substitutions. Our experiments warrant the two following conclusions:

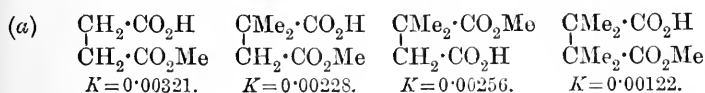

I. A single substitution of hydrogen by methyl in the group  $H_2\dot{C}\cdot CO_2H$  or  $H_2\dot{C}\cdot CO_2Me$  always raises the dissociation constant. Thus we have :

(b) Methyl hydrogen *as*-dimethylsuccinate from anhydride,  $K=0\cdot00228$ .

Methyl hydrogen trimethylsuccinate from anhydride,  $K=0\cdot00310$ .

II. On the other hand, a double substitution of methyl in the group  $H_2\dot{C}\cdot CO_2H$  or  $H_2\dot{C}\cdot CO_2Me$  involves a marked lowering of the constant, as, for example :

		$K$ .

The properties of the methyl hydrogen succinates are shown in the table on p. 540.

# EXPERIMENTAL.

## 1. Methyl Hydrogen Succinate, $CO_2H\cdot CH_2\cdot CH_2\cdot CO_2Me$ .

This acid ester has already been prepared by J. Walker (Trans., 1892, 61, 716). The method we adopted was as follows : 5 grams of succinic anhydride were boiled in a reflux apparatus for 45 minutes with twice the theoretical amount of pure methyl alcohol, the excess of alcohol was removed, and the residue crystallised from hot carbon disulphide. A small amount of insoluble material, melting at  $185^\circ$  and presumably succinic acid, was obtained together with an almost theoretical yield of the acid ester in the form of glistening, white plates melting at  $58^\circ$ .

In the case of these acid esters, we find that an analysis of the silver salt, or the titration of the ester itself with standard barium hydroxide, using phenolphthalein as indicator, is a more delicate test of purity than the estimation of carbon and hydrogen by the usual combustion method.

0.2492 silver salt gave 0.1132 Ag.  $Ag=45\cdot4$ .

$C_5H_7O_4Ag$  requires  $Ag=45\cdot2$  per cent.

## 2. Methyl Hydrogen Methylsuccinate.

### (a) From Anhydride.

The anhydride was prepared by heating the acid with excess of acetyl chloride for 2 hours; it distilled at 238—240° (uncorr.) under atmospheric pressure, slowly solidified to a crystalline mass melting at 30—32°, and when washed with cold carbon disulphide melted at 37°. Thirty grams of the anhydride were boiled with 10 grams of anhydrous methyl alcohol for an hour and the product distilled under diminished pressure; after two fractionations, an 80 per cent. yield of an oil distilling at 140° under 11 mm. pressure was obtained. The oil dissolved readily in the ordinary solvents, including water.

0.1574 gave 0.0671 Ag. Ag = 42.7.

$C_6H_9O_4Ag$  requires 42.7 per cent.

0.201 required 27.53 c.c. of  $N/20 Ba(OH)_2$ , the calculated value being 27.53 c.c.

A weighed amount of the acid methyl ester (1.3458 grams) was made up to 150 c.c. with distilled water and 15 c.c. of the solution titrated at given intervals.

1. $t$ in hours.....	0	1	30	48	72	384	600	
$N/20 Ba(OH)_2$ in c.c....	18.5	18.5	18.6	18.5	18.5	18.9	19.1	
2.153 grams made up to 150 c.c. with water and 15 c.c. titrated.

*(b) From the Normal Methyl Ester.*

Dimethyl methylsuccinate was prepared by boiling the acid with a 3 per cent. solution of hydrogen chloride in pure methyl alcohol for 3—4 hours. The product was distilled under reduced pressure and the fraction boiling at 115—125° under 46 mm. pressure collected separately. On distillation under atmospheric pressure, the ester was obtained as a colourless oil boiling at 197—198°.

A mixture of 26 grams of the normal ester and 20 grams of methyl alcohol was treated with 63.2 grams of a 14.4 per cent. solution of potassium hydroxide in pure methyl alcohol, and the whole kept for 5 hours. A little solid methyl-orange was added and hydrogen chloride passed into the liquid until a permanent pink coloration was produced. The potassium chloride was removed and the liquid distilled under reduced pressure. A certain amount of oil distilling below 120° under 15 mm. pressure was obtained and found to consist of unaltered normal ester. The fraction boiling at 135—150° was collected separately and rectified, the portion distilling at 142—143° under 15 mm. pressure being collected and analysed. A substance with a higher

boiling point was left in the flask and partially solidified on cooling. The yield of acid ester was about 25 per cent.

0.2135 gave 0.091 Ag.  $\text{Ag} = 42.6$ .

$\text{C}_6\text{H}_9\text{O}_4\text{Ag}$  requires  $\text{Ag} = 42.7$  per cent.

#### 4. Methyl Hydrogen trans-s-Dimethylsuccinate.

This ester was prepared in exactly the same manner as the isomeric *cis*-ester, and the solid obtained was crystallised from light petroleum (b. p. 30—40°). It separates in colourless plates, melts at 49°, is readily soluble in most organic solvents, and may be distilled under reduced pressure.

0.1466 gave 0.2834  $\text{CO}_2$  and 0.1009  $\text{H}_2\text{O}$ .  $\text{C} = 52.72$ ;  $\text{H} = 7.64$ .

$\text{C}_7\text{H}_{12}\text{O}_4$  requires  $\text{C} = 52.50$ ;  $\text{H} = 7.50$  per cent.

The *silver* salt crystallises in small needles and is moderately soluble in water.

0.1406 gave 0.0572 Ag.  $\text{Ag} = 40.7$ .

$\text{C}_7\text{H}_{11}\text{O}_4\text{Ag}$  requires  $\text{Ag} = 40.45$  per cent.

0.2 gram of the ester required 24.7 c.c. of  $N/19.72$   $\text{Ba(OH)}_2$  for neutralisation, using phenolphthalein as indicator, the calculated value being 24.65 c.c.

5. *Methyl, Hydrogen as-Dimethylsuccinate.*

(a) *From the Anhydride.*

The ester was prepared by the method already described for the *cis*- and *trans*-esters. The oil obtained when the excess of alcohol was evaporated, yielded in the course of two or three days a considerable quantity of large, flat plates. When recrystallised from light petroleum (b. p. 40—60°), the ester forms well developed, colourless prisms, melting at 52°.

0.1871 gave 0.3605  $\text{CO}_2$  and 0.1279  $\text{H}_2\text{O}$ .  $\text{C} = 52.55$ ;  $\text{H} = 7.59$ .

$\text{C}_7\text{H}_{12}\text{O}_4$  requires  $\text{C} = 52.5$ ;  $\text{H} = 7.50$  per cent.

0.154 silver salt gave 0.0626 Ag.  $\text{Ag} = 40.6$ .

$\text{C}_7\text{H}_{11}\text{O}_4\text{Ag}$  requires  $\text{Ag} = 40.45$  per cent.

0.3 gram of the ester required 37.45 c.c. of  $N/20$   $\text{Ba(OH)}_2$ , the calculated value being 37.5 c.c.

*(b) From the Normal Methyl Ester.*

The normal ester,  $\text{CO}_2\text{Me} \cdot \text{CMe}_2 \cdot \text{CH}_2 \cdot \text{CO}_2\text{Me}$ , obtained by the action of methyl iodide on the silver salt, is a colourless liquid distilling at 201—202° (uncorr.) under atmospheric pressure. For the preparation of the acid ester, 44.5 grams of the normal ester were mixed with the theoretical amount (285 c.c.) of methyl-alcoholic potash, and the mixture left overnight at the ordinary temperature. Next morning, the mixture was heated for 2 hours on the water-bath, and the alcohol then distilled off under reduced pressure. The syrupy residue was mixed with the theoretical amount of dilute hydrochloric acid, and the oily acid ester thus liberated extracted with pure ether. After drying the extract and removing the solvent, the ester was distilled under reduced pressure, when 26 grams of an oil distilling at 141° under 14 mm. pressure were obtained.

0.2967 silver salt gave 0.1213 Ag.  $\text{Ag} = 40.9$ .

$\text{C}_7\text{H}_{11}\text{O}_4\text{Ag}$  requires 40.45 per cent.

Although not quite pure, the conductivity and esterification constant of the oil were determined.

$$\text{Mean} = 0.0142; \text{HCl} = N/41.1.$$

$$E_{\text{MeOH}}^{15^\circ} = 1.34.$$

When kept for some time, the ester deposited large, flat plates, which were removed and crystallised from light petroleum. The amount of crystals was relatively small, being only about 7 grams from 26 grams of oil. The ester crystallised from light petroleum in snow-white, rhomboidal plates melting at  $40.5$ — $41^\circ$ . The numbers obtained for the electrical conductivity and esterification constant were very similar to those obtained for the original oil, thus proving that, although only 7 grams of the solid ester were obtained from the oil, yet the remainder must have consisted of the nearly pure ester.

0.2 gram required 25.1 c.c. of  $N/20$   $\text{Ba(OH)}_2$ , the calculated value being 25.0 c.c.

*(c) Acid Ester from the Acid.*

A solution of 16.5 grams of the acid melting at 140—141° in 40 c.c. of  $N/5$  methyl-alcoholic hydrogen chloride was boiled for 40 minutes in a reflux apparatus. The excess of alcohol and hydrogen chloride was removed under reduced pressure, and the residue fractionated under 14 mm. pressure. The fraction boiling below 110° gave 6 grams of the normal ester boiling at 200°, the second fraction distilling between 130° and 145° was rectified, and the portion distilling at 142—143° under 14 mm. pressure gave 4 grams of a solid, which, after crystallisation from light petroleum, melted at 52°. This ester was identical with the ester obtained from the anhydride, a mixture of the two melted at 52°, and the conductivities and esterification constants of the two were practically identical.

0.2 gram required 25.0 c.c. of  $N/20$  Ba(OH)<sub>2</sub>, the calculated value being 25.0 c.c.

6. *Methyl Hydrogen Trimethylsuccinate.*(a) *From the Anhydride.*

The anhydride was prepared by distilling the pure acid under atmospheric pressure, and was obtained in the form of a solid mass melting at  $33^\circ$ . Its purity was tested by titration with standard barium hydroxide, when 0.1 gram required 28 c.c. of  $N/20$   $\text{Ba(OH)}_2$ , the calculated value being 28.1 c.c.

Fourteen grams of the anhydride were boiled with 10 grams of pure methyl alcohol in a reflux apparatus for 4 hours, when the product dissolved readily in cold sodium carbonate solution. Titration with standard barium hydroxide indicated that the acid ester was not quite pure, as 0.2194 gram required 25.65 c.c. of  $N/20$   $\text{Ba(OH)}_2$ , instead of the calculated value, namely, 25.2 c.c. When the ester was distilled under reduced pressure, methyl alcohol was eliminated, and a considerable amount of the anhydride was regenerated. The following method of purification was therefore adopted. The ester was dissolved in cold sodium carbonate solution, and any unaltered anhydride removed by extraction with ether. The alkaline liquid was acidified with dilute hydrochloric acid, and the oily ester thus precipitated extracted twice with relatively large amounts of light petroleum (b. p.  $30-60^\circ$ ). This solvent was selected instead of ether, because it does not dissolve trimethylsuccinic acid to any appreciable extent. The petroleum extract was dried, and the solvent removed. The oily product finally obtained was not quite pure, but evidently contained neither acid nor anhydride.

0.2194 gram required 24.6 c.c. of  $N/20$   $\text{Ba(OH)}_2$ , instead of the calculated value, namely, 25.2 c.c.

7. *Methyl Hydrogen Tetramethylsuccinate.*

Tetramethylsuccinic acid was prepared by Meyer and Auwer's method (*Ber.*, 1890, 23, 304), and attempts were also made to obtain it by shaking a mixture of ethyl  $\alpha$ -bromoisobutyrate and finely-divided silver, but the yield was no better. The acid was transformed into anhydride by distillation under atmospheric pressure.

The acid ester was prepared by treating the anhydride (m. p. 147°) with the requisite amount of sodium methoxide dissolved in methyl alcohol, evaporating to dryness, and acidifying with hydrochloric acid; it crystallised from light petroleum (b. p. 30—40°) in the form of large, flat prisms melting at 63°, the yield being practically quantitative.

0.210 silver salt gave 0.0770 Ag.  $\text{Ag} = 36.66$ .

$\text{C}_9\text{H}_{15}\text{O}_4\text{Ag}$  requires  $\text{Ag} = 36.61$  per cent.

The silver salt is fairly readily soluble in water and forms long, felted needles.

*Electrical Conductivity at 25°.  $\mu = 350$ .*

<i>v.</i>	$\mu_v$	<i>m.</i>	100 <i>k.</i>
47.81	8.39	0.0239	0.00122

## LVI.—*Chemical Dynamics of the Alkyl Iodides.*

By KATHARINE ALICE BURKE and FREDERICK GEORGE DONNAN.

### *Introduction.*

ONE of the most important problems of modern chemistry is the investigation of the causes which give rise to the reactivity of substances. Perhaps the most interesting result of the physico-chemical researches of the last two decades has been the tracing of a connection between the chemical reactivity of salt-like substances in aqueous solution and the electrical conductivities of those solutions. The main result of these investigations may be summed up as follows. It is, in general, possible to ascribe this reactivity of salt-like substances in aqueous solution to something pre-existing in the solution and apart from the particular reaction studied. The possibility of doing this lies in the fact that this pre-existing condition or state can be qualitatively detected and quantitatively expressed by perfectly independent methods. As a consequence of this, a generalised theory of chemical reactivity has been developed. In the case, however, of organic chemistry, the great majority of substances do not possess, or, at all events, have not

as yet been shown to possess, a salt-like character, and it has not been hitherto possible—perhaps for the reason just stated—to discover any even approximately general method of measuring their reactivity. A good deal of the material with which a general theory of chemical reactivity must deal in the future, has, however, been accumulated by the accurate measurement of the velocity-coefficients of organic reactions. This, indeed, forms the only method whereby the problem can as yet be attacked ; but although chiefly restricted to comparatively simple cases,\* and apparently yielding numbers which are doubly, if not trebly, specific, that is, numbers which are dependent not only on the specific nature of the substances the reactivity of which is being measured, but also on that of the reagent employed, and even on that of the solvent, the method has already, in the hands of Menshutkin, Goldschmidt, Lobry de Bruyn, Hecht, Conrad and Brückner, Carrara, and others, yielded results of the highest interest.

It is natural that in the attempt to construct such a theory of reactivity, the alkyl haloids, in particular the iodides, should have received especial attention. These substances, besides being in general extremely reactive and of great practical importance, from their employment in many synthetical reactions of wide applicability, exhibit two peculiarities ; they are of a dualistic type, and many of their reactions bear a strong resemblance, although possibly only one of type and not of mechanism, to those which are characteristic of salts. Here, then, if anywhere, some insight into the hidden causes of reactivity among organic substances might legitimately be expected.

J. Wislicenus appears to have been the first investigator to attempt a determination of the reactivity of the alkyl haloids by means of velocity measurements (*Annalen*, 1882, 212, 239). He ascertained the time required by various alkyl haloids to react completely with ethyl sodioacetoacetate in ethyl-alcoholic solution. Although the experiments were not carried out at a strictly constant temperature, the results he obtained are of great interest and are very probably sufficiently accurate for comparative purposes. In the following table, the numbers given are inversely proportional to the times required for complete reaction, these numbers being probably proportional to the specific velocity-coefficients, for, from the equation

$$-dc/dt = k\phi(c),$$

one obtains

$$dt = -\frac{1}{k} \frac{dc}{\phi(c)},$$

\* By "simple" cases are meant those reactions the progress of which is uniquely determined by a single specific velocity-coefficient—a very limited class in organic chemistry.

and therefore

$$t \text{ (time of reaction)} = \frac{1}{k} \int_0^{c_0} \frac{dc}{\phi(c)},$$

where  $c_0$  = initial equivalent concentration (which was always the same).

*Wislicenus's Experiments.*

Iodide.	Relative velocity.	Iodide.	Relative velocity.
Methyl .....	196	<i>iso</i> Propyl ...	1—9
Ethyl .....	21	<i>tert.</i> -Butyl ...	Excessively small
<i>n</i> -Propyl .....	5	Allyl .....	>784

These figures show at a glance the great reactivity of methyl iodide as compared with other saturated iodides and the enormous reactivity due to the presence of the unsaturated allyl group. Other experiments made by Wislicenus demonstrated, however, the extremely small reactivity of vinyl iodide, so that the mere presence of a double linking is not in itself sufficient to produce great reactivity.

How far now are such relative "reactivity-coefficients" independent of the particular reagent (ethyl sodioacetoacetate) employed, that is, how far do they possess what may be called a singly specific character? This very interesting question may be answered by considering the results of other kinetic investigations dealing with the alkyl haloids.

In 1890, Menshutkin (*Zeit. physikal. Chem.*, 1890, 5, 589) investigated the velocity of combination with triethylamine in acetone solution at 100°. The reaction was found to be bimolecular, and the relative values of the velocity-coefficients found by him are given in the following table.

*Menschutkin's Experiments.*

Iodide.	Relative velocity-coefficient.	Iodide.	Relative velocity-coefficient.
Methyl .....	1140	<i>n</i> -Butyl .....	1·38
Ethyl .....	10·1	<i>n</i> -Heptyl .....	1·08
<i>n</i> -Propyl .....	1·93	<i>n</i> -Octyl.....	1

So far as the comparison extends, a striking resemblance between these results and those obtained by Wislicenus is at once evident. For example, methyl iodide is seen to be pre-eminently reactive in both series. Again, ethyl iodide is four times as reactive as *n*-propyl iodide in Wislicenus's reaction, and about five times as reactive in Menshut-

kin's reaction. Broadly speaking, therefore, these relative velocity-coefficients would appear to possess the character of reactivity-coefficients. We cannot, however, expect *a priori* to obtain identical series of reactivity-coefficients except by comparing velocity-coefficients at the same temperature and in the same solvent, for we know that this is not possible even in the case of substances possessing dualistic or salt-like character. That this is actually true in the case of the alkyl iodides is shown by considering the results obtained by Hecht, Conrad, and Brückner (*Zeit. physikal. Chem.*, 1889, 4, 273) in their study of the formation of ethers from the alkyl iodides and sodium ethoxide in ethyl-alcoholic solution at 30°.\* This reaction was also found to obey a bimolecular velocity-equation. The relative velocity-coefficients are tabulated below.

*Experiments of Hecht, Conrad, and Brückner.*

Relative velocity-coefficient.		Relative velocity-coefficient.	
Iodide.		Iodide.	
Methyl .....	61.72	isoPropyl .....	0.92
Ethyl .....	4.87	n-Heptyl .....	1.04
n-Propyl .....	1.71	n-Octyl.....	1.00

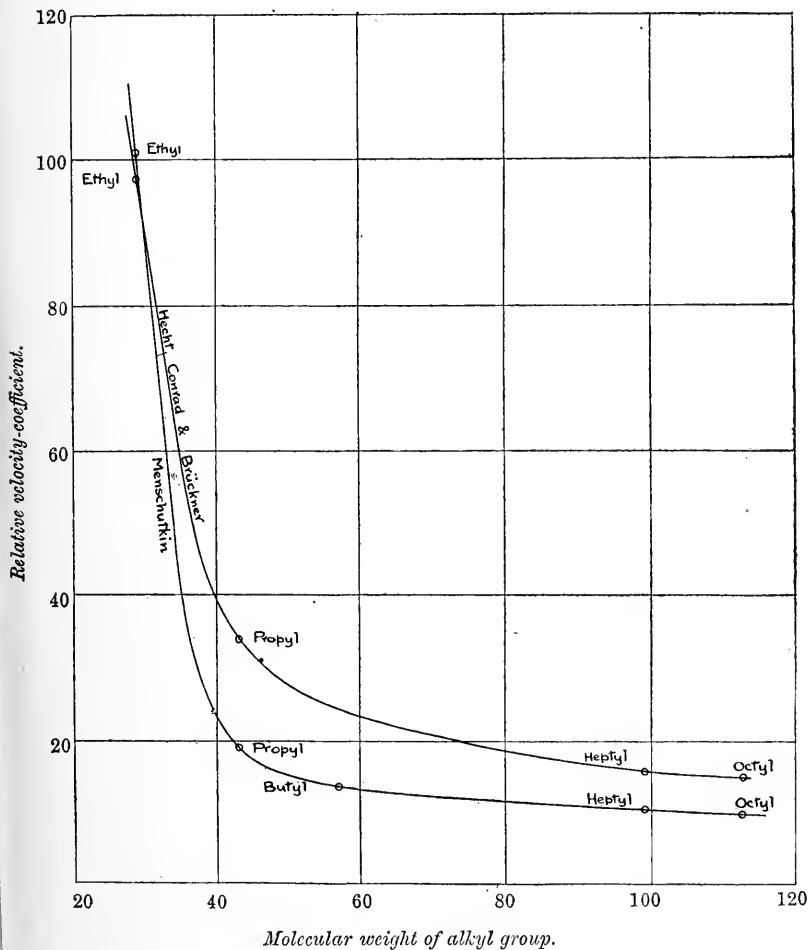

These figures exhibit a remarkable qualitative resemblance to those previously discussed, and in the cases of *n*-octyl, *n*-heptyl, and *n*-propyl iodides, even an approximately quantitative agreement with Menschutkin's figures; nevertheless, in the cases of ethyl and methyl iodides the quantitative comparison breaks down—as, indeed, might fairly be expected for the reasons given above. One important conclusion can, however, be drawn from all these results, namely, that in the reactions studied by Wislicenus, Menschutkin and Hecht, Conrad and Brückner, the reactivity of the alkyl iodides is due to the same condition or function of the molecule. This is rendered very evident by an inspection of Fig. 1 (p. 559), in which the general resemblance between the two curves is very striking.

The complexity of the problem of reactivity even in the relatively simple cases of the iodides becomes, however, at once apparent when we consider another type of reaction. The alkyl iodides, when heated with alcoholic potash or soda, yield in general a mixture of olefine and ether. This reaction has been studied very carefully and exhaustively by Nef (*Annalen*, 1899, 309, 126), but not with the object of determining relative velocity-coefficients. However, S. Brussoff (*Zeit. physikal. Chem.*, 1900, 34, 129) carried out a series of experiments dealing with this point. The alkyl iodides were heated

\* Somewhat similar experiments on a less extensive scale were made by F. Lengfeld (*Amer. Chem. J.*, 1889, 11, 40).

at 78°, with an approximately 2*N* solution of caustic potash in 96 per cent. alcohol. In Brussoff's experiments, the reaction mixture was not initially at 78°, so that the velocity of the reaction, measured by the

FIG. 1.

rate of evolution of the gaseous olefine, increased to a maximum and then fell regularly. In the following table are given the relative maximum velocities determined in this manner.

*Brussoff's Experiments.*

Iodide.	Relative maximum velocities of the evolution of olefine.	Iodide.	Relative maximum velocities of the evolution of olefine.
Ethyl.....	1.66	isoButyl.....	2.84
Propyl .....	2.24	sec.-Butyl .....	5.06
isoPropyl .....	2.84	tert.-Butyl .....	8.00
n-Butyl.....	1.00		

These figures are not nearly so trustworthy for the purposes of comparing the reactivity of the iodides as those quoted previously, since they only yield a measure, and that at best a rough one, of the rate of one of two reactions which are simultaneously brought about by the action of the alcoholic potash. A determination under conditions of constant temperature of the rate of diminution of alkalinity in the solution would probably have yielded numbers of much greater comparative value (compare Lobry de Bruyn and Steger, *Rec. trav. chim.*, 1899, 18, 41, 311). In spite of this, however, it is clear that we have here to deal with some molecular function or condition differing essentially from that observed in the cases cited previously. Thus *tert.*-butyl iodide is characterised by maximum reactivity, whereas in Wislicenus's experiments exactly the opposite is the case. Again, *isopropyl* iodide is more reactive than *n*-propyl iodide, and both more so than ethyl iodide. This is in direct opposition to the reactivities measured by Hecht, Conrad, and Brückner. It is clear that in the case of aqueous alcoholic potash the inner mechanism whereby the alkyl iodides react is quite different from that involved in the reactions with ethyl sodio-acetoacetate, triethylamine, and sodium ethoxide (in absolute alcohol). Hence, in the present state of our knowledge, any attempt to establish a general table of reactivities must meet with failure.

In the case of the reaction between the alkyl haloids and alcoholic potash, a theory of the mechanism of the process has been formulated by Nef (*loc. cit.*). He supposes that in alcoholic solution an alkyl haloid can undergo two modes of "dissociation," thus:

(a) "*Alkylidene*" dissociation,

(b) "*Alkylene*" dissociation,

The hydrogen iodide is neutralised by the caustic alkali or alkaline alkyloxide present, the free olefine is (in general) evolved as such, whilst the group  $\text{CH}_3\cdot\text{CH}$ : combines with alcohol to form an ether,  $\text{CH}_3\cdot\text{CH}< + \text{C}_2\text{H}_5\cdot\text{OH} = \text{C}_2\text{H}_5\cdot\text{O}\cdot\text{C}_2\text{H}_5$ . In proportion as the

alkylene or alkylidene dissociation predominates, so, according to Nef, will the yield of olefine exceed that of ether or *vice versa*.<sup>\*</sup> In this connection, the following table of results given by Brussoff (*loc. cit.*) is important. The total possible yield of olefine was 300 c.c. in every case. The figures give in c.c. the volumes of olefine actually obtained under similar conditions of temperature and (equivalent molecular) concentration.

*Comparative Yields of Olefine (Brussoff).*

Iodide.	Volume of olefine (0°, 760 mm.).	Iodide.	Volume of olefine (0°, 760 mm.).
Ethyl.....	54	<i>iso</i> Butyl.....	265
<i>n</i> -Propyl .....	122	<i>sec.</i> -Butyl .....	290
<i>iso</i> Propyl .....	278	<i>tert.</i> -Butyl .....	245
<i>n</i> -Butyl .....	117		

According to Nef's view, we must conclude from these figures that *isopropyl* and *isobutyl* iodides exhibit practically equal amounts of "alkylene" dissociation. It will be seen in what follows, however, that the velocity of reaction (in 100 per cent. alcohol) between *isopropyl* iodide and silver nitrate is at least one hundred and forty times greater than the velocity of reaction between *isobutyl* iodide and the silver salt. The result cannot be ascribed to the difference between the 96 per cent. alcohol employed by Brussoff and the absolute alcohol used in the experiments described below (compare p. 586), nor can it be explained on Nef's view by assuming that we have to deal with "alkylidene" dissociation in the reaction with silver nitrate, since, according to this investigation, the silver nitrate is converted into silver iodide by the reaction  $\text{AgNO}_3 + \text{HI} = \text{AgI} + \text{HNO}_3$ , and, for this purpose, hydrogen iodide produced by either sort of dissociation would appear to be equally efficient. There does not appear, therefore, to be any "dissociation" independent of the particular reagent employed, in which case alone can the concept of dissociation lead to results capable of experimental verification.

The formation of alcohol and ether can apparently be explained by Nef's assumption of "alkylidene" dissociation, but, as the actual existence of such a substance as, say,  $\text{CH}_3\text{:CH<}$  (ethylidene) is as yet problematical, it would seem much more natural to ascribe the formation of alcohol and ether (as is usually done) to the simultaneous reactions :

<sup>\*</sup> The problem is, however, complicated by the relative velocities of the processes of alkylene and alkylidene dissociations which are assumed to occur (see p. 563).

This involves, however, the assumption that sodium ethoxide, for example, can exist to some extent in an aqueous solution of alcohol. There are, however, very good reasons for believing that the equilibrium

really exists. Thus it is known that very dry alcohol cannot be completely dehydrated by distillation from sodium. The chief evidence is, however, afforded by the important researches of Lobry de Bruyn and A. Steger (*Rec. trav. chim.*, 1897, 18, 41 and 311).

The above equation represents in fact the hydrolysis of the salt,  $\text{Na}\cdot\text{OC}_2\text{H}_5$ , of "oxethylic" acid,  $\text{H}\cdot\text{OC}_2\text{H}_5$ , that is to say, the distribution of a base between the two acids  $\text{H}(\text{OH})$  and  $\text{H}(\text{OC}_2\text{H}_5)$ . Probably there is not a very great difference between the dissociation-constants of these two acids.

There is another point which must be carefully kept in mind in this connection. In order to explain the formation of a considerable amount of ether, it is not necessary to assume the pre-existence in the solution of a considerable amount of ethoxide. The actual output of ether (as compared with that of alcohol) depends also on the relative velocity of the reaction in which it is produced. Tautomeric equilibria and the outputs of reactions in which a reagent acts on one of the "dynamic" isomerides with relatively great velocity, have drawn attention in recent years to this important kinetic argument (Schiff, *Ber.*, 1898, 31, 205).

Considerable light is thrown on the question of alkylidene dissociation by the kinetic investigations of Lobry de Bruyn and Steger (*loc. cit.*). Consider the case of methyl iodide, where no alkylene dissociation is possible. The following table gives the mean values of the bimolecular velocity-coefficients for the reaction between methyl iodide and a solution of sodium in various mixtures of alcohol and water. The concentrations of the reacting substances were approximately  $N/20$ .

Percentage of Ethyl alcohol.	Mean velocity-coefficient.	Percentage of Ethyl alcohol.	Mean velocity-coefficient.
100	0.189	40	0.034
90	0.155	30	0.023
80	0.120	20	0.011
70	0.087	10	0.0062
60	0.066	0	0.0042
50	0.046		

In terms of Nef's theory, one may now assume either that (a) alkylidene dissociation is much greater in alcohol than in water, or that (b) the velocity of alkylidene dissociation is greater in alcohol than

in water; in the latter case, it is assumed that the neutralisation of the hydrogen iodide by sodium ethoxide or hydroxide proceeds very much faster than the dissociation of the alkyl iodide.

With respect to these assumptions, (a) is extremely improbable, considering the higher dissociating action of water, and (b) is purely gratuitous. The question of the order of the reaction may be now considered. According to Nef's theory, the reaction is the resultant of two others:

or the concurrent operation of these changes.

There are now several possibilities:—

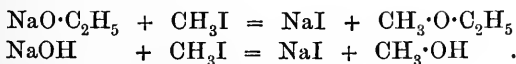

(a) The reaction or reactions enumerated under 2 proceed with relatively great velocity. We then measure the velocity of the unimolecular reaction indicated by 1.

(b) Reaction 1 proceeds with relatively great velocity. Even in the case of the aqueous solution where reaction 2 certainly possesses an enormously great velocity-coefficient, this assumption is a possible one, for if the alkylidene dissociation be of a sufficiently small order, the reaction 2 will proceed with measurable velocity. We now measure—to take the case of the aqueous solution—the velocity of the reaction  $\text{NaOH} + \text{HI} = \text{NaI} + \text{H}_2\text{O}$ . We may put  $c_{\text{OH}} = c_{\text{NaOH}}$ , and we must always have  $c_{\text{HI}} \times c_{\text{CH}_2} = k c_{\text{CH}_3\text{I}}$ , or since  $c_{\text{HI}} = c_{\text{CH}_3}$ ,  $c^2_{\text{HI}} = k c_{\text{CH}_3\text{I}}$ .

Hence, if  $v$  denote the velocity of the reaction,  $v = k' c_{\text{NaOH}} \sqrt{c_{\text{CH}_3\text{I}}}$ . (We may safely put  $c_{\text{H}} = c_{\text{HI}}$ ). So that in this case also the reaction will not proceed according to a bimolecular equation.

(c) The velocities of reactions 1 and 2 may be of the same order of magnitude. In this case the state of affairs will be very complicated, but it is very improbable that the bimolecular reaction-equation would be obeyed.

The evidence afforded by the results of Lobry de Bruyn and Steger would appear, therefore, to be against Nef's theory of alkylidene dissociation. It would seem much more reasonable to assume, as they do, the existence of the simultaneous reactions,

The velocity would then be expressed by the equation

$$v = k c_{\text{NaOEt}} \cdot c_{\text{CMeI}} + k' c_{\text{NaOH}} \cdot c_{\text{CMeI}}.$$

Let  $c_{\text{NaOEt}} / (c_{\text{NaOEt}} + c_{\text{NaOH}}) = \lambda$ ; then  $c_{\text{NaOH}} / (c_{\text{NaOEt}} + c_{\text{NaOH}}) = 1 - \lambda$ , and if we put

$$c_{\text{NaOH}} + c_{\text{NaOEt}} = c_{\text{Na}}$$

we obtain

$$v = k\lambda c_{\text{Na}} \cdot c_{\text{CH}_3\text{I}} + k'(1 - \lambda)c_{\text{Na}} \cdot c_{\text{CH}_3\text{I}}$$

or

$$v = \{k' + \lambda(k - k')\}c_{\text{Na}} \cdot c_{\text{CH}_3\text{I}}.$$

This is the equation of a bimolecular reaction, provided  $\lambda$  does not vary with  $c_{\text{Na}}$  during the course of the change.

This will be so provided that the adjusting equilibrium

proceeds with sufficient rapidity, for from this equation it follows that

$$\lambda / (1 - \lambda) = K \frac{c_{\text{EtOH}}}{c_{\text{H}_2\text{O}}}.$$

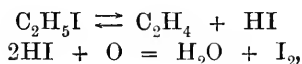

The ratio  $c_{\text{EtOH}} / c_{\text{H}_2\text{O}}$  will, however, remain practically constant during the reaction.

It is possible, therefore, to explain the results obtained by Lobry de Bruyn and Steger in the manner indicated, whereas it is difficult to see how they can be interpreted by the assumption of alkylidene dissociation.

When the alkylene dissociation assumed by Nef is considered, the matter is somewhat different. Both the products of the assumed dissociation are known substances. Moreover, it is difficult otherwise to understand the mechanism whereby olefine is produced, unless we relinquish any attempt to explain this mechanism by the formation of substances which pre-exist in the solution independently of the reagent and simply assume a "tendency" on the part of the alkyl iodide molecule to decompose in a certain way. The assumption of such a tendency, without the presence in the solution of the resulting products, is one which, in the present state of knowledge, eludes all precise treatment.

It is a fact in favour of Nef's assumption of alkylene dissociation that such a change has been actually shown to occur in the case of the heated vapours of alkyl bromides. Thus, for example, Aronstein (*Rec. trav. chim.*, 1880, 1, 134), who has investigated the dissociation of *n*-propyl and *isopropyl* bromides by Victor Meyer's air-displacement method, finds that at 210° these alkyl haloids are dissociated to the extent of 10.4 and 21.1 per cent. respectively. Similarly, Roozeboom (*Ber.*, 1881, 14, 2396) found that at 204° 60 per cent. of *tert.*-butyl

bromide undergoes dissociation. Hence a certain amount of the products of alkylene dissociation must exist in these vapours at every temperature, and therefore also in the liquids. It is possible also that the gradual discoloration of the alkyl iodides may be due to the following reactions :

the latter action being accelerated by light.\*

The chief argument advanced by Nef in support of his theory is the behaviour of the alkyl iodides towards silver nitrate in alcoholic solution. If we employ no solvent or only dry ether, the reaction proceeds normally, according to the usual method for the preparation of esters. If, however, ethyl alcohol is present, free nitric acid, an ether, and in some cases an olefine† are formed, besides silver iodide and the corresponding alkyl nitrate.

Thus methyl iodide gives free nitric acid and methyl ethyl ether; ethyl iodide yields nitric acid, diethyl ether, some ethyl nitrate, and a trace of ethylene. These reactions can be explained on Nef's theory by an alkylidene dissociation.

combined with the reactions

Any alkyl nitrate formed must then be due to the reaction :

Similarly, with propyl and *isopropyl* iodides in ethyl-alcoholic solution, the corresponding ethyl propyl ether and free nitric acid are produced. In the case of *isopropyl* iodide, however, a considerable amount of propylene is formed, which on Nef's theory points to an alkylene dissociation of this substance; this may be compared with the greater alkylene dissociation in the state of vapour of *isopropyl* bromide as compared with *n*-propyl bromide.

In the case of *isobutyl* iodide, it is necessary to assume both alkylene and alkylidene dissociations in order to explain the products of the reaction, which in one experiment were as follows :

\* The bromides, however, exhibit a similar change and in this case an analogous explanation is scarcely admissible.

† In the reaction between silver nitrate and ethyl iodide in aqueous solution, ethyl alcohol and nitric acid are formed besides silver iodide and ethyl nitrate.

	Per cent. of calculated amount.
Free nitric acid.....	46
Ethyl <i>tert.</i> -butyl ether .....	21
Ethyl <i>isobutyl</i> ether.....	5
<i>iso</i> Butyl nitrate.....	16
<i>iso</i> Butylene .....	29

It may be remarked that, from *isobutyl* iodide and alcoholic potash, Nef obtained 99 per cent. of the calculated amount of *isobutylene*, but no ethyl *isobutyl* ether; that is, in the presence of caustic potash there is only alkylene dissociation, whereas in the presence of silver nitrate both types of dissociation occur. But as the function of the caustic potash or silver nitrate according to the above view of the reaction is simply to remove the hydrogen iodide as fast as it is formed, it is difficult to see how the manner of dissociation of the alkyl iodide can be thereby affected.

In spite of this difficulty, it may be said that Nef's theory is the only rational attempt as yet put forward to explain the reaction between the alkyl iodides and silver nitrate in alcoholic solution. Although this reaction appears to be a very complicated one, its careful study from a kinetic standpoint might be expected to throw light on the causes which give rise to the reactivity of the alkyl haloids, and in particular to furnish evidence bearing on the validity of Nef's theory. In 1895, Chiminello (*Gazzetta*, 1895, 25, [ii], 410) described a few experiments which show that in equivalent *N*/20 solutions of ethyl iodide and silver nitrate in alcohol at 0°, the velocity of the reaction obeys the equation  $-dc/dt = kc^2$ . This would seem to point to a bimolecular reaction, which might be explained by assuming that the primary reaction is  $C_2H_5I + AgNO_3 = AgI + C_2H_5 \cdot NO_3$ . On raising the temperature to 10° or 15°, Chiminello found that the above equation was no longer obeyed, the value of the coefficient *k* falling off considerably as the reaction progressed. This he attributes to secondary reactions whereby the alcohol is oxidised to acetic acid\* and aldehyde. With methyl alcohol as solvent, he failed to obtain a constant coefficient in the foregoing velocity-equation, even at 0°.

On the basis of these and some other results, Nef's theory has been unfavourably criticised by E. von Biron (*J. Russ. Phys. Chem. Soc.*, 1900, 30, 667).

Taking the case of ethyl iodide and silver nitrate, we must have, according to Nef, a primary alkylidene dissociation (1) together with three other subsequent reactions (see p. 565). Measuring the velocity by the rate of disappearance of silver nitrate from the solution, we have to deal with reactions (1) and (2). Since (2) is an ionic reaction, it will pro-

\* As will be shown later, no acetic acid is formed under these conditions.

ceed with an incomparably greater speed than (1), hence the velocity measured will be that of reaction (1). But this is a unimolecular reaction; that is, it will obey the equation  $-dc/dt = kc$ , which is not in agreement with Chiminello's results at  $0^\circ$ .

This reasoning may be expressed as follows :

For reaction (1), we have

$$-dc_{\text{EtI}}/dt = k_1 c_{\text{EtI}} \quad . \quad . \quad . \quad . \quad . \quad (a).$$

For reaction (2)

$$-dc_{\text{AgNO}_3}/dt = k_2 c_{\text{AgNO}_3} \cdot c_{\text{HI}} \quad . \quad . \quad . \quad (b).$$

If (2) proceeds very much faster than (1), the value of  $c_{\text{HI}}$  will be extremely small, so that the value of  $c_{\text{EtI}}$  is sensibly equal to that of  $c_{\text{AgNO}_3}$  at every moment. Putting  $c_{\text{EtI}} = c_{\text{AgNO}_3} = c$ , we obtain the equations :

$$-dc/dt = k_1 c \quad . \quad . \quad . \quad . \quad . \quad (c),$$

$$-dc/dt = k_2 c \cdot c_{\text{HI}} \quad . \quad . \quad . \quad . \quad . \quad (d),$$

whence  $c_{\text{HI}}$  possesses the small constant value  $k_1/k_2$ , and equation (d), which is the one we really measure, assumes the same form as (c), that is, the unimolecular form. This argument is, however, inconclusive, because, even although we grant that  $k_2$  is, say, ten thousand times greater than  $k_1$ , the value of  $c_{\text{HI}}$  corresponding with the dissociation-equilibrium,  $\text{C}_2\text{H}_5\text{I} \rightleftharpoons \text{C}_2\text{H}_4 + \text{HI}$ , may very well be extremely small, say ten thousand times smaller than  $c_{\text{EtI}}$ , in which case the velocity of establishment of the above equilibrium may be of the same order of magnitude as the velocity of reaction (2).

A further discussion of this point must be deferred until we come to consider the bearing of the experimental results obtained in the present paper.

The other objections advanced by E. von Biron have no weight, as they are evidently due to a misunderstanding. He forgets that in Nef's theory both alkylene and alkylidene dissociations are supposed to occur, and so considers, as arguments against the theory, the fact that *tert.*-butyl iodide reacts with silver nitrate and that ethyl *iso*-propyl ether is obtained from *isopropyl* iodide, whereas ethyl *n*-propyl ether results from *n*-propyl iodide.

### *Experimental Results.*

The experiments described in this paper were carried out with the object of examining in detail the velocity of reaction between the alkyl iodides and silver nitrate in alcoholic solution.

The ethyl alcohol employed was carefully dehydrated by repeated boiling for many hours with fresh calcium oxide, the reflux condenser

being fitted with a calcium chloride guard-tube. After fractionation from the calcium oxide, it was found necessary to boil the alcohol gently for an hour or two with some silver nitrate, from which it was then finally distilled. Solutions of silver nitrate in alcohol purified in this manner could be kept in the dark for weeks without exhibiting any perceptible formation of silver. If the above precaution was not taken, the alcoholic silver nitrate solutions rapidly assumed a violet colour owing to the reduction of a small quantity of the silver nitrate by some impurity (aldehyde?) contained in the alcohol.

The alkyl iodides were shaken with silver powder, dried over calcium chloride, and fractionated.

Alcoholic solutions of silver nitrate and of the various iodides were prepared of such a strength that when equal volumes of each were mixed the resultant solution would have the required composition. In every case, a total volume of 6 c.c. was employed, 3 c.c. of alcoholic silver nitrate or alkyl iodide solution being separately warmed in the thermostat and then mixed in a small Erlenmeyer flask. In this way, various flasks were prepared and heated for different lengths of time in the thermostat. The flasks were kept tightly corked, and were covered with black cloth to exclude light. To stop the reaction in any flask at a given moment, a measured volume of  $N/100$  ammonium thiocyanate solution was quickly run in, the amount added being always in slight excess of that required to precipitate the whole of the silver remaining in solution. By subsequent titration of this excess of thiocyanate with  $N/100$  silver nitrate, using a ferric indicator, the amount of silver nitrate in the solution at the moment when the reaction was stopped could be readily determined.

The unit of mass employed in the following tables is the amount of silver nitrate contained in 1 c.c. of a  $N/100$  silver nitrate solution. Thus, as 6 c.c. of a  $N/40$  silver nitrate solution contain as much of the salt as 15 c.c. of a  $N/100$  solution, the mass of silver nitrate contained therein is 15. The unit of volume employed is 6 c.c. Hence the concentration of a  $N/40$  silver solution is 15, since it contains 15 of these units of mass per unit volume. It is clear, therefore, that in this system of units the concentration of the solution at any moment is equal to the number of c.c. of  $N/100$  thiocyanate required to precipitate exactly all the contained silver nitrate (since the total volume of the solution was always 6 c.c.).

The concentration of the alkyl iodide is expressed in terms of equivalent units, that is, the unit of mass of any alkyl iodide is the amount which is chemically equivalent to the silver nitrate contained in 1 c.c. of a  $N/100$  silver nitrate solution, chemical equivalence being defined for this purpose by the relation  $RI \equiv AgNO_3$ , where the symbol  $\equiv$  denotes chemical equality or equivalence.

All the experiments described in this paper were carried out at a constant temperature of  $24.5^{\circ}$  (except where otherwise stated). The values of  $k$  given in the following tables were calculated in the case of equivalent solutions by means of the bimolecular velocity equation,  $-dc/dt = kc^2$ , so that  $k = 1/t(1/c - 1/c_0)$ , where  $c_0$  = concentration at the time-zero,  $c$  = concentration at time  $t$  (unit of time = one minute). The time-zero was sometimes the moment of mixing the solutions, sometimes a time-point approximately ten minutes later.

The attempt to obtain the value of *k* for isopropyl iodide under similar conditions proved unsuccessful, owing to the relatively enormous velocity of this reaction. Thus, in *N*/40 solutions at 24.5° only about 2 per cent. of the original amount of silver nitrate remained in solution after 10 minutes. An experiment made with *N*/200 solutions of both isopropyl iodide and silver nitrate at the temperature of the laboratory (17°), which probably did not vary appreciably during the hour required for the determination, gave the following results:

These experiments, which provide us with a series of exact numbers † (velocity-coefficients) representing the reactivities of the alkyl iodides in alcoholic solution, as measured by the reacting silver nitrate, form, in some respects, a remarkably striking contrast to the experiments of Hecht, Conrad, and Brückner, in which the reactivities of the same substances dissolved in the same solvent were determined by a different reagent, namely, sodium ethoxide, but by exactly the same method.

\* This is the "isoamyl iodide" as sold by Kahlbaum.

† See Table 12 (p. 573).

Thus, in the experiments of these investigators, methyl iodide reacts thirteen times as rapidly as ethyl iodide and sixty-seven times as rapidly as *isopropyl* iodide, whereas in the foregoing experiments, ethyl iodide reacts two and a third times as rapidly as methyl iodide, and *isopropyl* iodide at least twenty-two\* times as rapidly. A greater contrast could not well be imagined, nor a better proof produced that no general tables of the reactivities of organic compounds of similar type can be constructed. The order of magnitude of the velocity-

FIG. 2.

coefficients obtained in the above experiments is very peculiar. Considering only the alkyl radicles of normal structure, the results shown graphically in Fig. 2 exhibit, in a striking manner, the anomalous position occupied in the "curve" by methyl iodide. If Nef's theory were established and it could be shown that the alkylene dissociation was the predominating one, or the one which occurred with the greatest velocity, the low value of the velocity-coefficient of

\* If *isopropyl* iodide had been measured in *N*/40 solution, this ratio would be much greater (compare p. 575).

methyl iodide might possibly be explained, since, in this case, an alkylidene dissociation only can occur. But the same difficulty occurs here as that referred to previously, namely, that this argument would apply equally well to the case where sodium ethoxide is the reagent, whereas in this instance methyl iodide is distinguished by a pre-eminently great velocity-coefficient.

Similarly, if we were to attempt to explain the great reactivity of isopropyl iodide in the present case by a relatively great alkylene dissociation or a relatively great velocity of alkylene dissociation, it is not clear why the reactivity of isopropyl iodide towards sodium ethoxide should be relatively so small.\*

Summarising the results obtained, we may say that whilst the reactivities of ethyl, *n*-propyl, *n*-butyl, and isoamyl iodides appear to stand in some sort of regular relation to the relative masses of the alkyl radicles, methyl and isobutyl iodides are characterised by an abnormally low, and isopropyl iodide by an abnormally high reactivity.

In all the preceding experiments, it was found that, after the necessary intervals of time, the whole of the silver was precipitated. In order to prove directly, however, that this precipitate consisted of silver iodide and did not contain any of the double compound of silver iodide and nitrate precipitated in Zeisel's method of estimating alkoxy groups, a weighed quantity of the precipitate obtained in the reaction between  $N/40$  silver nitrate and  $N/40$  ethyl iodide was digested with water and a few drops of nitric acid and then filtered and dried. Its weight was found to be unchanged.

Confirmatory evidence of the complete reaction between the silver and the iodine was obtained in an experiment carried out with propyl iodide, in which, after equivalent quantities of this compound and silver nitrate had been allowed to react, until the solution contained no soluble silver salt, a measured volume of silver nitrate solution of known strength was added, and the flask left for 24 hours in the thermostat. Subsequently, on titrating with thiocyanate, the whole of this silver was found to be present in the solution.

It should also be mentioned that in every case the reaction-mixture became strongly acid (Nef, *loc. cit.*). Reference to this point will be made later (see page 586).

In order to ascertain how far the velocity of the reaction depended on the particular alcohol employed as solvent, a parallel series of experiments was carried out with methyl alcohol. The results are given in the four following tables:

\* Compare also the enormous difference in reactivity between isopropyl and isobutyl iodides (as measured by the above experiments) with their practically equal reactivities towards alcoholic potash as measured by Brussoff (see p. 560). It is difficult to reconcile these results with Nef's theory.

The mean values of the velocity-coefficients in both ethyl and methyl alcohols, together with their ratios, are given in the following table ( $N/40$  equivalent concentration; temperature  $24.5^\circ$ ):

Table 12. Mean values of velocity-coefficients.

Iodide.	$k_{\text{EtOH}}$ .	$k_{\text{MeOH}}$ .	$k_{\text{MeOH}}/k_{\text{EtOH}}$ .
Methyl	0.000935	0.00180	1.92
Ethyl	0.00220	0.00442	2.00
$n$ -Propyl	0.000984	0.00226	2.29
$n$ -Butyl	0.000686	0.00145	2.11
$iso$ Butyl	0.000138	—	—
$iso$ Amyl	0.000565	—	—

The constancy of the ratio  $k_{\text{MeOH}}/k_{\text{EtOH}}$  is noteworthy. As previously noticed by many other observers, the velocity is greater in the medium of higher dissociating power.

It is a well-known fact that the alkyl iodides, when exposed to light, slowly decompose, yielding free iodine which dissolves in the liquid, giving it a yellow or brown colour. With respect to the alcoholic solutions employed in the above experiments, it was observed that a relation appeared to exist between the reactivities as measured in the preceding experiments and the rate of this production of free iodine. Thus, in spite of many precautions, it was not possible to keep alcoholic solutions of *isopropyl* iodide for many days before the above decomposition became manifest, whilst an alcoholic solution of *isobutyl* iodide, which was prepared fifteen months ago and has been exposed to daylight continuously for more than six months, is still absolutely colourless.

In order to examine this interesting point further, a set of test-tubes was prepared containing  $N/20$  solutions of the different iodides in ethyl alcohol. These were securely corked and placed in a row on a table facing a window. On the following day, the solution of *isopropyl* iodide exhibited a faint coloration. The other solutions became coloured in due course in the relative order of their velocity-coefficients, as given in Table 12 or shown graphically on p. 571, with the exception of methyl iodide, which appeared to have a rate of decomposition intermediate between *isopropyl* and ethyl iodides. After six months of exposure to light, the colorations were as follows:

<i>iso</i> Propyl iodide	} Deep brown.	Butyl iodide	} Pale yellow.
Methyl iodide		<i>iso</i> Amyl iodide	
Ethyl iodide ...	} Bright yellow.	<i>iso</i> Butyl iodide	Colourless.
Propyl iodide...			

A comparison of this list with Fig. 2 shows at once that there is a remarkable parallelism between the two phenomena. That these effects are complex is shown, however, not only by the anomalous position of methyl iodide in the above list, but also by the fact that a solution of ethyl iodide in methyl alcohol appears to decompose even more rapidly than the solution of *isopropyl* iodide employed in the above experiments. As already stated (see p. 565), this formation of free iodine may possibly be due to an oxidation of hydrogen iodide, the latter resulting from the dissociation of the iodides. Further experiments on this point are, however, necessary.

So far as the measurements recorded in the foregoing tables go, the reaction between an alkyl iodide and silver nitrate in absolute alcoholic solution appears to be a simple bimolecular one. Were this in reality the case, the result would be of great importance in a discussion of

Nef's theory. As mentioned previously (see p. 566), the experiments of Chiminello have been utilised for this purpose by E. von Biron, although it was shown above that the conclusion arrived at by the latter is not valid, quite apart from the validity of his major premise, namely, that the reaction is, chemically speaking, a bimolecular one. Now, as is well known, in order to prove by kinetic investigations that a given non-reversible reaction is a truly bimolecular one in the chemical sense, it is necessary, not only to show that the velocity-coefficient is constant during the course of a particular reaction, but also that it does not vary with the initial concentration of the reacting mixture, provided that these concentrations are sufficiently small (less than about  $N/20$ ). In the experiments about to be described, the initial concentrations varied from  $N/20$  to  $N/80$ . The results obtained with butyl iodide are given in the following tables:

Table 13.  $N/20$  *n*-butyl iodide ;

$N/50 = 0.0200$	0.00063
$N/80 = 0.0125$	0.00047

The values of  $k$  tabulated in Table 16 are the mean values obtained at different concentrations.

These numbers bring out at once the important fact that the velocity-coefficient of the bimolecular velocity-equation increases very

considerably with increase of initial concentration. The reaction is, therefore, not a simple bimolecular one, that is, its equation is not

$$dx/dt = k(A - x)^2,$$

but

$$dx/dt = k \cdot \phi(A) \cdot (A - x)^2,$$

where  $A$  = initial concentration and  $A - x$  = concentration at the time  $t$ . Hence, although from the chemical standpoint the reaction may still be bimolecular, this can only be proved, or at all events rendered probable, by explaining the variability of  $k$  with the initial concentration. It may be remarked in passing that the increase of  $k$  with increasing concentration does not favour the view that the mechanism of the reaction is connected with dissociation-phenomena.

In considering the law, according to which  $k$  varies with  $c$ , the logarithm of  $k$  was plotted against the logarithm of  $c$  on squared paper, and it was found that of the four points so obtained three lay exactly on a straight line, whilst the point corresponding to the  $N/50$  solution was considerably removed from this line. The obvious interpretation of this result is that some error has crept into this particular measurement, and that the phenomenon is represented by the exponential law,  $k = Kc^n$ . On calculating  $n$  by means of the equation

$$n = \frac{\log k_1 - \log k_2}{\log c_1 - \log c_2},$$

where correlated quantities are indicated by the same numerical suffix, we find the values 0.5272, 0.5299, and 0.5328, the mean of which is 0.53; hence  $k = Kc^{0.53}$ . We thus arrive at the result that the velocity-coefficient is approximately proportional to the square root of the initial (equivalent) concentration.

In order to obtain more data concerning the variation of the velocity-coefficient, and more particularly to ascertain how the variation in question is related to changes in the initial concentrations of each component, systematic experiments were now carried out with ethyl iodide. In the case of solutions not containing silver nitrate and iodide in equivalent concentrations, the value of  $k$  was calculated by means of the equation

$$-dc_1/dt = kc_1c_2.$$

Since the reacting substances disappear simultaneously in equivalent quantities,

$$dc_1 = dc_2, \text{ hence } c = c_1 + K.$$

Therefore

$$-\frac{dc_1}{c_1c_2} = -\frac{dc_1}{c_1(c_1 + K)} = \frac{1}{K} \left( \frac{dc_1}{c_1 + K} - \frac{dc_1}{c_1} \right) = \frac{1}{K} d \log \frac{c_1 + K}{c_1} =$$

$$\frac{1}{K} d \log \frac{c_2}{c_1} = d(kt),$$

whence

$$\frac{1}{K} \log \frac{c_2}{c_1} = kt + \text{const.}$$

Denoting initial concentrations by the suffix  $o$ ,  $\frac{1}{K} \log \frac{c_{02}}{c_{01}} = \text{const.}$ ,

hence

$$\frac{1}{K} \log \frac{c_2 c_{01}}{c_1 c_{02}} = \frac{1}{(c_{02} - c_{01})} \log \frac{c_2 c_{01}}{c_1 c_{02}} = kt. *$$

\* With ordinary logarithms

$$k = \frac{1}{0.4343(c_{02} - c_{01})t} \log \frac{c_2 c_{01}}{c_1 c_{02}}.$$

It is necessary to be careful about this point in comparing non-equivalent with equivalent reaction-mixtures, as in the latter case the formula is not logarithmic.

Table 22. Mean velocity-coefficients for  $C_2H_5I$  and  $AgNO_3$  in ethyl alcohol.

Concentration of $C_2H_5I$ .	Concentration of $AgNO_3$ .	Value of $k$ .
$N/40$	$N/80$	0.00139
$N/80$	$N/80$	0.00150
$N/20$	$N/40$	0.00186
$N/40$	$N/40$	0.00220
$N/80$	$N/40$	0.00231
$N/40$	$N/20$	0.00342

The mean values of the velocity-coefficients are tabulated in table 22, and from this we learn the following facts:

1. In the case of solutions of equivalent initial concentrations, the value of  $k$  increases with increasing initial concentration as in the case of butyl iodide, and in the same ratio. Thus comparing  $N/80$  and  $N/40$  solutions, the ratio of the increase of  $k$  is 1.45 for butyl iodide and 1.46 for ethyl iodide.

2. When the initial concentration of the silver nitrate remains constant ( $N/40$ ) the value of  $k$  increases with diminishing concentration of ethyl iodide. Thus comparing  $N/20$  and  $N/80$  solutions, the ratio of increase is 1.24.

3. When the initial concentration of the ethyl iodide remains constant ( $N/40$ ), the value of  $k$  diminishes with diminishing initial

concentration of silver nitrate. The ratio of change is here very much greater; thus, comparing  $N/20$  and  $N/80$  solutions, the ratio of decrease is 2.46.

It is clear that the variation of  $k$  with the variation of the initial concentrations of the reacting components is chiefly due to the silver nitrate. For, whilst the values of  $k$  are in round numbers proportional to 19, 22, and 23 for constant initial concentration of silver nitrate, the corresponding values for constant initial concentration of ethyl iodide and varying initial concentration of silver nitrate are 14, 22, and 34.

This result throws some light on the inner mechanism of the reaction. For if the silver nitrate were supposed to react with practically infinite velocity on hydrogen iodide (or iodine ions) produced by a comparatively slow primary reaction (as in E. von Biron's interpretation of Nef's theory) then it would be very improbable that the concentration of the silver nitrate should exert such a profound influence on the intrinsic velocity of the whole reaction. It is, in fact, clear that the concentration and hence the molecular state of the silver nitrate in the alcoholic solution plays a very important part in determining the velocity. As regards the relation between the coefficient  $k$  and the initial concentration  $c$  of the silver nitrate (the initial concentration of the ethyl iodide remaining constant), it will be noticed that of the numbers 14, 22, and 34, the second is equal approximately to  $14 + \frac{1}{2} \times 14$  and the third is similarly equal to  $22 + \frac{1}{2} \times 22$ ; that is to say, these values of  $k$  are approximately in geometrical progression. Now the corresponding values of  $c$  are also in geometrical progression. But if two series of correlated numbers are each in geometrical progression, the functional relation between a correlated pair is of the form  $k = Kc^n$ . Applying this equation to calculate  $n$  in the manner indicated previously, the values 0.64 and 0.65 are obtained. The relation between  $k$  and  $c$  in this case approximates, therefore, to the equation  $k = Kc^{\frac{2}{3}}$ .

Hence in those cases where the initial concentration of the ethyl iodide remains constant, whilst that of the silver nitrate varies from  $N/20$  to  $N/80$ , it is found that the velocity of the reaction can be represented by the equation

$$-dc/dt = K\phi(c_{01})c_1^2c_2,$$

where  $c_1$  = concentration of  $\text{AgNO}_3$ ,  $c_2$  = concentration of  $\text{C}_2\text{H}_5\text{I}$ ,  $K$  = a constant, and  $c_{01}$  = initial value of  $c_1$  (as shown above,  $\phi(c_{01}) \equiv \frac{c_1^{\frac{2}{3}}}{c_{01}^{\frac{2}{3}}}$  approximately).

In any particular reaction the concentration of the silver nitrate continuously decreases, passing through the initial values of all reactions commencing with weaker solutions, and it is therefore clear

that the term  $\phi(c_{01})$  can only be regarded as a purely formal representation. In fact, the constancy of the velocity-coefficient in any particular reaction may be mathematically represented by expressing it as a function of  $c_{01}$ , but obviously its constancy cannot be explained by this means, that is to say, by representing it as a function of the initial value of a varying parameter, since so far as the manifold of values of this parameter is concerned, the initial value is of no more importance than any other. In considering whether any other mode of formulation is possible which might subsequently lend itself to chemical interpretation, this expression must satisfy two requirements.

(a) It must coincide mathematically with the foregoing, in order to represent the experimental data.

(b) It must express the velocity-coefficient of any particular reaction as a function of the concentration of some chemical parameter, which remains constant during the particular reaction; but which varies from one case to another if the initial concentration of the silver nitrate varies.

These conditions are both satisfied by writing  $\phi(c_{\text{NO}_3})$  instead of  $\phi(c_{01})$ , where  $c_{\text{NO}_3}$  is taken to be the concentration of the group  $\text{NO}_3$  in the reacting mixture, whether this occurs in  $\text{AgNO}_3$ ,  $\text{C}_2\text{H}_5\cdot\text{NO}_3$ ,  $\text{HNO}_3$ , or as free ion. Since, as will be shown presently, there is no appreciable oxidation of alcohol to acetic acid or aldehyde, the group  $\text{NO}_3$  is conserved in the reaction, and therefore satisfies the first part of condition (b). It is obvious that it satisfies the second part of (b), and as all concentrations are expressed in terms of equivalent units,  $c_{\text{NO}_3} = c_{01}$ , and thus condition (a) is also fulfilled.

The following differential equation,

$$-dc/dt = K\phi(c_{\text{NO}_3})c_1c_2,$$

therefore equally well expresses the results. This second formulation cannot, however, be regarded as standing in a much closer relation to the actual mechanism of the reaction, owing to the peculiar significance attached to  $c_{\text{NO}_3}$ . If no ethyl nitrate were formed, the  $\text{NO}_3$  of the  $\text{AgNO}_3$  all appearing as  $\text{HNO}_3$ , then by supposing the dissociation-constant of the  $\text{AgNO}_3$  to equal that of  $\text{HNO}_3$ , it would follow that  $c_{\text{NO}_3}$  (where this symbol now denotes the concentration of the  $\text{NO}_3$  ion) remains constant in any particular reaction. Since, moreover,  $c_{\text{NO}_3} = F(c_{01})$ , the differential equation might be written as

$$-c/dt = Kf(c_{\text{NO}_3})c_1c_2.$$

If the form of  $F(c_{01})$  were known, that of  $f(c_{\text{NO}_3})$  would at once be found, at least approximately, since  $\phi(c_{01})$  is roughly equal to  $Kc_1^2$ .

Any such formulation would be, however, of little interest, even

if the assumptions involved were well-founded, unless the form of the function  $f(\text{CNO}_3)$  could be reconciled with some probable (or at least possible) mode of reaction between the constituents. It has not, however, been found possible to find any hypothesis which yields an equation of the form given by the experimental results. Even the assumption that the primary reaction determining the speed is one between silver and iodine ions will not apparently explain the observed results.

This constancy of the bimolecular velocity-coefficient in any particular case, and its variation with change of initial concentration have been observed also by Hecht, Conrad, and Brückner in the case of the ether-formation already mentioned (*Zeit. physikal. Chem.*, 1890, 5, 289). Calling  $v$  the reciprocal of the initial equivalent concentration of the reaction-mixture, they found their results were well represented by the formula  $k_n = k_1 + a \log v$ , where  $a$  is independent of concentration. Suspecting that the cause might be the influence of the reaction products (ether and sodium iodide), they made experiments in which certain amounts of these were added to the reaction-mixture from the start, but found that the velocity-coefficients were not appreciably affected. They also found in different experiments, in which the initial alkyloxide concentration was the same, but the initial alkyl iodide concentration varied, the same value for the velocity-coefficient, showing that the variation in  $k$  must be due to changes in the molecular condition of the alkyloxide. In fact, they give numbers which support the view that the increase of  $k$  with increasing dilution would seem to point to an electrolytic dissociation of the alkyloxide. The reaction has been discussed from the ionic standpoint by Steger (*Rec. trav. chim.*, 1899, 18, 13).

On the supposition that  $\text{C}_2\text{H}_5 \cdot \text{ONa}$  is dissociated into  $\text{C}_2\text{H}_5 \cdot \bar{\text{O}}$  and  $\text{Na}^+$ , and that it is the  $\text{C}_2\text{H}_5 \cdot \bar{\text{O}}$  ions which react to form ether, the constancy of  $k$  in any particular case can be explained, provided the assumption is made that the sodium iodide is dissociated to the same extent as the sodium ethoxide. Steger quotes the results of conductivity experiments obtained by Carrara (*Gazzetta*, 1896, 26, i, 119) which support this assumption.

If the reaction is one of ionic nature, as supposed by Steger, it should follow that the velocity-coefficient would be diminished by adding sodium iodide to the reacting mixture, contrary to the results obtained by Hecht, Conrad, and Brückner. Steger, however, shows that by working in more dilute solution, the velocity-coefficient is actually diminished by the addition of sodium iodide.

Taking all these facts into account, there is therefore considerable qualitative evidence that the ionisation of the alkyloxide plays an

essential part in the reaction. The question cannot, however, be regarded as settled yet, nor is the matter by any means so simple as might appear from the above remarks.

The anomalies observed in the case of ether-formation from alkyl-oxide and alkyl iodide are in so many respects similar to those which occur in the reaction between silver nitrate and ethyl iodide that a discussion of the validity of Steger's theory is of extreme importance. Now Steger's theory necessarily involves some assumption as to the law obeyed by the ionisation of salts in absolute alcohol. In the first instance, it is assumed that the ordinary law of mass action holds good. The reaction, the velocity of which determines the speed, is

$$\text{C}_2\text{H}_5\cdot\bar{\text{O}} + \text{C}_2\text{H}_5\text{I} = \text{C}_2\text{H}_5\cdot\text{O}\cdot\text{C}_2\text{H}_5 + \bar{\text{I}}^*$$

The ionic equilibria,

$$\text{Na}^+ + \text{C}_2\text{H}_5\cdot\bar{\text{O}} = \text{C}_2\text{H}_5\cdot\text{ONa} \quad \text{and} \quad \text{Na}^+ + \bar{\text{I}} = \text{NaI},$$

being supposed to readjust themselves with relatively very great velocity, lead to the equations:

$$kc_u = c_{\text{Na}} \cdot c_{\text{OEt}} \dots\dots\dots (1)$$

$$kc'_u = c_{\text{Na}} \cdot c_{\text{I}} \dots\dots\dots (2)$$

where  $c_u$  = concentration of undissociated sodium ethoxide

$c'_u$  = " " " " sodium iodide.

The condition of electrical equivalence gives the equation

$$c_{\text{I}} + c_{\text{OEt}} = c_{\text{Na}} \dots\dots\dots (3)$$

Denoting by  $c_i$  the initial concentration of total ethoxide,

$$c_u + c'_u + c_{\text{Na}} = c_i \dots\dots\dots (4)$$

Denoting by  $c_s$  the total quantity of ethoxide at any moment (as determined by titration with acid),

$$c_u + c_{\text{OEt}} = c_s \dots\dots\dots (5)$$

$$\text{From (1), (2), and (3), } c_u + c'_u = \frac{c_{\text{Na}}^2}{k}.$$

Substituting in (4), one obtains  $c_{\text{Na}}^2 + kc_{\text{Na}} = kc_i$ ,

$$\text{whence } c_{\text{Na}} = \frac{1}{2}(\sqrt{4kc_i + k^2} - k) \dots\dots (6)$$

\* By writing the reaction equation in this form, we avoid any assumption as to a possible ionisation of the ethyl iodide. Such an ionisation may occur, but there is not as yet any experimental proof of it (compare Lobry de Bruyn and A. Steger, *Rec. trav. chim.*, 1899, 18, 325).

From (1) and (5),

$$c_s = c_{\text{OEt}} + \frac{c_{\text{Na}} \cdot c_{\text{OEt}}}{k}$$

Substituting in this equation the value of  $c_{\text{Na}}$  from (6), the following

$$\text{equation is obtained: } c_{\text{OEt}} = 1 + \frac{2c_s}{\sqrt{1 + 4c_i/k}} \dots\dots\dots (7)$$

It follows from (7) that in any particular reaction, that is, for any given value of  $c_i$ , the ratio  $c_{\text{OEt}}/c_s$  remains constant. It also follows that the smaller is  $c_i$  the greater will be the value of  $c_{\text{OEt}}$  for any given value of  $c_s$ .

The velocity of the reaction may now be considered. As  $\text{C}_2\text{H}_5\text{O}^-$  and  $\text{C}_2\text{H}_5\text{I}$  are the reacting constituents, the fundamental velocity-

$$\text{equation will be } -\frac{dc_{\text{OEt}}}{dt} = Kc_{\text{OEt}} \cdot c_{\text{EtI}} \dots\dots\dots (8)$$

This transforms, however, by means of (7) into

$$-\frac{dc_s}{dt} = Kc_s \cdot c_{\text{EtI}} \dots\dots\dots (9)$$

Equation (9) expresses the velocity in terms of the quantities which are actually measured.\* But since its velocity-coefficient does not involve  $c_i$ , it cannot explain the observed facts. Hence the ionic theory of the reaction proposed by Steger does not lead any further towards an explanation, if the form of the equation of equilibrium given by the ordinary law of mass action is assumed.

The question then arises as to whether any form of the equation of equilibrium would satisfy the requirements of the case.

In order that equation (8) should transform into an equation of the form (9), it is clearly necessary that

$$\frac{d \log c_{\text{OEt}}}{dt} = \phi_1(k, c_i) \frac{d \log c_s}{dt},$$

the solution of which is

$$c_{\text{OEt}} = c_s^{\phi_1(k, c_i)} \cdot \phi_2(k, c_i) \dots\dots\dots (10)$$

If this relation holds, then (8) transforms into

$$-\frac{dc_s}{dt} = \frac{K}{\phi_1} \cdot c_s c_{\text{EtI}} \dots\dots\dots (11)$$

\* Since, in determining total dissolved ethoxide by titration with hydrochloric acid, the reaction occurring is  $\text{EtO}^- + \text{H}^+ = \text{EtOH}$ ,

Equation (11) is not necessarily incompatible with the observed facts. Hence any law of equilibrium leading to a relation between  $c_{\text{OEt}}$  and  $c_s$  of the form (10) (provided  $\phi_1$  does not reduce to a constant) might possibly explain the given facts. According to the results of Hecht,

Conrad, and Brückner,  $\frac{K}{\phi_1} = k' + a \log v = k' - a \log c_i$ , hence one

can write  $\phi = \frac{a}{b - c \log c_i}$  where  $a$ ,  $b$ , and  $c$  are independent of concentration. The relation between  $c_s$  and  $c_{\text{OEt}}$  must then have the form

$$c_{\text{OEt}} = c_s^{\frac{a}{b - c \log c_i}} \cdot \phi_2(c_i).$$

It is possible that some of the newer forms of the equations of ionic equilibrium (compare Nernst, *Zeit. physikal. Chem.*, 1901, 38, 487) might lead to a relation of this sort, but it does not seem very probable. As the molecular conductivities of sodium ethoxide in alcohol have been measured by Tijmstra (*Proc. Roy. Acad. Sci. Amsterdam*, 1903, 104) and those of sodium iodide in alcohol by Völlmer (*Wied. Annalen*, 1894, 52, 328), the material for such a calculation is available.

When we attempt to apply a similar ionic explanation to the reaction between the alkyl iodides and silver nitrate, we are met by still more serious difficulties. In this case, the velocity-coefficient decreases with diminishing initial concentration, whereas it increases in the case of ether-formation. And this occurs notwithstanding the fact that the molecular conductivity of silver nitrate dissolved in ethyl alcohol increases with diminishing concentration, as shown by Völlmer (*loc. cit.*).

The decrease of the velocity-coefficient with decrease of initial concentration might suggest the idea that it is the undissociated silver nitrate molecules which take part in the primary reaction. Völlmer found that the molecular conductivity of solutions of silver nitrate in alcohol could be represented by the formula

$$\lambda_c = a / (1 + \beta c^{\frac{1}{2}} + \gamma c^{\frac{3}{2}}),$$

where  $a = 354$ ;  $\beta = -0.443$ ;  $\gamma = 26.3$ ; and  $c$  = concentration in gram-molecules per litre.

Assuming that the ratio  $\lambda_c/\lambda_0$  gives a measure of the dissociation  $x$ , it follows from Völlmer's formula that

$$x = \frac{1}{1 + \beta c^{\frac{1}{2}} + \lambda c^{\frac{3}{2}}}$$

and hence

$$1 - x = \frac{\beta c^{\frac{1}{2}} + \lambda c^{\frac{3}{2}}}{1 + \beta c^{\frac{1}{2}} + \lambda c^{\frac{3}{2}}}$$

$$\text{and} \quad c(1-x) = \frac{\beta c^{\frac{1}{2}} + \lambda c^{\frac{5}{2}}}{1 + \beta c^{\frac{1}{2}} + \lambda c^{\frac{5}{2}}}.$$

On making this calculation, it will be found that the values of  $c(1-x)$  (the initial concentration of undissociated silver nitrate) for the  $N/20$ ,  $N/40$ , and  $N/80$  solutions, that is, for the values  $c=0.05$ ,  $c=0.025$ , and  $c=0.0125$ , are proportional to the numbers 0.773, 0.3397, and 0.1419. These numbers are, however, very far from being proportional to the corresponding velocity-coefficients, 0.00342, 0.00220, and 0.00139. A weak point in the above argument lies, however, in the assumption  $x=\lambda_c/\lambda_0$ . All that can be said, therefore, is that it has not been found possible as yet to explain the abnormal results obtained by arguments derived from the theory of electrolytic dissociation.

Moreover, as it has not been possible to elucidate the inner mechanism of the reaction, the experimental results do not necessarily justify the view that the reaction is a chemically bimolecular one. The formula \*

$$n = \log \frac{t_2 - t_{02}}{t_1 - t_{01}} / \log \frac{c_{01}}{c_{02}},$$

where  $n$  = order of the reaction;  $c_{01}$ ,  $c_{02}$  = initial concentrations of two equivalent reaction-mixtures;  $t_{01}$ ,  $t_{02}$  = corresponding initial times;  $t_1$ ,  $t_2$  = times at which the same proportionate change has taken place in each solution, cannot be employed here, since the velocity-coefficient is a function of the initial concentration. For example, if the time-concentration curves for  $N/40$  and  $N/80$  equivalent solutions be plotted, they will be found to cross each other.†

In order to ascertain how far the presence of small quantities of water might exert a disturbing effect on the numbers obtained, a special experiment was made with a composite solvent consisting of alcohol (90 per cent.) and water (10 per cent.). The results are given in Table 23.

\* It may be remarked that if this formula is nevertheless applied to the time-concentration curves for  $N/40$  and  $N/80$  equivalent solutions, it gives  $n=2.4$  for the case of ethyl iodide and  $n=2.3$  to  $n=2.6$  for the case of  $n$ -butyl iodide (mean value,  $n=2.47$ ).

† In view of the negative nature of the above result, it may be worth while to point out that, although we have not succeeded in elucidating the mechanism of the reaction, the final products of the reaction may be explained just as well by the following equations as by Nef's theory: (a)  $C_2H_5 \cdot OH = C_2H_5 \cdot \bar{O} + \bar{H}^+$ , (b)  $C_2H_5 \cdot \bar{O} + C_2H_5I = C_2H_5 \cdot O \cdot C_2H_5 + \bar{I}^+$ , (c)  $\bar{Ag} + \bar{I} = AgI$ .

TABLE 23.  $N/40$   $C_2H_5I$ ;  $N/40$   $AgNO_3$ ; ethyl alcohol, 90 per cent.; water, 10 per cent.

$$\text{Mean} = 0\cdot00236$$

The mean value for absolute alcohol at the same temperature is 0·00220. We see, therefore, that 10 per cent. of water produces only a comparatively small increase in the value of  $k$ . There is no fear, therefore, of the results communicated in this paper having been modified by the entrance of small quantities of water into the stock of dehydrated alcohol employed for the experiments.

In this connection, another experiment was made in order to determine the effect produced on the velocity of the reaction by the addition of 10 per cent. of dry benzene (Table 24).

Table 24.  $N/40$   $C_2H_5I$ ;  $N/40$   $AgNO_3$ ; ethyl alcohol, 90 per cent., benzene, 10 per cent.

117·00	3·20	0·00210

---

$$\text{Mean} = 0\cdot00205$$

The non-dissociating solvent, benzene, thus produces a decrease in the value of  $k$ .

As remarked previously, the reaction-mixture always became strongly acid during the experiments recorded in this paper. According to Nef, this acid is nitric, but Chiminello implies that acetic acid is formed. As the present experiments were carried out at a much lower

temperature and with much more dilute solutions than those of Nef, it was considered advisable to ascertain whether the products of reaction were substantially those described by him. It may be said at once that such was found to be the case.

A large volume of an equivalent  $N/20$  mixture of ethyl iodide and silver nitrate in dry ethyl alcohol was prepared and allowed to remain in the thermostat at  $24.5^{\circ}$  until all the silver was precipitated. On opening the flask, a strong odour of ether was apparent, and the presence of a very small trace of aldehyde could be detected by Schiff's reagent. As no acid except nitric could be found by qualitative tests, 200 c.c. of the filtered solution were neutralised with sodium hydroxide, and the solution evaporated to dryness. A careful examination of the residue failed to detect the presence of acetate.

Thirty c.c. of the filtered reaction-mixture required 10.5 c.c. of  $N/10$  sodium carbonate solution for neutralisation (using methyl-orange).<sup>\*</sup> On the assumption that this acidity is all due to nitric acid, it follows that 70 per cent. of the "theoretical" amount of ethyl nitrate must exist as nitric acid (and ordinary ether).

The quantitative estimation of this nitric acid was then made in the following manner: 200 c.c. of the filtered alcoholic solution were shaken with an excess of dry barium carbonate, until the solution ceased to be acid towards methyl-orange. The precipitated barium salts were filtered off, washed with absolute alcohol, and then treated with boiling water and the barium carbonate collected. The aqueous filtrate and washings were then evaporated to dryness in a weighed platinum basin. In this way, 0.9162 gram of barium salt was obtained, which agrees well with 0.9142, the quantity of barium nitrate calculated from the acidity of the solution. The barium salt thus produced was then decomposed in the nitrometer with mercury and strong sulphuric acid, and found to correspond with 99 per cent. of barium nitrate as compared with a control experiment with the pure recrystallised nitrate.

In order to prove the presence of ethyl nitrate in the reaction-mixture, about 450 c.c. were neutralised with solid barium carbonate, filtered, and distilled; the first fraction had a strong odour of ether, whilst the last, after saponification with caustic potash, was found to contain potassium nitrate. No appreciable residue remained in the distilling flask, thus proving the absence of any barium salt soluble in alcohol which might have been formed from the free acid. It is thus conclusively shown that nitric acid is the only acid produced under the conditions of the experiments described in this paper, the other products being ether, ethyl nitrate, and a trace of aldehyde.

<sup>\*</sup> Neither a sharp end-point nor concordant results could be obtained by using barium hydroxide solution and phenolphthalein.

*Summary of Conclusions.*

The main conclusions arrived at in this paper may be summarised as follows :

1. The reaction between silver nitrate and an alkyl iodide in absolute alcohol at  $25.4^{\circ}$  and at concentrations varying from  $N/20$  to  $N/80$  can be expressed by a special form of the bimolecular velocity-equation, in which the velocity-coefficient is a function of the initial concentrations of the reacting components.

2. It is found that in solutions containing the reagents in equivalent amounts, the velocity-coefficient  $k$  increases with the initial molecular concentration  $c$ , the relation between  $k$  and  $c$  being  $k = Kc^{0.53}$ , where  $K$  is independent of concentration.

3. This variation of  $k$  is chiefly due to the silver nitrate. For solutions containing the same  $N/40$  initial concentration of ethyl iodide, and varying ( $N/20$  to  $N/80$ ) initial concentration  $c$  of silver nitrate, the relation between  $k$  and the latter is approximately  $k = Kc^3$ . For solutions containing the same initial concentration of silver nitrate, and varying initial concentration of ethyl iodide, the value of  $k$  decreases as the latter increases, but the rate of decrease is relatively small as compared with the rate of increase produced by silver nitrate.

4. It has not been found possible to explain the variation of  $k$  referred to in 1, 2, and 3. In particular, the assumption that it is the silver ions which take part in the fundamental reaction which regulates the speed does not appear to offer a simple explanation.

5. Similar anomalies have been observed by Hecht, Conrad, and Brückner in the case of ether-formation from sodium alkyloxide and alkyl iodide in alcoholic solution, but the explanation of these anomalies proposed by Steger, based on assumptions concerning the ionisation of the sodium alkyloxide and alkyl iodide in alcoholic solution, does not appear to hold good if the ordinary law of equilibrium is assumed.

6. The theory of alkylene and alkylidene dissociation of the alkyl iodides, proposed by Nef, does not appear to give a satisfactory account of the observed results.

7. The only acid produced in the reaction is nitric, as stated by Nef. Chiminello's statement that acetic acid is formed appears to be incorrect. The other products of the reaction are ether and alkyl nitrate, as stated by Nef.

8. If the reactivities of the alkyl iodides are measured by the velocity-coefficients of the reaction with silver nitrate in absolute alcohol ( $N/40$  equivalent solutions at  $24.5^{\circ}$ ), the order (beginning

with the greatest) is *isopropyl*, *ethyl*, *n-propyl*, *methyl*, *n-butyl*, *isoamyl*, *isobutyl*.

9. This order of reactivities corresponds with the rate of production of free iodine in the alcoholic solutions when exposed to air and light, with the single exception of methyl iodide, the solution of which becomes discoloured at a rate between those of *isopropyl* and *ethyl* iodides.

10. The relative reactivities referred to in (8) do not agree in many respects with those observed in other reactions which have been studied kinetically, such as the reactions with *ethyl sodioacetoacetate* (Wislicenus), *triethylamine* (Menschutkin), *sodium alkyl oxide* (Hecht, Conrad, and Brückner). Compared with these results, *isopropyl iodide* reacts with abnormally great, *methyl iodide* with abnormally small velocity. It does not appear possible, therefore, to ascribe the reactivity of the alkyl haloids to any uniform cause (such, for example, as a dissociation, whether "alkylidene," "alkylene," or electrolytic).

11. So far as the final products and not the kinetics of the reaction are concerned, the production of ether and nitric acid can be accounted for by ionic reactions just as well as by Nef's hypothesis.

The experiments described in this paper are being extended in several directions, for example, to other alkyl and aryl iodides and bromides, and especially to solutions of the alkyl haloids in composite solvents, such as aqueous alcohol.

In conclusion, our best thanks are due to Professor Sir William Ramsay, who suggested the research and whose valuable advice and assistance were constantly at our disposal.

LVII.—*Isomeric Change of Diacylanilides into Acyl-aminoketones. Transformation of the Dibenzoyl-toluidines into the Isomeric Benzoylaminomethylbenzophenones.*

By FREDERICK DANIEL CHATTAWAY and WILLIAM HENRY LEWIS.

It has been shown recently (this vol., p. 386) that acyl groups must be included among those which, under suitable conditions, can pass from the nitrogen of an aromatic amine into the nucleus, thereby displacing a hydrogen atom in a para- or an ortho-position relatively to the nitrogen.

An excellent illustration of this intramolecular rearrangement in the diacylanilides is furnished by the behaviour of the dibenzoyl-toluidines, which, at a high temperature under the influence of hydrogen chloride, are converted into the isomeric benzoylamino-methylbenzophenones, thus :

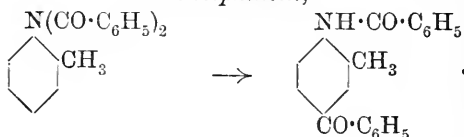

In the transformation of dibenzoyl-*o*-toluidine, where a para- and an ortho-position are unoccupied, the benzoyl group apparently takes up exclusively a para-position with respect to the nitrogen, whilst in the transformation of dibenzoyl-*p*-toluidine an ortho-position is assumed, this being the only vacant position into which the migrating group can enter.

As in the analogous intramolecular rearrangement of the acylchloroamines, interchange between a para-hydrogen atom and the acyl group takes place more readily than that in which an ortho-hydrogen is concerned.

The properties of the aminomethylbenzophenones produced are exactly those which might have been predicted from our knowledge of the properties of the *o*- and *p*-aminobenzophenones obtained by the intramolecular rearrangement of dibenzoylaniline. For example, the compound in which the benzoyl group occupies the ortho-position relatively to the nitrogen has a bright yellow colour, is volatile in steam, and has a low melting point, whilst the isomeride in which the benzoyl group is in the para-position is almost colourless, is not volatile in steam, and melts at a much higher temperature.

*Transformation of Dibenzoyl-o-toluidine into Benzoyl-4-amino-5-methylbenzophenone,*

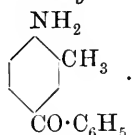

The authors have proved that when the benzoyl derivative of either *o*- or *p*-toluidine is heated with benzoyl chloride, the hydrogen chloride

formed being removed, the dibenzoyl derivative of the base is produced. It is unnecessary, however, to isolate these derivatives in order to study their transformation, as the hydrogen chloride acts as a catalyst and brings about the intramolecular rearrangement. The following procedure gave a good result.

*o*-Toluidine (1 mol.) was added gradually to the equivalent quantity of benzoyl chloride (2 mols.) and the whole gradually heated in an oil-bath up to 220—230°, this temperature being maintained for about 15 hours. A brown, viscid liquid was produced, which solidified on cooling to a hard, resinous mass. The benzoyl-4-amino-3-methylbenzophenone can be isolated from this product with some difficulty, but it is best to hydrolyse it, as the corresponding base can be much more readily separated. The whole mass was therefore dissolved in excess of alcohol containing about half its bulk of concentrated hydrochloric acid, and heated to boiling for 14 hours. A rapid current of steam was then blown through the liquid, when alcohol and ethyl benzoate distilled over successively. The strongly acid residue was then boiled for some time with a quantity of water, and the hot solution containing the hydrochlorides of the bases present filtered from the brown, tarry matter which is always formed in considerable amount in the transformation. The filtrate was next made slightly alkaline with caustic soda and again distilled in steam. A little *o*-toluidine (about 10 per cent. of that used), derived from untransformed dibenzoyl-*o*-toluidine, first passed over. On continuing the distillation, a perfectly colourless\* distillate was obtained, showing that no appreciable transference of the benzoyl group into the vacant ortho-position had taken place. After cooling, the solid separating from the alkaline liquid in the distillation flask was filtered off and extracted with alcohol. This alcoholic solution was evaporated to a small bulk, and a few drops of strong sulphuric acid added; on diluting with a little ether, the almost pure base crystallised in colourless needles. It can be obtained perfectly pure by one recrystallisation from water slightly acidified with sulphuric acid. The yield, which is about 50 per cent. of the weight of *o*-toluidine used, can be slightly increased by adding a small quantity of dry powdered zinc chloride to the mixture of benzoyl chloride and *o*-toluidine before heating.

\* A brilliant yellow colour and volatility in steam are among the most characteristic properties of *o*-aminobenzophenone and its homologues, and a very small quantity of these ketones can be recognised by the yellow colour of the distillate.

## 4-Amino-3-methylbenzophenone,

This compound is very sparingly soluble in hot water, but readily so in alcohol; it crystallises from boiling water in glistening, transparent, flattened prisms, almost colourless, but showing a faint yellow tint. The hot aqueous solution shows a distinct pale yellow colour. From its solution in alcohol, which has a deep yellow colour, the base separates in very pale yellow, flattened prisms with domed ends; it melts at  $112^\circ$ .

0.2224 gave 0.6502  $\text{CO}_2$  and 0.1244  $\text{H}_2\text{O}$ .  $\text{C} = 79.73$ ;  $\text{H} = 6.26$ .

0.3016 „ 17.6 c.c. nitrogen at  $15^\circ$  and 732 mm.  $\text{N} = 6.69$ .

$\text{C}_{14}\text{H}_{13}\text{ON}$  requires  $\text{C} = 79.57$ ;  $\text{H} = 6.21$ ;  $\text{N} = 6.65$  per cent.

The base readily dissolves in hot dilute sulphuric acid, forming a sparingly soluble sulphate,  $2\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3(\text{CH}_3) \cdot \text{NH}_2, \text{H}_2\text{SO}_4$ , which crystallises out on cooling the solution in glistening, transparent, colourless plates. When heated rapidly, the sulphate softens and begins to decompose at about  $105$ — $110^\circ$ .

0.2663 yielded 0.1192  $\text{BaSO}_4$ .  $\text{SO}_4 = 18.42$ .

$2\text{C}_{14}\text{H}_{13}\text{ON}, \text{H}_2\text{SO}_4$  requires  $\text{SO}_4 = 18.46$  per cent.

It also dissolves readily in warm concentrated hydrochloric acid, forming a sparingly soluble chloride,  $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3(\text{CH}_3) \cdot \text{NH}_2, \text{HCl}$ , which crystallises from the cooled solution in thin, colourless, transparent, four-sided plates. On heating rapidly, the chloride reddens strongly, and melts with decomposition at about  $215$ — $220^\circ$ .

0.2624 yielded 0.1520  $\text{AgCl}$ .  $\text{Cl} = 14.32$ .

$\text{C}_{14}\text{H}_{13}\text{ON}, \text{HCl}$  requires  $\text{Cl} = 14.32$  per cent.

A number of derivatives of this base and of its isomeride have been prepared, either by the action of the corresponding acyl chloride or anhydride, or by condensing the base with methyl or ethyl chloro-carbonate. As a rule, equivalent quantities were heated together for a short time on the water-bath, the acid liberated being then removed by warming with a dilute solution of potassium hydrogen carbonate. The solid product was repeatedly crystallised from alcohol. In preparing the acetylchloroamino-derivatives, the acetyl compound was dissolved in alcohol and the solution shaken with a well-cooled slightly acid solution of bleaching powder. To complete the conversion, the

product was extracted with chloroform, and the solution repeatedly shaken with cold, freshly prepared bleaching powder solution slightly acidified with acetic acid. Finally, the chloroform solution was separated, dried over calcium chloride, and the solvent driven off in a current of dry air.

*Acetyl-4-amino-3-methylbenzophenone,*

crystallises from alcohol, in which it is readily soluble in glistening, transparent, flattened rhombs or rhombic plates melting at  $175^\circ$ .

*Acetyl-4-chloroamino-3-methylbenzophenone,*

is very soluble in chloroform, but dissolves only sparingly in light petroleum; it crystallises from the latter solvent in small, colourless, slender prisms melting at  $110^\circ$ .

0.2080 liberated I = 14.3 c.c. *N*/10 I. Cl (as NCl) = 12.18.

$\text{C}_{16}\text{H}_{14}\text{O}_2\text{NCl}$  requires Cl (as NCl) = 12.32 per cent.

*Propionyl-4-amino-3-methylbenzophenone,*

is readily soluble in alcohol, from which it crystallises in colourless, silky, needle-shaped crystals (m. p.  $128^\circ$ ).

0.4120 gave 19.2 c.c. nitrogen at  $17^\circ$  and 758 mm. *N* = 5.50.

$\text{C}_{17}\text{H}_{17}\text{O}_2\text{N}$  requires *N* = 5.25 per cent.

*Benzoyl-4-amino-3-methylbenzophenone,*

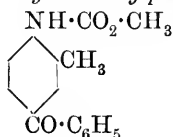

crystallises from alcohol in glistening, colourless, transparent prisms with domed ends which melt at  $158^\circ$ .

0.3632 gave 13.6 c.c. nitrogen at  $16^\circ$  and 752 mm. *N* = 4.40.

$\text{C}_{21}\text{H}_{17}\text{O}_2\text{N}$  requires *N* = 4.45 per cent.

*Methyl 4-Benzoyl-2-methylphenylcarbamate,*

This substance crystallises from alcohol, in which it is very readily soluble, in clusters of transparent, colourless, glistening plates (m. p.  $107^\circ$ ).

0.3051 gave 13.2 c.c. nitrogen at  $14^\circ$  and 756 mm. *N* = 5.14.

$\text{C}_{16}\text{H}_{15}\text{O}_3\text{N}$  requires *N* = 5.22 per cent.

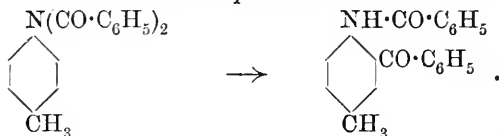

*Ethyl 4-Benzoyl-2-methylphenylcarbamate,*  
 $\text{C}_6\text{H}_5 \cdot \text{CO} \cdot \text{C}_6\text{H}_3(\text{CH}_3) \cdot \text{NH} \cdot \text{CO}_2 \cdot \text{C}_2\text{H}_5,$

This compound is very soluble in chloroform and alcohol, sparingly so in light petroleum; it crystallises from the latter in small, slender, glistening, transparent, colourless prisms (m. p.  $88^\circ$ ).

0.2480 gave 10.2 c.c. nitrogen at  $15^\circ$  and 758 mm.  $N = 4.88$ .

$\text{C}_{17}\text{H}_{17}\text{O}_3\text{N}$  requires  $N = 4.96$  per cent.

*Transformation of Dibenzoyl-p-toluidine into Benzoyl-2-amino-3-methyl benzophenone.*

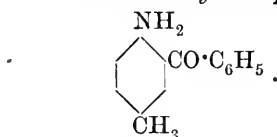

*p*-Toluidine (1 mol.) was added gradually to the equivalent quantity of benzoyl chloride (2 mols.) and the whole gradually heated in an oil-bath to  $220$ — $230^\circ$ , this temperature being maintained for about 15 hours. A brown, viscid liquid was produced which solidified on cooling to a yellowish-brown, semi-crystalline mass; this was hydrolysed by heating for 14 hours with excess of a mixture of alcohol and strong hydrochloric acid, and the alcohol and ethyl benzoate expelled in a rapid current of steam. The acid liquid in the distilling flask was then filtered while hot from the considerable amount of viscid, tarry matter produced, and the latter was several times extracted with boiling dilute hydrochloric acid. The mixed filtrates containing the hydrochlorides of the bases were then made slightly alkaline with caustic soda and again distilled in steam. At first, *p*-toluidine, derived from the untransformed dibenzoyl derivative, passed over; a clear, bright yellow distillate was then obtained from which 2-amino-3-methylbenzophenone separated in deep yellow, oily drops which soon solidified.

The *o*-aminoketone only comes over very slowly in steam, and the distillation must be continued for many hours until the distillate is no longer yellow. The compound is obtained perfectly pure by one crystallisation from alcohol, in which it is very easily soluble. The yield amounts to about 20 per cent. of the weight of *p*-toluidine used. The transference of the benzoyl group from the nitrogen to the ortho-position in the ring does not appear to take place so readily as the corresponding migration into the para-position when the latter is vacant, and resembles in this respect the analogous transference of a

halogen atom. Corresponding with this greater difficulty of transformation, a larger percentage of the toluidine used is recovered, and a larger amount of tarry matter, which appears to be the only other product obtained in the transformation, is also formed. As before, a little zinc chloride may be added with advantage, as this appears to facilitate the transformation.

*2-Amino-3-methylbenzophenone,*

This compound crystallises from alcohol in long, transparent, brilliant yellow, four-sided, rhombic prisms terminated by basal faces. It is very easily soluble in alcohol, chloroform, or acetone, sparingly so in petroleum or water. It is intensely coloured, and a very small quantity gives a distinct pure yellow colour to a large bulk of any solvent. It melts at 66°.

0.2364 gave 0.6884 CO<sub>2</sub> and 0.1320 H<sub>2</sub>O. C = 79.42; H = 6.25.

0.3192 „ 17.8 c.c. nitrogen at 13° and 749 mm. N = 6.59.

C<sub>14</sub>H<sub>13</sub>ON requires C = 79.57; H = 6.21; N = 6.65 per cent.

The base dissolves readily in dilute sulphuric acid, forming a colourless, very soluble sulphate. It also dissolves easily in warm dilute hydrochloric acid, forming a colourless solution from which the hydrochloride C<sub>6</sub>H<sub>5</sub>·CO·C<sub>6</sub>H<sub>3</sub>(CH<sub>3</sub>)·NH<sub>2</sub>·HCl separates on cooling in colourless, transparent, flattened prisms which partially decompose and become yellow on washing with water or alcohol, owing to the liberation of the base, but are permanent in dry air. The hydrochloride, when heated rapidly, reddens and melts with decomposition at about 195—197°.

0.3400 gave 0.1988 AgCl. Cl = 14.46.

C<sub>14</sub>H<sub>13</sub>ON, HCl requires Cl = 14.32 per cent.

*Acetyl-2-amino-3-methylbenzophenone,*

crystallises from alcohol in large, colourless, four-sided, rhombic plates (m. p. 159°).

0.2259 gave 10.7 c.c. nitrogen at 13° and 752 mm. N = 5.62.

C<sub>16</sub>H<sub>15</sub>O<sub>2</sub>N requires N = 5.55 per cent.

*Acetyl-2-chloroamino-5-methylbenzophenone,*

is very soluble in chloroform, moderately so in warm light petroleum,

from which it crystallises in colourless, transparent, four-sided plates (m. p. 116°).

0.2668 liberated I = 18.7 c.c. N/10 I. Cl (as NCl) = 12.42.

$C_{16}H_{14}O_2NCl$  requires Cl (as NCl) = 12.32 per cent.

*Propionyl-2-amino-5-methylbenzophenone,*

is very readily soluble in alcohol, and crystallises from it in transparent, colourless, rhombic plates (m. p. 99°).

0.3535 gave 16.1 c.c. nitrogen at 16° and 762 mm. N = 5.42.

$C_{17}H_{17}O_2N$  requires N = 5.25 per cent.

*Benzoyl-2-amino-5-methylbenzophenone,*

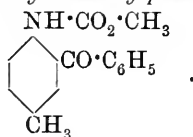

is moderately soluble in alcohol, from which it crystallises in long, slender, very pale yellow prisms (m. p. 118°).

0.2706 gave 10.5 c.c. nitrogen at 17° and 755 mm. N = 4.56.

$C_{21}H_{17}O_2N$  requires N = 4.45 per cent.

All the acyl derivatives of 2-amino-5-methylbenzophenone give yellow solutions, but only the benzoyl derivative shows any yellow tint in the crystalline form.

*Methyl 2-Benzoyl-4-methylphenylcarbamate,*

This ester crystallises from alcohol, in which it is readily soluble, in colourless, transparent, rhombic plates (m. p. 110°).

0.3132 gave 13.6 c.c. nitrogen at 14° and 752 mm. N = 5.13.

$C_{16}H_{15}O_3N$  requires N = 5.22 per cent.

*Ethyl 2-Benzoyl-4-methylphenylcarbamate,*

This compound is very soluble in chloroform, alcohol or light petroleum; from the last of these solvents it crystallises in transparent, very pale yellow, four-sided prisms (m. p. 58°).

0.2576 gave 10.4 c.c. nitrogen at 18° and 758 mm. N = 4.74.

$C_{17}H_{17}O_3N$  requires N = 4.96 per cent.

LVIII.—*Estimation of Hydrogen Peroxide in the presence of Potassium Persulphate by means of Potassium Permanganate.*

By JOHN ALBERT NEWTON FRIEND, M.Sc.

WHILE Dr. Price and I were engaged in investigating Caro's acid, we noticed that hydrogen peroxide could not be correctly estimated by titration with potassium permanganate when this acid was present. The amount of permanganate required always fell short of the theoretical amount (compare Price, Trans., 1903, 83, 546).

Since we obtained Caro's acid by the action of strong sulphuric acid on potassium persulphate, it was natural to inquire whether the potassium persulphate itself might not act in a similar manner. At the suggestion of Dr. Price, whom I take this opportunity of thanking, I have investigated the subject, and my results show that, in ordinary circumstances, a correct estimate of the hydrogen peroxide is not obtained by titration with potassium permanganate when potassium persulphate is present. This fact has an important bearing on much of the work done in connection with persulphates, as many investigators have used this method for the estimation of hydrogen peroxide, believing it to be trustworthy.

In the sequel,  $N/50$  permanganate was used, except where otherwise indicated. The potassium persulphate was recrystallised and free from sulphate; the hydrogen peroxide was obtained from Merck, and guaranteed pure. All the experiments were conducted at the ordinary temperature.

1. *Time of Titration.*

It was found that the amount of permanganate varied considerably with the rate at which it was poured from the burette into the mixture of hydrogen peroxide and potassium persulphate solutions. In each of the following series, the volume titrated and the amounts of hydrogen peroxide, potassium persulphate, and sulphuric acid present were constant throughout, but the rapidity with which the titrations were effected was varied.

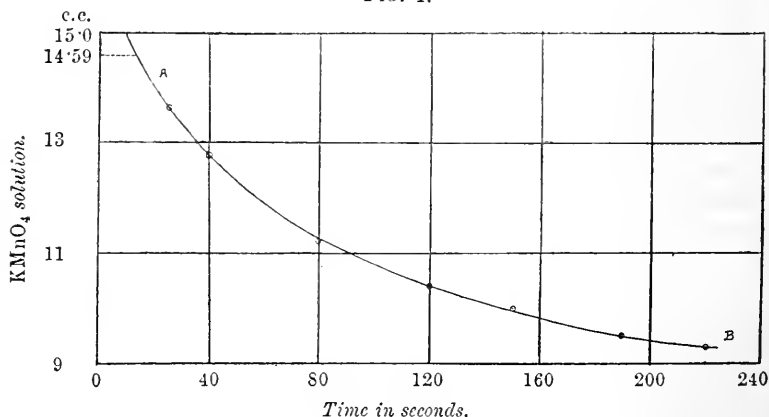

Series I. $m/85 \text{ K}_2\text{S}_2\text{O}_8$ .		Series II. $m/102 \text{ K}_2\text{S}_2\text{O}_8$ .

theoretical value		theoretical value	
12.26		10.54	

The results of Series I are shown in Fig. 1. If the curve be produced in the direction of *A*, it will not meet the vertical axis at the zero

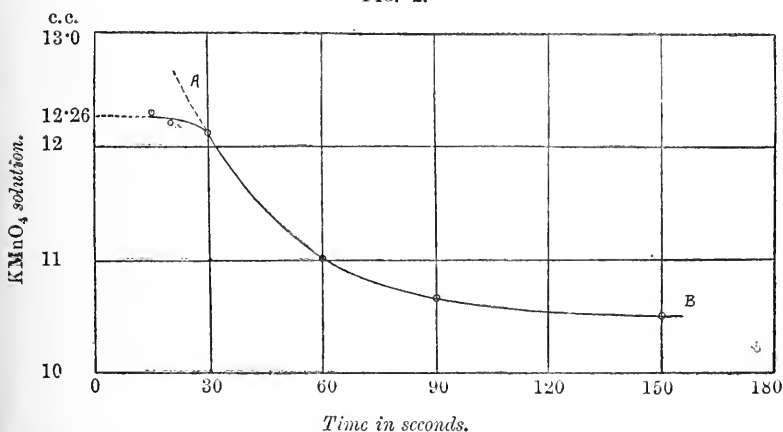

FIG. 1.

of time at a point corresponding with the theoretically correct titration (14.59 c.c.). If, however, very rapid titrations are effected, it is found that the amount of permanganate required does not exceed the theoretical amount. The curve suddenly departs from its original course, becoming nearly parallel to the horizontal axis. This is seen in Fig. 2, which represents the results of Series III. As it is almost impossible to effect a titration of any value in fewer than about 10 seconds, we cannot follow the curve right up to the zero of time.

The results of Series IV show that if the time of titration is greatly prolonged, the amount of permanganate required does not become constant, so that the curve (Figs. 1 and 2) produced in the direction

FIG. 2.

of *B* shows no signs of becoming parallel to the horizontal axis.

It will be clear from the above that if it is desired to compare titrations of different mixtures of hydrogen peroxide and potassium persulphate, the times of titration must be the same. The most convenient interval is perhaps 1 minute, for the curve is then not so steep as for a shorter period, and any slight error in the time of titration causes a smaller experimental error than would otherwise be the case.

In the sequel, all the titrations have been performed during this interval of time.

## 2. Concentration of Persulphate.

In each of the following series, the volume, time of titration, and amount of acid present were kept constant throughout, but the concentration of the potassium persulphate was varied.

In Series VIII, *N*/75 permanganate was employed.

Series VI.*		Series VII.		Series VIII.	
Concentration of $K_2S_2O_8$ .	Titre in c.c. $KMnO_4$ .	Concentration of $K_2S_2O_8$ .	Titre in c.c. $KMnO_4$ .	Concentration of $K_2S_2O_8$ .	Titre in c.c. $KMnO_4$ .
$m/119$	24.73	$m/119$	13.69	$m/85$	11.21
$m/159$	25.40	$m/159$	13.90	$m/122$	12.06
$m/238$	25.80	$m/238$	14.19	$m/189$	12.95
$m/476$	26.63	$m/476$	14.50	$m/283$	13.68
$m/795$	27.02	$m/795$	14.70	$m/425$	14.17
$m/1590$	27.30	$m/1590$	14.90	$m/850$	15.10
$m/3400$	27.50	$m/3400$	15.02	$m/\infty$	16.22
$m/\infty$	27.70	$m/\infty$	15.36	—	—

It is clear from the foregoing tabulation that the greater the amount of potassium persulphate present, the greater is the deviation of the permanganate required from the theoretical amount. This is precisely what one might expect.

### 3. Dilution.

In each of the following series, the amounts of hydrogen peroxide, potassium persulphate, and sulphuric acid were kept constant, as also the time of titration, the volume alone being altered by the addition of distilled water.

Series IX.		Series X.		Series XI.	
Total volume titrated.	Titre in c.c. $KMnO_4$ .	Total volume titrated.	Titre in c.c. $KMnO_4$ .	Total volume titrated.	Titre in c.c. $KMnO_4$ .
20	14.90	20	23.90	20	10.92
25	14.82	25	23.68	25	10.90
30	14.62	30	23.60	30	10.88
35	14.50	35	23.40	35	10.76
45	14.28	45	23.22	45	10.69
55	13.97	55	22.95	55	10.43
70	13.70	70	22.68	70	10.03
90	13.32	—	—	—	—

As the dilution increases, the effect of the potassium persulphate becomes correspondingly greater. It is quite possible that a dissociation of persulphate may account for this.

\* The symbol  $m$  in the tables signifies one gram-molecule of the substance dissolved in one litre of water.

4. Concentration of Sulphuric Acid.

In each of the following series, the volume was kept constant, as also the amounts of persulphate and hydrogen peroxide, and the time of titration, but the quantity of sulphuric acid was varied.

Series XII.  $m/238 \text{ K}_2\text{S}_2\text{O}_8$ .

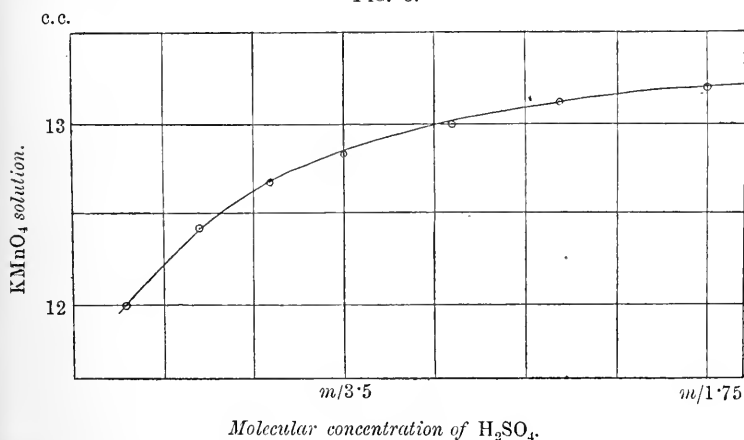

Strength of $\text{H}_2\text{SO}_4$ .	Titre in c.c. $\text{KMnO}_4$ .
$m/8.9$	12.00
$m/5.93$	12.42
$m/4.4$	12.67
$m/3.5$	12.83
$m/2.7$	12.99
$m/2.2$	13.12
$m/1.75$	13.20
Theoretical	13.62

Series XIII.  $m/238 \text{ K}_2\text{S}_2\text{O}_8$ .

Strength of $\text{H}_2\text{SO}_4$ .	Titre in c.c. $\text{KMnO}_4$ .
$m/12$	25.40
$m/7$	25.60
$m/5$	25.77
$m/2.3$	26.52
$m/1.8$	26.88
$m/0.9$	27.23
$m/0.6$	27.20
Theoretical	27.23

The results of Series XII are shown in Fig. 3; this diagram indicates a curve which is exactly opposite to those previously obtained.

FIG. 3.

By increasing the amount of sulphuric acid, the titration approaches more and more nearly to the true value, and indeed finally reaches it if the excess of acid is sufficiently great.

### 5. Estimation of Hydrogen Peroxide.

From the foregoing, it appears that a correct titration might be obtained if attention were paid to the following points.

1. The rapidity with which the titration is effected should be as great as possible.

2. The volume of the solution titrated should be reduced to a minimum.

3. Great excess of sulphuric acid should be employed.

That such is possible will be evident from a consideration of the following results.

Column I gives the volume of the solution titrated.

Columns II and III indicate respectively the molecular strengths of the sulphuric acid and potassium persulphate present in the solution.

Column IV gives the number of c.c. of permanganate required, and Column V the theoretical value, that is, the number which would have been required had no persulphate been present. The time of titration was about 30 seconds.

Volume.	H <sub>2</sub> SO <sub>4</sub> .	K <sub>2</sub> S <sub>2</sub> O <sub>8</sub> .	KMnO <sub>4</sub> required.	KMnO <sub>4</sub> . Theoretical value.
25 c.c.	m/1.5	m/170	24.10 c.c.	24.16 c.c.
25	m/1.5	m/170	20.20	20.20
20	m/1.0	m/134	24.10	24.16
20	m/1.0	m/134	20.16	20.20
20	m/1.0	m/134	17.50	17.57
20	m/1.5	m/227	24.13	24.16
20	m/1.5	m/227	20.15	20.20

The above numbers show a moderate agreement, the greatest error being 0.4 per cent.

In a future paper I hope to show the cause of the varying titrations, and to give in more detail the most favourable conditions for effecting a correct titration.

THE GRAMMAR SCHOOL,  
WATFORD.

LIX.—*The Heat of Formation of Glucinum Chloride.*

By JAMES HOLMS POLLOK, B.Sc.

SINCE the discovery of glucinum by Vauquelin in 1798, it has been the subject of numerous researches by many chemists; but so far as I am aware the heat of formation of the glucinum compounds has never been determined; and very little work has been done on the thermo-chemistry of this element, beyond the determination of the heat of neutralisation of hydrofluoric and sulphuric acids by the base.

This research was undertaken with the view of obtaining the heat of formation of the chloride direct from the metal, so as to supply the necessary data for the calculation of the heats of formation of other salts from the heats of neutralisation of the various acids by the base.

1. *Extraction of Glucina from Beryl.*

The sample of beryl procured from Limoges had a pale green colour and consisted of opaque plates or sheets, not showing any signs of hexagonal crystals; it seemed of uniform character, and not contaminated with rock or other minerals. The whole quantity (10 pounds) was disintegrated, mixed, sampled, and a fine sample carefully ground for analysis. The mean results of a number of fairly concordant analyses were as follows:

	Per cent.		Per cent.
Silica .....	64.41	Magnesia .....	0.02
Alumina.....	18.82	Nickel and zinc oxides	0.74
Glucina .....	11.65	Combined water .....	1.22
Lime .....	0.65	Alkali chlorides .....	0.68
Copper .....	a trace		—
Ferrous oxide .....	1.46		99.65

To separate the glucina, 2,000 grams of ground beryl were fused with their own weight of caustic soda, in a large salamander crucible for about one hour, the contents of the crucible then being perfectly liquid. When cold, the fused mass was ground up, treated with excess of strong hydrochloric acid, the whole boiled with steam, and the silica separated on a linen filter and thoroughly washed. The solution was now precipitated by ammonia, and the very bulky precipitate of iron, alumina, and glucina collected, dissolved in hydrochloric acid, and the solution saturated with hydrogen chloride, which precipitates nearly all the aluminium as chloride, but leaves the whole of the iron and glucina in solution. The pre-

cipitated aluminium chloride was filtered at the pump through glass wool and the precipitate washed with concentrated hydrochloric acid. The pure white, crystalline aluminium chloride was easily collected. On boiling off the hydrochloric acid from the solution and concentrating, a reddish-yellow, syrupy solution was obtained, containing the iron and glucina as chlorides. This solution was added in quantities of 100 c.c. at a time to two litres of saturated ammonium carbonate solution, and shaken up in "Winchester quarts." At first, a heavy, curdy precipitate was produced, which, on shaking, redissolved completely to a perfectly clear solution; in about five minutes, this became cloudy, and in ten minutes quite a heavy precipitate separated, this very curious phenomenon being repeated exactly in each vessel. This precipitate consists chiefly of alumina with a little iron and glucina, and about 80 grams were collected for further examination.

The clear solution of glucina in ammonium carbonate was now treated with a few drops of ammonium sulphide and left for two days, when the black precipitate was collected. This precipitate consisted chiefly of iron, zinc, and nickel sulphides, but another substance appeared to be present; its amount was, however, too minute to admit of any satisfactory conclusion being drawn regarding it. This sulphide has also been observed by Kruss and Morah. The ammonium carbonate solution of glucina, now free from silica, alumina, and iron, was boiled and evaporated to about half its bulk, the glucinum being precipitated as a beautiful white basic carbonate containing only a small quantity of alumina. Other experiments were similarly conducted, and I finally obtained more than 800 grams of pure white basic glucinum carbonate.

To purify the basic carbonate, I used the method of fractional solution in ammonium carbonate, the product giving the following numbers on analysis: glucina, 37.9; carbon dioxide, 22.9; and water, 39.2 per cent., these data corresponding with the formula  $\text{GlCO}_3, 2\text{GlH}_2\text{O}_2, 2\text{H}_2\text{O}$ .

A quantity of the purified basic carbonate was dissolved in dilute sulphuric acid and the filtered solution left over sulphuric acid under diminished pressure, when a good crop of large crystals of sulphate was obtained.

On analysis, this salt gave the following data:  $\text{GlO} = 14.34$ ,  $\text{SO}_4 = 46.60$ , and  $\text{H}_2\text{O} = 39.06$  per cent.  $\text{GlSO}_4, 4\text{H}_2\text{O}$  requires  $\text{GlO} = 14.17$ ,  $\text{SO}_4 = 45.17$ , and  $\text{H}_2\text{O} = 40.66$  per cent.

## 2. *Anhydrous Glucinum Chloride.*

A number of preliminary experiments showed that the best method of making anhydrous glucinum chloride was to mix the oxide with four

times its own weight of sugar, and char in a Hessian crucible at a dull red heat; then to place the intimate mixture of carbon and glucina thus formed in a porcelain tube, maintained at a bright red heat in a furnace with a Fletcher burner, and pass a steady stream of perfectly dry chlorine over the heated mass. The chloride formed freely, and condensed in pure white, silky needles at a point just beyond the red-hot zone of the tube, whilst the part next to the tube fused to a white mass. In the earlier experiments, the chloride was yellow, the colour being due to the presence of iron.

In one experiment, 10 grams of glucina ignited with 20 grams of sugar gave 25 grams of anhydrous chloride and 1 gram of unaltered residue, and other experiments gave similar results. Theoretically, 10 grams of dry glucina should yield about 32 grams of anhydrous chloride.

A careful analysis of the chloride gave the following numbers:  $\text{Gl} = 11.87$ ,  $\text{Cl} = 88.13$ , whilst  $\text{GlCl}_2$  requires  $\text{Gl} = 11.38$ ,  $\text{Cl} = 88.62$  per cent.

### 3. *Metallic Glucinum.*

The production of metallic glucinum in a state of reasonable purity was found to be a task of great difficulty. I first tried the electrolytic decomposition of the anhydrous chloride, fused in a test-tube surrounded by the vapour of boiling sulphur, and although not successful as a method of obtaining pure metal, the experiment was interesting, as the jacket of sulphur vapour had just the right temperature to keep the chloride perfectly molten without vaporising any. Evidently glucinum chloride melts at about  $400^\circ$ , and boils at about  $500^\circ$ ; and I cannot understand how Carnelly came to give the melting point as lying between  $585^\circ$  and  $617^\circ$ , and maintained the accuracy of these figures after Nilson and Pettersson had pointed out that the chloride boiled at  $520^\circ$ . There is absolutely no doubt that the anhydrous chloride melts below, and near to, the boiling point of sulphur ( $440^\circ$ ), and that its vapour condenses just below a red heat, as can easily be seen when its preparation is conducted in a glass tube. As a red heat begins somewhere between  $500^\circ$  and  $550^\circ$ , according to the manner in which the observation is made, this agrees very well with Nilson and Pettersson's figure.

After a number of trials, the following method of procedure was adopted:

A piece of sodium was pressed into the bottom of a good-sized nickel crucible, the anhydrous chloride was rapidly introduced, more sodium placed on the top, and the crucible gently heated until the reaction set in. The lid, which was blown off, was quickly replaced, and the crucible plunged into absolute alcohol in order to dissolve out

the excess of sodium, the whole being thoroughly boiled once or twice with fresh portions of absolute alcohol, and then finally washed with hot water. There always seemed to be a good deal of action when the water was first applied, and this was, no doubt, due to the impossibility of completely removing all the sodium hydroxide, and this alkali has a vigorous action on glucinum. After washing, the water had no further action on the metal, even on boiling. The glucinum thus obtained was in the form of a dark grey powder, which assumed a bright grey or white metallic lustre under the burnisher. A nickel crucible is quite unacted on by metallic sodium, and in this way comparatively large quantities may be operated on with safety.

It was hoped that, by using an excess of metallic sodium, crystalline glucinum might be obtained, after the manner employed by Moissan in preparing calcium; but it was found that glucinum did not alloy with sodium. A portion of the metal was analysed by dissolving in hydrochloric acid, the hydrogen evolved being collected and measured; the specimen was found to contain glucinum, 59.16; glucina, 40.84 per cent., and traces only of iron oxide, &c.

#### 4. *The Volatility of Metallic Glucinum.*

An attempt was now made to fuse the glucinum under salt, but without success, although platinum, nickel, and lime crucibles were tried. At a high temperature, the glucinum alloyed with the two former, and with the latter the salt and metal were both volatilised before the latter seemed to melt, but no doubt, if I had taken more pains with this method, and had stopped at the right moment, the experiment might have been successful, as J. E. Reynolds succeeded in producing a small fused mass by this method, although he also noticed a great loss of metal. I then tried the electric arc in an atmosphere of hydrogen, by making a hollow in the end of the positive carbon, surrounded by a small lime cylinder, kept in position by a little copper wire bound round the carbon, and then placing a little of the glucinum powder in the miniature electric furnace thus formed. An ordinary lamp-chimney was corked over the upper and negative carbon and kept full of hydrogen gas. Contact was now made by passing the positive carbon up through the foot of the chimney, when an arc was formed; after a few minutes, the current was switched off, and the carbon and lime crucible allowed to cool in hydrogen. It was found that the glucinum showed no sign of fusion, but on the copper wire bound round the carbon to support the lime jacket there was a film of the metal, which showed that under atmospheric pressure it volatilised without fusion, and this would explain the

great difficulty all investigators have found in producing any large quantity of fused glucinum.

Nilson and Pettersson succeeded in fusing glucinum under salt in some quantity, but they did this under pressure in an iron crucible with the lid screwed down.

### 5. *Thermo-chemical Notation.*

In recording and calculating the results of my experiments I have adopted the notation described in my paper to the Royal Dublin Society, 1899. The solid, liquid, gaseous, and dissolved states are indicated by a dot, dash, T, or circle ( $\cdot$  — T  $^{\circ}$ ) placed under the formula of the substance. The heat of formation of a compound is indicated by  $\xi$  placed before its formula. The heat of a reaction is indicated by enclosing the equation in brackets and placing  $\xi$  before it. The heat evolved in the transition from one state to another is indicated by  $\xi$  with the sign for the initial and final state at the bottom and top respectively, K $^{\circ}$  and k $^{\circ}$  represent kilogram- and gram-degrees of heat. Thus,  $\xi^{\circ}\text{GlCl}_2 = 44\cdot5\text{K}^{\circ}$  indicates that the heat of solution of anhydrous glucinum chloride is 44·5 kilogram-degrees per gram-molecule, whilst  $\xi\text{GlCl}_2 = 155\text{K}^{\circ}$  indicates that the heat of formation of a gram-molecule of solid glucinum chloride is 155 kilogram-degrees.

The expression  $\xi[\overset{\cdot}{\text{Gl}} + 2\overset{\circ}{\text{HCl}} = \overset{\circ}{\text{GlCl}_2} + \overset{\text{T}}{\text{H}_2}] = 121\cdot1\text{K}^{\circ}$  indicates that the heat evolved in the solution of a gram-atom of glucinum in hydrochloric acid is 121·1 kilogram-degrees.

The advantage of this notation over that of Thomsen or Berthelot is that every symbol preceded by the letter  $\xi$  indicates a definite algebraic quantity of heat. The formulæ and equations retain their ordinary chemical interpretation, and all the equations are algebraically correct.

### 6. *Heat of Solution of Glucinum Compounds.*

The heat of solution of anhydrous glucinum chloride was determined by projecting a quantity of the pure dry chloride from a weighing-bottle into a calorimeter of very thin glass, surrounded by an outer glass vessel so as to form an air-jacket. The calorimeter contained 187 c.c. of water, which, together with the thermal equivalent of the beaker, stirrer, and thermometer, was equal to 200 grams of water. The thermometer used was specially made for the experiments, and had a long, thin bulb, equal to the depth of liquid in the beaker, so as to give the rise of temperature quickly with the minimum of stirring, on the principle of Bottomley's integrating thermometer; the stem was

graduated in fiftieths of a degree, from  $10^{\circ}$  to  $30^{\circ}$ , and could easily be read to  $0.01^{\circ}$ .

In the first experiment, 0.845 gram of chloride dropped into the calorimeter dissolved almost instantly, and gave a rise of  $2.26^{\circ}$ . Thomsen has established that, for the purposes of this class of experiment, the heat capacity of a dilute solution may be taken as equal to that of the water; so, multiplying by 200, this gives us 452 gram-degrees per 0.845 gram of anhydrous chloride. Multiplying by 80, and dividing by 0.845, this gives 42.9 kilogram-degrees as the heat of solution of a gram-molecule of anhydrous glucinum chloride. Thus :

$$\frac{0.845}{80.1} \xi^{\circ} \text{GlCl}_2 = 2.26 \frac{\text{K}^{\circ}}{5}. \quad \xi^{\circ} \text{GlCl}_2 = \frac{2.26 \times 80}{0.845 \times 5} \text{K}^{\circ} = 42.9 \text{K}^{\circ}.$$

The advantage of this notation is that the equation can always be written down direct from the experimental figures, without any other explanation whatever. The results of all the experiments may be summarised as follows :

Grams of substance.	Rise of temperature.	Gram-degrees of heat.	Molecular heat of solution.
0.845	$2.26^{\circ}$	452k $^{\circ}$	42.9K $^{\circ}$
1.356	3.80	760	45.0
1.221	3.38	676	44.3
1.332	3.69	738	44.3

Neglecting the first experiment, this gives the mean value of the heat of solution of anhydrous glucinum chloride,

$$\xi^{\circ} \text{GlCl}_2 = 44.5 \text{K}^{\circ}.$$

Ten grams of the sulphate, when dissolved, gave a rise of  $0.24^{\circ}$ , equal to 48 gram-degrees of heat. In a second experiment, 10 grams gave precisely the same result. This gives 0.85 kilogram-degrees for the molecular heat of solution of crystallised glucinum sulphate,

$$\frac{10}{177} \xi^{\circ} \text{GlSO}_4 \cdot 4\text{H}_2\text{O} = 48 \text{k}^{\circ}. \quad \xi^{\circ} \text{GlSO}_4 \cdot 4\text{H}_2\text{O} = 0.85 \text{K}^{\circ}.$$

As anhydrous glucinum chloride dissolves freely in absolute alcohol with great rise of temperature, I thought it would be interesting to determine the molecular heat of solution in this solvent. On projecting 0.724 gram of chloride into 200 c.c. of alcohol and stirring, the temperature rose from  $14.82^{\circ}$  to  $18.00^{\circ}$ , a rise of  $3.18^{\circ}$  in two minutes. A second portion of 0.781 gram projected into the same solution raised the temperature from  $17.56^{\circ}$  to  $20.78^{\circ}$ , a rise of  $3.22^{\circ}$  in two minutes. After cooling for two minutes, the temperature

was  $20.52^{\circ}$ , thus giving a decrement of  $0.26^{\circ}$ . The undissolved residue of carbon from both experiments weighed 0.0955 gram; deducting this, and adding the results of both experiments and half the rate of cooling, we have a rise of  $6.68^{\circ}$  on the solution of 1.41 grams of anhydrous chloride in 200 c.c. of absolute alcohol. The specific heat of alcohol is 0.615, the specific gravity of the sample being 0.801. This gives 37.4 kilogram-degrees for the molecular heat of solution of glucinum chloride in alcohol.

### 7. Heat of Formation of Glucinum Chloride.

For the heat of formation of the chloride, a thin glass globe was used with a spiral to cool the escaping gases, and a small tap-funnel to supply the acid. The globe being immersed in a calorimeter containing a quantity of water such, that this liquid, together with the corrections for the glass of the apparatus, including the thermometer and stirrer and hydrochloric acid added, was just equivalent to one kilogram-degree; so that the thermometer read off in gram-degrees direct, without the necessity of a separate correction for each experiment. Surrounding the calorimeter was an outer vessel to act as an air-jacket.

The thermometer used was similar to that employed for determining the heat of solution, having a long, narrow mercury bulb, of the same length as the depth of liquid in the calorimeter; and the stem was graduated to fiftieths of a degree, and easily read to  $0.01^{\circ}$ .

In each experiment, a quantity of glucinum powder was dropped into the glass globe: 25 c.c. of moderately strong hydrochloric acid were put in the funnel, the acid being as nearly as possible at the same temperature as the water of the calorimeter. The exit from the spiral tube was connected with a pneumatic trough, with a graduated cylinder to collect the hydrogen evolved. When all was ready, the temperatures of the water in the calorimeter, the acid in the funnel, and the air in the outer jacket of the calorimeter were noted. The acid was then run in, the water in the calorimeter well stirred until all action had ceased, and the temperature of the water in the calorimeter again noted. The hydrogen evolved by the reaction was carefully measured and the volume corrected to  $0^{\circ}$  and 760 mm., of course allowing for the 25 c.c. of acid run into the globe. From the volume of hydrogen liberated, the weight of glucinum dissolved in the experiment was calculated.

The details of one of the most satisfactory experiments were as follows: temperature of the air jacket,  $15.5^{\circ}$ ; temperature of the acid,  $15.55^{\circ}$ ; temperature of the water in the calorimeter before the experiment,  $15.54^{\circ}$ ; and after the experiment,  $17.08^{\circ}$ ; rise,  $1.54^{\circ}$ ;

the hydrogen evolved corrected to 0° and 760 mm. measured 277·8 c.c., equal to 0·1157 gram of glucinum. The solution of 0·1157 gram of glucinum therefore evolved 1·54 kilogram-degrees of heat, and on multiplying by 9·1, dividing by 0·1157, and adding 78·6—the heat of formation of hydrochloric acid in solution—we get 199·7 kilogram-degrees for the molecular heat of formation of glucinum chloride in solution. The results may be stated thus :

$$\begin{aligned} \frac{0\cdot1157}{9\cdot1} \xi [\text{Gl} + 2\text{HCl} = \text{GlCl}_2 + \text{H}_2] &= 1\cdot54\text{K}^\circ, \\ - \xi \text{Gl} - 2\xi \text{HCl} + \xi \text{GlCl}_2 + \xi \text{H}_2 &= \frac{1\cdot54 \times 9\cdot1}{0\cdot1157} \text{K}^\circ, \\ \text{O} - 78\cdot6 + \xi \text{GlCl}_2 + \text{O} &= 121\cdot1\text{K}^\circ; \\ \therefore \xi \text{GlCl}_2 &= 199\cdot7\text{K}^\circ. \end{aligned}$$

The results of all the experiments are summarised in the following table :

Glucinum dissolved.	Rise of temperature.	Molecular heat of formation.
0·0920 gram	1·14°	191·4K°
0·0125 „	0·16	195·1 „
0·0333 „	0·50	215·2 „
0·1157 „	1·54	199·7 „
0·0868 „	1·14	189·2 „
0·1543 „	2·07	200·7 „

Taking the average of the last three results, we have, for the heat of formation of glucinum chloride in solution,

$$\xi \text{GlCl}_2 = 199\cdot5\text{K}^\circ;$$

deducting the heat of solution, we get 155 kilogram-degrees for the molecular heat of formation of anhydrous glucinum chloride,

$$\xi \text{GlCl}_2 = 155\cdot0\text{K}^\circ.$$

Comparing these results with the heat of formation and solution of anhydrous aluminium chloride, we have :—

	$\text{Al}_2\text{Cl}_6$ .	$\frac{1}{2}\text{Al}_2\text{Cl}_6$ .	$\text{AlCl}_3$ .
Heat of formation.....	323·6	107·9	155·0
Heat of solution .....	152·6	50·9	44·5

so that for equivalent quantities, the heat of formation of glucinum chloride is much higher than that of aluminium chloride, and the heat of solution somewhat less.

Comparing glucinum, magnesium, and zinc chlorides, we have:—

	GICl	MgCl <sub>2</sub> .	ZnCl <sub>2</sub> .
Heat of formation .....	155·0	151·0	97·4
Heat of solution .....	44·5	36·0	15·6

In each case, a fall in the heats of formation and solution accompanies the rise of atomic weight.

DUBLIN.

## LX.—*The Action of Ethyl $\beta$ -Iodopropionate on Ethyl Disodioethanetetracarboxylate.*

By OSWALD SILBERRAD, Ph.D.

THE  $\beta$ -iodopropionic acid required for this investigation was prepared by the direct addition of yellow phosphorus (220 grams) to a mixture of crude glyceric acid of sp. gr. 1·26 (1000 c.c.) and iodine (1700 grams). By thus modifying Beilstein's method (*Annalen*, 1861, 120, 226 ; 122, 336), the preliminary preparation of phosphorus iodide was avoided.

*Ethyl butane- $\alpha\gamma\gamma\delta\delta$ -pentacarboxylate,*

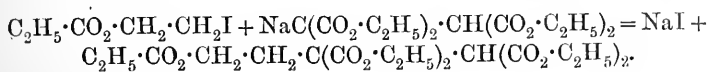

—This ester was obtained by heating together 450 grams of ethyl  $\beta$ -iodopropionate and 360 grams of dry ethyl disodioethanetetracarboxylate for 8 hours at 200°. The product after washing with water and drying with potassium carbonate, was systematically fractionated under 17 mm. pressure ; in this manner, five distinct fractions were ultimately obtained, of which the fourth was by far the largest.

This was analysed with the following result :

Found C = 54·01 ; H = 7·22.  $\text{C}_{19}\text{H}_{30}\text{O}_{10}$  requires C = 54·5 ; H = 7·2 per cent.

The compound, which is a colourless oil boiling at 215—218° (17 mm.), is produced in accordance with the following equation :

The formation of ethyl monosodioethanetetracarboxylate is probably due to a secondary action between ethyl  $\beta$ -iodopropionate and the disodium derivative of ethyl ethanetetracarboxylate, in which ethyl  $\Delta^{\beta\gamma}$ -dihydromuconate is produced.

The new ester is thus to be regarded as ethyl butane- $\alpha\gamma\gamma\delta\delta$ -pentacarboxylate; it readily forms sodium and haloid derivatives, the latter of which give rise to an interesting lactonic acid on treatment with silver oxide and subsequent saponification.

*Butane- $\alpha\gamma\gamma\delta\delta$  pentacarboxylic acid,*

—Fifty grams of ethyl butane- $\alpha\gamma\gamma\delta\delta$ -pentacarboxylate were saponified with alcoholic potash in order to isolate the corresponding pentacarboxylic acid. On acidifying with dilute nitric acid, a slight evolution of carbon dioxide occurred; the solution was accordingly neutralised and treated with silver nitrate, the precipitated silver salt of the acid was then suspended in water and decomposed with hydrogen sulphide. On evaporating the solution, a viscid syrup resulted from which no crystalline substance was obtained even after leaving the product for several weeks over sulphuric acid in a vacuum desiccator. A small quantity of the acid was therefore reconverted into the silver salt and the latter analysed.

Found  $\text{Ag} = 66.1$ .  $\text{C}_9\text{H}_5\text{O}_{10}\text{Ag}_5$  requires  $\text{Ag} = 66.4$  per cent.

*Butane- $\alpha\gamma\delta$ -tricarboxylic acid,*

—Ten grams of the pentacarboxylic acid were boiled with hydrochloric acid as long as carbon dioxide was evolved; the syrupy residue left on evaporation was then placed over sulphuric acid in a vacuum desiccator. In the course of a few days, the product solidified to a mass of prismatic needles.

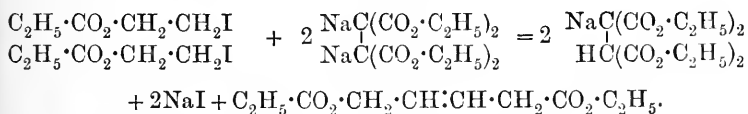

Found  $\text{C} = 44.04$ ;  $\text{H} = 5.45$ .  $\text{C}_7\text{H}_{10}\text{O}_6$  requires  $\text{C} = 44.2$ ;  $\text{H} = 5.3$  per cent.

The acid melts at  $122^\circ$  and is evidently butane- $\alpha\gamma\delta$ -tricarboxylic acid, for which the melting point is given as  $116\text{--}120^\circ$  (Auwers, Köbner, and Meyenburg, *Ber.*, 1891, 24, 2895).

*Ethyl  $\Delta^{\beta\gamma}$ -dihydromuconate,*  $\text{C}_2\text{H}_5 \cdot \text{CO}_2 \cdot \text{CH}_2 \cdot \text{CH} \cdot \text{CH} \cdot \text{CH}_2 \cdot \text{CO}_2 \cdot \text{C}_2\text{H}_5$ .  
—Of the minor fractions, the first and third proved to be unaltered ethyl  $\beta$ -iodopropionate and ethanetetracarboxylate respectively. The second, which obstinately retained traces of iodine and boiled at  $120\text{--}125^\circ$  (17 mm.), appeared on analysis to have the formula  $\text{C}_{10}\text{H}_{16}\text{O}_4$ .

Found  $\text{C} = 59.40$ ;  $\text{H} = 7.84$ .  $\text{C}_{10}\text{H}_{16}\text{O}_4$  requires  $\text{C} = 60.0$ ;  $\text{H} = 8.0$  per cent.

From which it would appear that the compound is ethyl  $\Delta^{\beta\gamma}$ -dihydromuconate, probably produced by the condensation of two molecules of ethyl  $\beta$ -iodopropionate with loss of hydrogen iodide, on heating in the presence of ethyl disodioethanetetracarboxylate :

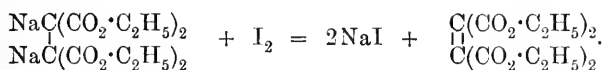

$\Delta^{\beta\gamma}$ -Dihydromuconic acid,  $\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CH}:\text{CH}\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$ .—In order to establish fully the identity of the foregoing ester, 10 grams were saponified by warming with alcoholic potash. After neutralisation, the silver salt was precipitated, washed, suspended in water, decomposed with hydrogen sulphide, and the filtrate concentrated on the water-bath. From the acid purified in this manner, the silver salt was prepared and analysed.

Found  $\text{Ag} = 60.72$ .  $\text{C}_6\text{H}_6\text{O}_4\text{Ag}_2$  requires  $\text{Ag} = 60.3$  per cent.

Ethyl ethylenetetracarboxylate,  $(\text{CO}_2\cdot\text{C}_2\text{H}_5)_2\text{C}:\text{C}(\text{CO}_2\cdot\text{C}_2\text{H}_5)_2$ .—The fifth fraction of the original mixture boiled at  $227-233^\circ$  (15 mm.).

Found  $\text{C} = 53.11$ ;  $\text{H} = 6.52$ .  $\text{C}_{14}\text{H}_{20}\text{O}_8$  requires  $\text{C} = 53.2$ ;  $\text{H} = 6.3$  per cent.

The formation of this ester is probably to be traced to the interaction of ethyl disodioethanetetracarboxylate and free iodine, produced by the decomposition of ethyl  $\beta$ -iodopropionate at the high temperature of the reaction :

Ethylenetetracarboxylic Acid,  $(\text{CO}_2\text{H})_2\text{C}:\text{C}(\text{CO}_2\text{H})_2$ .—In order to establish fully the identity of the preceding ester, the acid potassium salt of this acid was prepared and analysed. To this end, 5 grams of the ester were saponified with alcoholic potash, and the solution rendered slightly acid with acetic acid; a thick, brown precipitate slowly settled, which was collected, washed with a little dilute alcohol, and dissolved in water. Absolute alcohol was then added to the solution until a slight turbidity became permanent, when the mixture was placed over quicklime in a vacuum desiccator. In the course of a few days, tiny crystals separated and were recrystallised from water and analysed.

Found  $\text{K} = 27.62$ ;  $\text{C}_6\text{H}_2\text{O}_8\text{K}_2$  requires  $\text{K} = 27.86$  per cent.

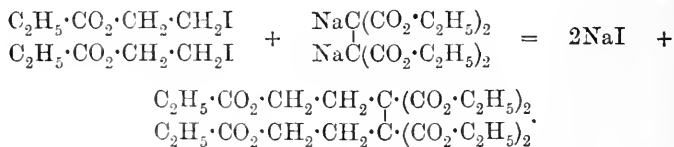

*Hexane- $\alpha\gamma\delta\zeta$ -tetracarboxylic Acid (aa-Diglutaric Acid),*  
 $\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{H})\text{CH}(\text{CO}_2\text{H})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}.$

On continuing the fractionation, the thermometer rose to  $240^\circ$  (17 mm.), when distillation practically ceased, and on raising the temperature still higher, decomposition set in. The black, tarry product still remaining in the flask was therefore subjected to the following operations, which ultimately led to the isolation of hexane- $\alpha\gamma\delta\delta\zeta$ -hexacarboxylic acid: (1) the residue saponified with alcoholic potash, diluted, neutralised, and filtered to remove neutral tarry matter; (2) the potassium salt precipitated with silver nitrate; (3) the silver salt suspended in water and decomposed with hydrogen sulphide; (4) the free acid concentrated (a) on the water-bath, and (b) in a vacuum desiccator; (5) the acid dissolved in water and saturated with calcium carbonate; (6) the calcium salt submitted to a prolonged series of fractional precipitation from aqueous solution by the addition of alcohol; (7) the least soluble fraction of calcium salt converted into silver salt by precipitation with silver nitrate; (8) the silver salt suspended in water and decomposed with hydrogen sulphide; (9) the free acid concentrated (a) on the water-bath, and (b) in a vacuum desiccator.

A small quantity of the free acid was then reconverted into the silver salt, which is an amorphous white powder obtained by adding silver nitrate to a neutral solution of the ammonium salt.

The salt appeared to be a mixture of silver hexanehexa- and tetracarboxylates. Found  $\text{Ag} = 64.04$ ;  $\text{C}_{10}\text{H}_{10}\text{O}_8\text{Ag}_4$ , requires  $\text{Ag} = 62.6$ ;  $\text{C}_{12}\text{H}_8\text{O}_{12}\text{Ag}_6$ , requires  $\text{Ag} = 65.3$  per cent.

The formation of ethyl hexane- $\alpha\gamma\delta\delta\zeta$ -hexacarboxylate is indicated as follows:

In order to convert the hexabasic acid present into the tetrabasic acid, the product was boiled with hydrochloric acid until the evolution of carbon dioxide ceased. The syrupy liquid left after evaporating the solution on the water-bath was placed in a vacuum desiccator over caustic potash to remove adhering hydrochloric acid; the residue was then dissolved in water, neutralised with ammonia, precipitated with silver nitrate, and subjected to the following treatment: (1) the silver salt suspended in water and decomposed with hydrogen sulphide; (2)

the free acid concentrated (a) on water-bath and (b) in a vacuum desiccator ; (3) the acid dissolved in water and saturated with calcium carbonate ; (4) the calcium salt fractionally precipitated by the addition of alcohol ; (5) the least soluble fraction of the calcium salt converted into silver salt by precipitation with silver nitrate ; (6) the silver salt suspended in water and decomposed with hydrogen sulphide ; (7) the free acid concentrated (a) on the water-bath and (b) in a vacuum desiccator ; (8) the free acid dissolved in water, just sufficient alcohol added to produce turbidity, and the solution placed in a vacuum desiccator over quicklime.

As the percentage of alcohol increased, owing to the absorption of the water by the quicklime, a granular, gummy solid slowly separated. The acid was then washed with dilute alcohol, dried, dissolved in anhydrous acetone, an equal volume of benzene added, and the solution allowed to remain in a vacuum desiccator over strong sulphuric acid. A gummy, semi-crystalline mass slowly separated, which, on being again subjected to this treatment, became distinctly crystalline, and after washing with ice-cold water and several crystallisations from water was obtained pure.

0.08 gave 0.13275  $\text{CO}_2$  and 0.0399  $\text{H}_2\text{O}$ . Found C = 45.26 ; H = 5.54.  
 $\text{C}_{10}\text{H}_{14}\text{O}_8$  requires C = 45.84 ; H = 5.34 per cent.

The acid crystallises in colourless prisms, sparingly soluble in organic solvents, but more readily in hot water. It melts at  $215^\circ$  with decomposition, and appears to be identical with the acid obtained by Sell and Easterfield on reducing quinhydroketopyridine (Trans., 1894, 65, 830), to which they assigned the above constitution. Unfortunately, the extremely small yield (0.108 gram) rendered further comparison impossible.

I wish to express my thanks to the Government Grant Committee of the Royal Society for a grant in aid of this investigation.

# LXI.—*A Comparison of the Products of the Hydrolysis of Potato Starch with those obtained from Cereal Starches.*

By JAMES O'SULLIVAN.

A COMPARISON of the results obtained by Lintner's method for determining the relative diastatic power of malts (Abstr., 1887, 52, 165), with those yielded by a somewhat similar process with which I had prior experience, showed that something remained to be explained before these two series of data could be reconciled. In the latter method, potato starch paste was used, whilst in Lintner's method his soluble starch was employed. On investigating the matter, I became convinced that the products of the hydrolysis of potato starch paste by malt extract under like conditions, calculated as maltose and dextrin, were not of the same percentage composition as those yielded by Lintner's starch, the latter giving a very much higher proportion of maltose.

I have now extended this inquiry to the following starches: (1) potato starch purified by alternate treatment with large volumes of very dilute potassium hydroxide and hydrochloric acid, the product being finally washed with water until neutral; (2) malt starch and (3) barley starch I, similarly prepared; (4) barley starch II, purified, or rather prepared from the same barley as barley I by washing with water only; (5) maize starch and (6) rice starch purchased as pure; (7) Lintner's starch, prepared by Lintner's process from the above potato starch.

The water, ash, and albuminoids ( $N \times 6.25$ ) in these starches were as follows:

	Potato.	Lintner's	Malt.	Barley I.	Barley II.	Maize.	Rice.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Water .....	18.3	20.44	15.00	18.97	16.05	13.90	14.00
Ash .....	0.24	0.17	0.09	0.06	0.19	0.35	0.62
Albuminoids ...	0.17	0.09	0.30	0.23	3.42	0.23	0.45

Although it must be admitted that numbers such as these do not of themselves show the purity of starch preparations, yet, if taken in conjunction with the results obtained for them by the best method of estimating starch, devised by C. O'Sullivan (Trans., 1884, 45, 1),\* as

\* Digestion at 62—63° for one hour.

tabulated in table V, I am of opinion that with the exception of barley starch II they leave little to be desired as regards purity. If the amount of starch deduced from the maltose and dextrin, as in O'Sullivan's method, is found to be within 2 or 3 per cent. of the total quantity taken, it might be considered pure, this being apparently the only way of testing the purity of the starch preparation.

The experimental methods employed in the study of potato starch transformations are now so well known, owing to C. O'Sullivan's researches, that I need not refer to them here. It is, however, necessary to give descriptions of the preparation of the starch pastes and the preliminary treatment of the diastase and malt extract.

The amount of water in the starches employed in each series of transformations being known, the quantity of starch taken was such that the amount of dry starch in every case was the same. The quantity of dry starch is shown in column 3 of the tables.

The starch was thoroughly mixed with 25 c.c. of water, and constantly stirred, while the temperature was raised to 40°, then 50 c.c. of boiling water were added, and the beaker immersed in a steam-bath, the paste being stirred continuously with a thermometer until the temperature rose to 97°, at which temperature it was kept for 5 minutes. The beaker with its contents was placed in a bath of constant temperature, and kept covered with a watch-glass to prevent evaporation from the surface of the paste, which produces a very insoluble scum. From time to time, the pastes were stirred, and when all were at the same temperature, the hydrolytic agent was added.

The diastase "a" indicated in the tables was prepared from malt made in the usual way, and diastase "b" was obtained from a malt prepared in the laboratory and air-dried. The malt-extract was prepared from malt made in the usual way.

The quantity of diastase required for each paste in the series of transformations was carefully mixed with 10 c.c. of water in a small beaker, stirred continuously with a thermometer, and heated rapidly on a sand-bath until, in about 3—4 minutes, the required transformation temperature was reached. The diastase thus prepared was immediately added to the starch paste, the residue adhering to the small beaker being washed in as quickly as possible with water at the same temperature. The malt extract was treated in the same way as the diastase. On adding the hydrolytic agent to the paste, the mixture was quickly stirred so as to ensure a rapid and equally distributed action.

At the expiration of the time required for the digestion, the beakers containing the solutions were immersed in a steam-bath continuously stirred, and heated at 97° for 5 minutes.

The solutions, the results of which are given in tables I, II, V and VI, were cooled, and made up to 125 c.c. at  $15.5^{\circ}$ ; those of tables III and IV were concentrated and made up to 100 c.c. at  $15.5^{\circ}$ , both the solutions being then filtered through rapid filters. In each experiment, the volume of the solution undergoing hydrolysis was practically 100 c.c. The soluble solids of the diastase and malt-extract, treated as in the transformations, were determined together with their properties, and all the numbers in the tables are corrected for these. Weighed quantities of the solutions were used in determining the cupric oxide reducing power.

An allowance was made for the hydration from starch to maltose ( $\frac{\text{maltose}}{1.055} = \text{starch}$ ) in calculating the percentage of starch in column 8.

The factors employed throughout are: (1) divisor for solids in solution deduced from the density of the solution (3.95), (2) cupric oxide reducing power of maltose (K62.5), (3) dextrin ( $[\alpha]_j$  222), (4) maltose ( $[\alpha]_j$  154).

On comparing the results of the six series of transformations given in the tables, it will be seen (1) that under similar conditions of hydrolysis with diastase or malt-extract, the results obtained from potato starch show no quantitative relationship with those obtained from the other starches, potato starch differing entirely from these; (2) that the percentage composition of the products of the other starches could not be inferred from the results obtained by the hydrolysis of potato starch.

LXII.—*A Lævorotatory Modification of Quercitol.*

By FREDERICK BELDING POWER and FRANK TUTIN.

QUERCITOL has hitherto only been found in the fruits (acorns) of certain species of *Quercus*, in which it exists as a dextrorotatory modification. The lævorotatory modification now described was obtained by us from the leaves of *Gymnema sylvestre* (Br.), a plant belonging to the family of *Asclepiadaceæ*, and indigenous to Banda and the Deccan Peninsula (compare "Pharmacographia Indica," vol. II, p. 450).

In the course of an examination of a large quantity of *Gymnema* leaves, a colourless, crystalline substance having the empirical formula  $C_6H_{14}O_6$  was isolated, which melted at  $174^\circ$  and had  $[\alpha]_D -73.9^\circ$ . When heated at  $110^\circ$ , it lost one molecular proportion of water; it formed a penta-acetyl derivative,  $C_6H_7(O \cdot C_2H_3O)_5$ , and a pentabenzoyl derivative,  $C_6H_7(O \cdot C_7H_5O)_5$ . From these facts it was seen that the above formula,  $C_6H_{14}O_6$ , could be appropriately modified to  $C_6H_7(OH)_5 \cdot H_2O$ , which represents the substance as a hydrated isomeride of quercitol.

The constitutional formula of quercitol, first proposed by Kanonnikoff, represents it as pentahydroxyhexahydrobenzene,

The correctness of this formula was proved by Kiliani and Schaefer (*Ber.*, 1896, 29, 1762), who obtained malonic acid on oxidation with potassium permanganate. Moreover, the same investigators have shown that *d*-quercitol, on oxidation with aqueous bromine, forms a diketone,  $C_6H_8O_5$ , which was isolated in the form of its dihydrazone,  $C_{18}H_{20}O_3N_4$ .

The substance isolated from the leaves of *Gymnema sylvestre*, when oxidised with potassium permanganate and sodium hypobromite respectively, showed a behaviour identical with that of *d*-quercitol. Like the latter, it afforded, on the one hand, malonic acid, and, on the other, a diketotrihydroxyhexahydrobenzene, which was isolated in the form of its dihydrazone (m. p.  $209^\circ$ ).

It was thus demonstrated that our substance has the same constitution as *d*-quercitol, and can only differ from the latter stereo

chemically; but, since *d*-quercitol has  $[\alpha]_D + 24.16^\circ$ , the one cannot be the optical antipode of the other.

Pentahydroxyhexahydrobenzene has four asymmetric groupings, and eight optically active modifications are therefore possible, which may be represented as follows:

By uniting these four pairs, the corresponding racemic modifications would be obtained. The following two unresolvable inactive modifications are also possible:

Until a further number of these isomerides of quercitol are known, it will be impossible to assign a definite configuration either to *d*-quercitol or to the *l*-quercitol isolated from *Gymnema sylvestre*.

#### EXPERIMENTAL.

The leaves of *Gymnema sylvestre* were extracted with hot alcohol and the liquid concentrated to a viscid syrup. Water was then added and the greater part of the remaining alcohol removed on the water-bath. After being allowed to cool, the precipitated resins were removed by filtration. Sulphuric acid was added to the clear filtrate until no further precipitate was produced, and this precipitate, which soon agglomerated to a resinous mass, was likewise removed by filtration. The free sulphuric acid was then removed by barium hydroxide, a slight excess of basic lead acetate subsequently added to remove the colouring matter, and the combined precipitates filtered off. After depriving the filtrate of lead by means of hydrogen sulphide, it was concentrated under reduced pressure to the consistency of a viscid syrup and then diluted with alcohol, when, after a few days, the *l*-quercitol separated in a nearly pure, crystalline form, which, after being filtered at the pump, thoroughly washed with alcohol, and recrystallised from dilute alcohol, was obtained in a perfectly pure state. The amount of this substance contained in the air-dried leaves is 0.6 per cent.

*l*-Quercitol melts at  $174^\circ$ . A determination of its specific rotatory power in aqueous solution gave the following result:  $\alpha - 2^\circ 59'$ ;  $l = 1$  dcm.;  $c = 4.035$ ;  $[\alpha]_D - 73.9^\circ$ .

It is readily soluble in water, very sparingly so in alcohol, and insoluble in all other ordinary solvents. It crystallises from water in

colourless prisms containing one molecule of water, which is not lost on recrystallisation from absolute alcohol, but is eliminated when the substance is heated for some time at  $100^{\circ}$ . When crystallised from alcohol, it is obtained in the form of fine, colourless needles.

A portion of *l*-quercitol which had been recrystallised from alcohol was analysed :

0.1139 gave  $0.1650 \text{ CO}_2$  and  $0.0800 \text{ H}_2\text{O}$ .  $\text{C} = 39.5$  ;  $\text{H} = 7.8$ .

$\text{C}_6\text{H}_{12}\text{O}_5 \cdot \text{H}_2\text{O}$  requires  $\text{C} = 39.5$  ;  $\text{H} = 7.7$  per cent.

In another portion, which had been recrystallised from dilute alcohol, the water was determined by heating at  $110^{\circ}$ .

0.8963 lost  $0.0881 \text{ H}_2\text{O}$ .  $\text{H}_2\text{O} = 9.8$ .

$\text{C}_6\text{H}_{12}\text{O}_5 \cdot \text{H}_2\text{O}$  requires  $\text{H}_2\text{O} = 9.9$  per cent.

This dried substance was then recrystallised from absolute alcohol, in which it was even more sparingly soluble than the hydrated substance, and analysed :

0.1009 gave  $0.1600 \text{ CO}_2$  and  $0.0674 \text{ H}_2\text{O}$ .  $\text{C} = 43.2$  ;  $\text{H} = 7.4$ .

$\text{C}_6\text{H}_{12}\text{O}_5$  requires  $\text{C} = 43.9$  ;  $\text{H} = 7.3$  per cent.

It was therefore practically anhydrous.

*Penta-acetyl-l-quercitol*,  $\text{C}_6\text{H}_7(\text{O} \cdot \text{C}_2\text{H}_3\text{O})_5$ .

When *l*-quercitol is heated with acetic anhydride and sodium acetate, a vigorous reaction takes place before the boiling point of the anhydride is reached. After boiling for about one hour, the mixture was poured into water, when a heavy oil separated, which in a few minutes became solid. After recrystallisation from dilute alcohol, the substance was obtained in a pure state.

Penta-acetyl-*l*-quercitol crystallises in colourless needles, which melt at  $124$ — $125^{\circ}$  when anhydrous, and at  $87$ — $97^{\circ}$  when containing benzene of crystallisation. A determination of its specific rotatory power in chloroform solution gave the following result :  $\alpha = 0^{\circ}42'$  ;  $l = 1 \text{ dm.}$  ;  $c = 2.697$  ;  $[\alpha]_D - 26.0^{\circ}$ .

It is readily soluble in alcohol, ethyl acetate, acetone, benzene, ether, and chloroform, sparingly so in light petroleum, and insoluble in water. When crystallised from benzene, or a mixture of benzene and light petroleum, it contains one molecule of benzene, but from dilute alcohol it separates in an anhydrous state. The anhydrous acetyl derivative was analysed :

0.1320 gave  $0.2467 \text{ CO}_2$  and  $0.0706 \text{ H}_2\text{O}$ .  $\text{C} = 51.0$  ;  $\text{H} = 5.9$ .

0.1068 „  $0.2007 \text{ CO}_2$  „  $0.0576 \text{ H}_2\text{O}$ .  $\text{C} = 51.2$  ;  $\text{H} = 5.9$ .

$\text{C}_{16}\text{H}_{22}\text{O}_{10}$  requires  $\text{C} = 51.3$  ;  $\text{H} = 5.8$  per cent.

An attempt was made to determine the molecular weight of *l*-quercitol in phenol solution, but it was not sufficiently soluble. The acetyl derivative was therefore selected for this purpose, and its molecular weight was determined by the cryoscopic method in benzene solution.

0.4288 in 24.38 benzene gave  $\Delta t = 0.248^\circ$ . M. W. = 348.

$C_{16}H_{22}O_{10}$  requires M. W. = 374.

The number of acetyl groups in this compound was determined by hydrolysing a weighed quantity of the substance with a known volume of standard alcoholic solution of sodium hydroxide and titrating the excess of alkali with standard acid. The percentage of acetyl found by this means was 80.3, the theoretical percentage for five acetyl groups being 78.9.

It was observed that the penta-acetyl-*l*-quercitol which had been crystallised from benzene melted at  $87-97^\circ$ , but after heating to  $80^\circ$  for a short time melted at  $124-125^\circ$ , which is the melting point of the anhydrous substance. The whole of the benzene was also given off in the course of two or three days at the ordinary temperature.

A portion of the acetyl derivative was crystallised from benzene, pressed on a porous tile until free from adhering solvent, and the amount of benzene of crystallisation determined by heating at  $100^\circ$  until the weight of the residue remained constant.

0.5200 lost 0.0880  $C_6H_6$ .  $C_6H_6 = 16.9$ .

0.7142 „ 0.1239  $C_6H_6$ .  $C_6H_6 = 17.3$ .

$C_{16}H_{22}O_{10}$ ,  $C_6H_6$  requires  $C_6H_6 = 17.3$  per cent.

*Pentabenzoyl-l-quercitol*,  $C_6H_7(O \cdot C_7H_5O)_5$ .

The *l*-quercitol was benzoylated by the Schotten-Baumann method, and also by heating it with an excess of benzoyl chloride until hydrogen chloride ceased to be evolved; the products obtained were identical.

Pentabenzoyl-*l*-quercitol shows the same behaviour towards solvents as the acetyl derivative; it separates from alcohol in an amorphous state, melts at  $133^\circ$ , and is anhydrous. A determination of its specific rotatory power in chloroform solution gave the following result:  $\alpha = 2.14'$ ;  $l = 1$  dm.;  $c = 2.826$ ;  $[\alpha]_D = 79.0^\circ$ .

On adding a quantity of light petroleum to a solution of the substance in a mixture of warm ethyl acetate and alcohol, needle-shaped crystals containing one molecule of alcohol slowly separated. These crystals, when dried in the air, melt at  $116^\circ$ , but the melting point is raised to

148° after drying at 100° for some hours. The amount of alcohol of crystallisation was estimated by heating at 120°.

0.7703 lost 0.0503  $C_2H_6O$ .  $C_2H_6O = 6.5$ .

$C_{41}H_{32}O_{10}$ ,  $C_2H_6O$  requires  $C_2H_6O = 6.3$  per cent.

The dried substance was then analysed :

0.1000 gave 0.2630  $CO_2$  and 0.0436  $H_2O$ .  $C = 71.7$  ;  $H = 4.8$ .

$C_{41}H_{32}O_{10}$  requires  $C = 71.9$  ;  $H = 4.7$  per cent.

*l*-Quercitol readily forms a phenylurethane, but this derivative crystallises with difficulty, and we were unable to obtain it in a pure state ; it melts indefinitely between 245° and 260°.

*Oxidation with Sodium Hypobromite. Formation of a Diketotrihydroxyhexahydrobenzene*,  $C_6H_5O_2(OH)_3$ .

By the oxidation of *d*-quercitol with bromine in the presence of water, Kiliani obtained a diketone which he isolated in the form of its dihydrazone, but did not obtain this in a state of purity (*Ber.*, 1896, 29, 1762). In the case of *l*-quercitol, we have found that its oxidation can be effected much more quickly and more satisfactorily by the use of sodium hypobromite.

Twenty grams of *l*-quercitol and 90 grams of crystallised sodium carbonate were dissolved in water (about 400 c.c.) and the mixture cooled in ice. Thirty-five grams of bromine were then gradually added, and the mixture allowed to remain at the ordinary temperature for about 2 hours, when the colour of the bromine had disappeared. A slight excess of sulphuric acid was then added, and the liberated bromine removed by means of sulphur dioxide. The liquid, after being made slightly alkaline with potassium hydroxide, was acidified with acetic acid. Thirty grams of phenylhydrazine, dissolved in 30 grams of 50 per cent. acetic acid, were then added, and in the course of two days the mixture deposited a large quantity of dark red, tarry matter, mixed with minute needles of the dihydrazone. This sticky mass was collected at the pump, and the red, tarry matter removed by washing with ethyl acetate. A bright yellow, crystalline substance remained on the filter, which, after crystallisation from alcohol, in which it was somewhat sparingly soluble, melted with decomposition at 209°.

0.0963 gave 0.2233  $CO_2$  and 0.0519  $H_2O$ .  $C = 63.2$  ;  $H = 5.9$ .

0.1046 „ 0.2424  $CO_2$  „ 0.0566  $H_2O$ .  $C = 63.2$  ;  $H = 6.0$ .

0.1334 „ 19.8 c.c. moist nitrogen at 23° and 770 mm.  $N = 16.9$ .

$C_{18}H_{20}O_3N_4$  requires  $C = 63.5$  ;  $H = 5.9$  ;  $N = 16.5$  per cent.

*Oxidation with Potassium Permanganate. Formation of Malonic Acid.*

A cold, dilute, aqueous potassium permanganate solution was gradually added to a cold, dilute, aqueous solution of *l*-quercitol. The colour of the permanganate was only very slowly discharged at first, but after a few portions had been introduced, the reaction proceeded much more quickly. When the equivalent of nearly eight atoms of oxygen had been added, the colour of the permanganate ceased to be discharged. The precipitated manganese dioxide was then removed and the oxalic and carbonic acids subsequently precipitated by the addition of an excess of calcium chloride. The filtrate was then evaporated to dryness, the powdered residue mixed with absolute alcohol, and the mixture boiled in a reflux apparatus for six hours, while dry hydrogen chloride was simultaneously passed through it. After distilling off the greater part of the alcohol, water was added, when the characteristic odour of ethyl malonate was perceptible. This liquid was then extracted with ether, and, after removing the latter, the residue was distilled, first under reduced, and finally under the ordinary pressure. A fraction boiling at 197—202° was analysed.

0.1175 gave 0.2256 CO<sub>2</sub> and 0.0804 H<sub>2</sub>O. C = 52.3; H = 7.6.

C<sub>7</sub>H<sub>12</sub>O<sub>4</sub> requires C = 52.5; H = 7.5 per cent.

Kiliani (*loc. cit.*) identified the malonic acid formed by the oxidation of *d*-quercitol by analyses of its barium and calcium salts.

LXIII.—*The Constituents of the Essential Oil of Californian Laurel.*

By FREDERICK BELDING POWER and FREDERIC HERBERT LEES.

THE Californian laurel, *Umbellularia Californica* (Nuttall), is a handsome, evergreen tree, which is distributed from the valleys of Oregon through the California coast ranges and along the high western slopes of the Sierra Nevada to the southern slopes of the San Bernardino Mountains (compare "The Silva of North America," by Charles Sprague Sargent, vol. vii, pp. 19—22, tab. cccvi.). It is also known under the names of "mountain laurel," "cajeput," "spice tree," "California olive," "California bay-tree," and "pepper-wood."\*

\* The name of "pepper-wood" has also been given to a species of *Xanthoxylum*.

The essential oil, which is distilled from the leaves,\* has been described as having a pale yellow colour, and a pungent, aromatic odour, resembling that of a mixture of nutmeg and cardamom. When inhaled in any considerable amount, it attacks the mucous membranes, produces headache, and excites a flow of tears ("Die aetherischen Oele," by Gildemeister and Hoffmann, p. 527).

The only chemical examination hitherto made of this oil which requires notice is that by Stillman (*Ber.*, 1880, 13, 629, and *Amer. Chem. J.*, 1880, 2, 38), who obtained by its fractional distillation two principal fractions, boiling respectively at 167—168° and 215—216°. The fraction 167—168° was regarded by Stillman as having the formula  $C_{20}H_{32}.H_2O$ , and as corresponding with the "terpinol" of Wiggers, which, however, has since been shown to be a mixture of several substances. To the fraction 215—216°, which he observed to possess the pungency characteristic of the original oil, was assigned the formula  $C_8H_{12}O$  and the name of "umbellol," but without any determination of its chemical nature. From the results of our investigation, it is evident that both of the fractions analysed by Stillman consisted of a mixture of substances.

#### EXPERIMENTAL.

The oil employed in this investigation (1200 grams), which was specially distilled for us in California, and was therefore perfectly genuine, had a pale yellow colour, and an odour which at first was agreeably aromatic and somewhat camphoraceous, but, as has previously been noticed, when strongly inhaled it is exceedingly pungent, affecting particularly the mucous membranes of the nose and eyes. Its sp. gr. was 0.9483 at 16°/16°, and its optical rotatory power - 22° in a 100 mm. tube. The oil was completely soluble in 1.5 parts of 70 per cent. alcohol; it formed no solid compound with sodium hydrogen sulphite. As it was thought that it might contain sulphur or nitrogen compounds, special tests were made for these elements, but with negative results.

A determination of the amount of free acids and of esters gave the following data: 10.35 grams of the oil required 1.5 c.c. of a seminormal alcoholic solution of sodium hydroxide to neutralise the free acids. On subsequently adding an excess of the alkali solution and boiling, it was found that only 0.8 c.c. was required to hydrolyse the esters present. These, if calculated as  $C_{10}H_{17}.C_2H_3O_2$ , would therefore only amount to 0.8 per cent. It was observed that, on boiling the oil with

\* Schimmel & Co., in the appendix to their *Bericht* for October, 1887, p. 47, have recorded a yield of 7.6 per cent. of essential oil from the leaves of Californian laurel, and others have noted yields varying between 2.5 and 4 per cent.

an excess of an alcoholic solution of sodium hydroxide, its pungent odour was not destroyed.

The separation of the small amount of uncombined acids was effected by shaking the oil four times with dilute aqueous sodium carbonate and finally with water. The combined aqueous liquids, after shaking with ether to remove adhering oil, were evaporated to a small volume, acidified with sulphuric acid, and distilled in steam. From the distillate, ether extracted 2·3 grams of a light yellow, somewhat pungent, oily acid, which was converted through the ammonium salt into a silver salt. The latter formed a dense, white, amorphous precipitate, and was obtained in two fractions, which were analysed :

(a) 0·1523 gave 0·0495 Ag.  $\text{Ag} = 32\cdot5$ .

(b) 0·1277 „ 0·0599 Ag.  $\text{Ag} = 46\cdot9$  per cent.

The aqueous liquid from which the oily acids had been extracted still contained an acid, which was converted into its barium salt. This was crystalline, but, in attempting to prepare the corresponding silver salt, the dense, white precipitate first produced almost immediately became reduced. Another portion of the barium salt gave a precipitate of calomel with a solution of mercuric chloride. The oil thus evidently contains an exceedingly small amount of formic acid, associated with a mixture of some higher fatty acids.

#### *Identification of Eugenol.*

The whole of the oil, after the removal of the fatty acids, was shaken six times with 5 per cent. aqueous potassium hydroxide, and finally several times with water. The combined alkaline liquids were then shaken with ether to remove adhering oil, and acidified with sulphuric acid, when a quantity of an oily liquid separated ; this was taken up with ether, the ethereal solution washed, dried, and the ether removed. The residual oil, amounting to 20 grams, was then distilled under 80 mm. pressure, when it passed over completely between  $170^{\circ}$  and  $175^{\circ}$ , but principally at  $170$ — $172^{\circ}$ . A fraction collected at the latter point was analysed :

0·1106 gave 0·2964  $\text{CO}_2$  and 0·0749  $\text{H}_2\text{O}$ .  $\text{C} = 73\cdot1$  ;  $\text{H} = 7\cdot5$ .

$\text{C}_{10}\text{H}_{12}\text{O}_2$  requires  $\text{C} = 73\cdot2$  ;  $\text{H} = 7\cdot3$  per cent.

It gave a blue coloration with ferric chloride, and afforded a benzoyl derivative, which, after crystallisation from alcohol, melted at  $69$ — $70^{\circ}$ . It is thus shown that the oil contains an appreciable amount of eugenol.

*Fractional Distillation of the Oil.*

The whole of the oil remaining from the foregoing treatment was mixed with a quantity of ether and dried with calcium chloride. After the removal of the ether, the residual oil was first distilled under the ordinary pressure until the temperature had reached  $207^{\circ}$ , and then under diminished pressure. In this way, a small amount of dark, non-volatile matter was removed. The whole of the distilled oil was then subjected to a prolonged series of fractional distillations under the ordinary pressure, when a number of fractions were obtained boiling between the following ranges of temperature:  $150-165^{\circ}$ ;  $165-169^{\circ}$ ;  $169-173^{\circ}$ ;  $173-175^{\circ}$ ;  $175-180^{\circ}$ ;  $180-185^{\circ}$ ;  $185-195^{\circ}$ ;  $195-205^{\circ}$ ;  $205-215^{\circ}$ ;  $215-217^{\circ}$ ;  $217-222^{\circ}$ ;  $222-227^{\circ}$ ;  $227-235^{\circ}$ ;  $235-245^{\circ}$ ;  $245-250^{\circ}$ .

*Identification of Pinene.*

*Fraction*  $150-165^{\circ}$  (sp. gr. =  $0.8659$  at  $16^{\circ}/16^{\circ}$ ;  $\alpha_D - 20^{\circ}$  in a 100 mm. tube).—This was a colourless, limpid liquid, having a terpene-like odour, and was practically insoluble in 70 per cent. alcohol.

$0.1491$  gave  $0.4672$   $\text{CO}_2$  and  $0.1567$   $\text{H}_2\text{O}$ .  $\text{C} = 85.5$ ;  $\text{H} = 11.7$ .

$\text{C}_{10}\text{H}_{16}$  requires  $\text{C} = 88.2$ ;  $\text{H} = 11.8$  per cent.

This fraction, which evidently consisted chiefly of a hydrocarbon, associated with a small amount of an oxygenated substance which could not be eliminated by fractional distillation, was shown to contain *l*-pinene by the formation of a crystalline nitrosocbchloride, from which were prepared the nitrolpiperidine and nitrolbenzylamine, melting respectively at  $119-120^{\circ}$  and  $124-125^{\circ}$ .

*Fraction*  $165-169^{\circ}$  (sp. gr. =  $0.8770$  at  $16^{\circ}/16^{\circ}$ ;  $\alpha_D - 18^{\circ}20'$  in a 100 mm. tube).—This fraction had an odour recalling that of pinene, but was also somewhat camphoraceous; it consisted principally of pinene, but contained more of the oxygenated substance than the preceding fraction.

*Fraction*  $169-173^{\circ}$  (sp. gr. =  $0.8903$  at  $16^{\circ}/16^{\circ}$ ;  $\alpha_D - 13^{\circ}12'$  in a 100 mm. tube).—This fraction had a more highly camphoraceous odour than the preceding fraction; it was specially tested for phellandrene, but with a negative result.

*Fraction*  $173-175^{\circ}$ .—This was relatively small in amount.

*Identification of Cineol.*

*Fraction* 175—180° (sp. gr. = 0.9092 at 16°/16°;  $n_D - 3^{\circ}30'$  in a 100 mm. tube).—This very large fraction was a colourless liquid, possessing the characteristic, camphoraceous odour of cineol.

0.1144 gave 0.3381 CO<sub>2</sub> and 0.1205 H<sub>2</sub>O. C = 80.6; H = 11.7.

C<sub>10</sub>H<sub>18</sub>O requires C = 77.9; H = 11.7 per cent.

This fraction evidently consisted principally of an oxygenated substance, associated with only a small proportion of a hydrocarbon. With tetraiodopyrrole it afforded the crystalline, double compound of cineol, C<sub>10</sub>H<sub>18</sub>O, C<sub>4</sub>I<sub>4</sub>NH, which melted at 115° with decomposition (Hirschsohn, *Pharm. Zeit. Russ.*, 1893, 32, 49, 67). Cineol hydrobromide was accordingly prepared by saturating a cooled solution of the fraction in light petroleum with hydrogen bromide, and then decomposed with sodium carbonate, when the regenerated cineol\* was recognised by its physical properties and by analysis:

0.1293 gave 0.3672 CO<sub>2</sub> and 0.1368 H<sub>2</sub>O. C = 77.5; H = 11.8.

C<sub>10</sub>H<sub>18</sub>O requires C = 77.9; H = 11.7 per cent.

Sp. gr. = 0.9276 at 16°/15°. Optically inactive.

Limonene and dipentene were also sought for in this fraction by attempting to form their respective crystalline tetrabromides, but only an oily bromo-compound resulted, which did not become crystalline even after several days.

*Fractions* 180—185° and 185—195°.—These two fractions were relatively very small in amount. They had a pronounced odour of cineol, and evidently consisted of that substance together with a small amount of the constituents of the fractions of higher boiling point.

*Fraction* 195—205° (sp. gr. = 0.9308 at 15°/15°;  $n_D - 22^{\circ}48'$  in a 100 mm. tube).—This was a very small fraction.

0.1036 gave 0.3015 CO<sub>2</sub> and 0.1012 H<sub>2</sub>O. C = 79.4; H = 10.9.

0.1020 „ 0.2978 CO<sub>2</sub> and 0.0990 H<sub>2</sub>O. C = 79.6; H = 10.8 per cent.

It had the odour of the preceding fractions containing cineol and also the peculiar pungency of a fraction of higher boiling point. It was specially tested for linalool by the oxidation of 5 grams of the liquid

\* The presence of cineol in this oil appears to have first been observed by Schimmel & Co., since, in the appendix to their *Bericht* of October, 1893, p. 27, and also of April, 1897, p. 31, it is recorded as the only known constituent of the oil. This has been overlooked in the notice of the oil given in “*Die aetherischen Oele*,” by Gildemeister and Hoffmann, p. 527.

with chromic acid, but no evidence of the formation of citral was obtained.

*Fraction 205—215°* (sp. gr. = 0.9460 at 15°/15°;  $\alpha_D - 30.3'$  in a 100 mm. tube).—This fraction, which was comparatively small, had a very pungent odour, and did not differ very essentially from the large, principal fraction collected at 217—222°.

0.1036 gave 0.3011 CO<sub>2</sub> and 0.0944 H<sub>2</sub>O. C = 79.2; H = 10.1.

0.0870 „ 0.2510 CO<sub>2</sub> „ 0.0810 H<sub>2</sub>O. C = 78.7; H = 10.3 per cent.

Although these results indicated that this fraction consisted principally of the constituent of the large fraction boiling at 217—222°, the possibility of the presence of a small amount of camphor or of borneol was not precluded. In order to test for these two substances, 10 grams of the liquid were oxidised by warming for half an hour on a water-bath, with occasional vigorous shaking, with a solution of 80 grams of potassium dichromate and 120 grams of sulphuric acid in 200 c.c. of water. During the oxidation, the odour of camphor did not become apparent, and on subsequently diluting the mixture with water and distilling in steam no camphor was found in the distillate.

*Fraction 215—217°* (sp. gr. = 0.9546 at 15.5°/15°;  $\alpha_D - 34.35'$  in a 100 mm. tube).—These and other characters afforded evidence that this consisted to a very large extent of the constituent of the following fraction.

#### *Isolation of a New Ketone, Umbellulone, C<sub>10</sub>H<sub>14</sub>O.*

*Fraction 217—222°* (sp. gr. = 0.9614 at 15.5°/15°;  $\alpha_D - 36.33'$  in a 100 mm. tube).—This fraction, which was the largest obtained and contained the most interesting constituent of the oil, was colourless, had a somewhat mint-like odour, and possessed in a high degree the peculiar pungency characteristic of the original oil.

0.1144 gave 0.3309 CO<sub>2</sub> and 0.1014 H<sub>2</sub>O. C = 78.9; H = 9.9 per cent.

During the distillation of this large fraction, it was observed that the most constant boiling point was 218° (752 mm.). A quantity collected at this point was also analysed, and the physical constants determined:

0.1226 gave 0.3566 CO<sub>2</sub> and 0.1078 H<sub>2</sub>O. C = 79.3; H = 9.8.

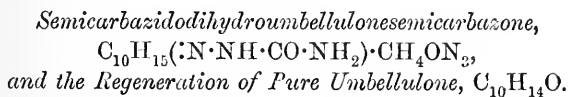

0.0958 „ 0.2780 CO<sub>2</sub> „ 0.0847 H<sub>2</sub>O. C = 79.1; H = 9.8 per cent.

Sp. gr. = 0.9584 at 15°/15°;  $\alpha_D - 37'$  in a 100 mm. tube.

From these data, and from a consideration of the analytical figures and physical constants of the smaller fractions boiling below the fraction 217—222°, it seemed evident that this consisted mainly of a substance

having the formula  $C_{10}H_{14}O$ , which requires  $C=80.0$ ;  $H=9.3$  per cent. The substance readily interacted with semicarbazide and hydroxylamine respectively, but did not respond to Schiff's rosaniline test for aldehydes; it is, therefore, a ketone. Among all the ketones which have hitherto been isolated from essential oils, none has the peculiar and extreme pungency of this substance, and there is only one of the naturally occurring ketones, namely, carvone, with which it is isomeric. Furthermore, a study of its behaviour towards many reagents has shown that it is not identical with any of the ketones hitherto described. We have, therefore, in consideration of its botanical source, given it the designation of *umbellulone*.

Umbellulone does not combine with sodium hydrogen sulphite, nor does it, like its isomeride, carvone, form a compound with hydrogen sulphide. It combines directly with two atomic proportions of bromine in the cold, and readily decolorises a cold solution of potassium permanganate. It, therefore, would seem to contain only one ethylenic linking, and, since it has the formula  $C_{10}H_{14}O$ , would appear to be a cyclic ketone with two closed rings. Its behaviour towards semicarbazide and hydroxylamine is abnormal, inasmuch as under the usual conditions these bases not only interact with the carbonyl group with the elimination of water to form a semicarbazone and oxime respectively, but at the same time their elements become attached to the two carbon atoms of the ethylenic linking. This behaviour of certain unsaturated open chain and closed ring ketones has previously been observed by Harries and his pupils (*Ber.*, 1897, 30, 230), by Tiemann (*Ber.*, 1897, 30, 251, and 1900, 33, 562), and more recently, with regard to the action of semicarbazide, by Rupe and Schlochoff (*Ber.*, 1903, 36, 4377).

To a solution in the minimum amount of water of a large excess of semicarbazide hydrochloride (40 grams) and sodium acetate (50 grams) were added umbellulone (20 grams) and just sufficient methyl alcohol to form a clear solution. After three days, during which interval nothing separated, a quantity of water was added, which caused the deposition of a bulky, white, crystalline substance. This was collected and drained at the pump, and then washed well with water in order to remove the uncombined ketone, since it was found that after the first two days the reaction proceeds very slowly, and the yield of product therefore never greatly exceeded 50 per cent. of the calculated amount. As thus obtained, the compound melted at  $216^\circ$  with

evolution of gas, and was practically pure. It was recrystallised from ethyl alcohol, when it separated almost completely from the cooled solution in compact rosettes of fine needles, which melted at  $217^{\circ}$  with evolution of gas.

0.1751 gave 0.3276  $\text{CO}_2$  and 0.1260  $\text{H}_2\text{O}$ .  $\text{C} = 51.0$ ;  $\text{H} = 8.0$ .

0.1222 „ 0.2288  $\text{CO}_2$  „ 0.0885  $\text{H}_2\text{O}$ .  $\text{C} = 51.1$ ;  $\text{H} = 8.0$  percent.

It is readily soluble in hot water, without decomposition, and on cooling it separates in small, transparent, cubical crystals, which melt at  $217^{\circ}$  with evolution of gas.

0.1128 gave 0.2120  $\text{CO}_2$  and 0.0810  $\text{H}_2\text{O}$ .  $\text{C} = 51.2$ ;  $\text{H} = 8.0$ .

0.1268 „ 32.2 c.c. moist nitrogen at  $22^{\circ}$  and 766 mm.  $\text{N} = 29.0$ .

$\text{C}_{12}\text{H}_{22}\text{O}_2\text{N}_6$  requires  $\text{C} = 51.1$ ;  $\text{H} = 7.8$ ;  $\text{N} = 29.8$  per cent.

Semicarbazidodihydroumbellulonesemicarbazone is soluble in dilute mineral acids, and, on warming the solutions, it is decomposed, regenerating umbellulone in quantitative yield. This process has been utilised in order to prepare a pure specimen of the ketone for the determination of its physical constants.

A quantity of the semicarbazidosemicarbazone, mixed with about 500 c.c. of water and sufficient sulphuric acid added to effect decomposition, was distilled in steam; the umbellulone contained in the distillate was extracted with ether, the ethereal solution dried with calcium chloride, and the ether removed. The residual liquid was then distilled, when it was found to boil at  $219\text{--}220^{\circ}$  (corr.) under 749 mm. pressure. It is a perfectly colourless liquid, the odour of which is at first pleasant, somewhat resembling that of mint, but when more strongly inhaled is exceedingly pungent, producing the effects already described.

0.1634 gave 0.4778  $\text{CO}_2$  and 0.1370  $\text{H}_2\text{O}$ .  $\text{C} = 79.7$ ;  $\text{H} = 9.3$ .

0.1400 „ 0.4083  $\text{CO}_2$  „ 0.1195  $\text{H}_2\text{O}$ .  $\text{C} = 79.5$ ;  $\text{H} = 9.5$ .

$\text{C}_{10}\text{H}_{14}\text{O}$  requires  $\text{C} = 80.0$ ;  $\text{H} = 9.3$  per cent.

Sp. gr. = 0.9581 at  $15^{\circ}/15^{\circ}$ ;  $[\alpha]_{\text{D}} - 37^{\circ}$ .

*Hydroxylaminodihydroumbelluloneoxime*,  $\text{C}_{10}\text{H}_{15}(\text{N}\cdot\text{OH})\cdot\text{NH}\cdot\text{OH}$ .

Umbellulone (15 grams) was added to a solution of hydroxylamine (four molecular proportions), formed by adding a solution of sodium methoxide in methyl alcohol (9.2 grams Na in 300 c.c. methyl alcohol) to a solution of hydroxylamine hydrochloride (28 grams) in the same solvent (300 c.c.). The mixture was then boiled for two hours. After removing the methyl alcohol completely by distillation, the residue, consisting of the product of the reaction mixed with sodium

chloride, was mixed with water and the undissolved viscid oil extracted with ether, the ethereal liquid being then washed, dried, and distilled to remove the solvent. The product, which weighed 18 grams, was a clear, nearly colourless liquid of a honey-like consistency.

In order to remove a small amount of substance which had not been converted into oxime, the product was mixed with dilute sulphuric acid, in which the hydroxylamino-oxime is readily soluble, and the small amount of non-basic matter which remained as an oil was then removed by extraction with ether. By the addition of sodium carbonate to the acid aqueous liquid, the base was again set free; it was then extracted with ether, dried, and the ether removed by distillation on the water-bath and by subsequently exposing the substance in a vacuum-desiccator over paraffin wax. The base was thus obtained as a hard, slightly green, glistening, amorphous substance, which could readily be powdered; it has thus far not been possible to obtain it in a definite crystalline form.

0.2035 gave 23.2 c.c. moist nitrogen at 23° and 768 mm.  $N = 13.0$ .

$C_{10}H_{18}O_2N_2$  requires  $N = 14.1$  per cent.

Although the percentage of nitrogen obtained is somewhat less than that required by theory for the pure substance, the result is sufficiently conclusive to show its composition, inasmuch as the normal oxime,  $C_{10}H_{14}N \cdot OH$ , would require  $N = 8.5$  per cent. The discrepancy is in all probability due to the product containing a small amount of hydroxylaminodihydroumbellulone,  $C_{10}H_{15}O \cdot NH \cdot OH$ , which would not only be more readily formed than the normal oxime, but would be markedly basic, and therefore more likely to be present than the latter, which, on account of its feebly basic properties, would be readily removed by ether from a solution of the product in dilute acids (compare Harries, *loc. cit.*, and Tiemann, *loc. cit.*).

Hydroxylaminodihydroumbelluloneoxime very closely resembles diacetonehydroxylamine (*Ber.*, 1898, 31, 1376), hydroxylaminodihydropulegone (pulegonehydroxylamine, *ibid.*, 1809), and hydroxylaminodihydrocarvoxime (oxaminocarvoxime, *ibid.*, 1810). It is readily soluble in dilute alkali hydroxides and also in dilute acids, forming salts. Its solution in aqueous sodium hydroxide reduces Fehling's solution with extraordinary readiness, even in the cold.

Fraction 222—227° (sp. gr. = 0.9842 at 15°/15°;  $\alpha_D - 29.17'$  in a 100 mm. tube).—This was a comparatively small fraction, which had a pronounced odour of umbellulone and a faint one of safrole; it consisted chiefly of umbellulone, with smaller amounts of the constituents of the following fractions.

*Identification of Safrole.*

*Fraction 227—235°* (sp. gr. = 0.9976 at 15°/15°;  $\alpha_D - 20^\circ 27'$  in a 100 mm. tube) —This fraction, which was somewhat larger than the preceding one, was slightly pungent, but at the same time possessed the unmistakable odour of safrole.

While distilling this fraction it was observed that it boiled most constantly at 230—231°. A small amount was therefore separately collected at this point for analysis and the determination of its physical constants:

0.0851 gave 0.2411 CO<sub>2</sub> and 0.0680 H<sub>2</sub>O. C = 77.3; H = 8.9 per cent.

Sp. gr. = 0.9930 at 16°/16°;  $\alpha_D - 25^\circ 4'$  in a 100 mm. tube.

In order to confirm the above indication of the presence of safrole, and at the same time to ascertain whether geraniol was present, 10 grams of the liquid were oxidised by warming gently on a water-bath, with occasional shaking, with a solution of 50 grams of potassium dichromate and 16 grams of sulphuric acid in 160 c.c. of water. The brown oily product, when isolated by extraction with ether, had the odour of piperonal, but not of citral; it was vigorously shaken with a saturated solution of sodium hydrogen sulphite, when, after some time, a crystalline compound separated, which was collected, washed with ether, and decomposed with a dilute solution of sodium hydroxide. The small amount of liberated oil which was extracted with light petroleum became crystalline on introducing a trace of piperonal. The crystals melted at 35°, and had the characteristic odour of piperonal. It was thus shown that the essential oil contains safrole, but only in very small amount.

*Fraction 235—245°* (sp. gr. = 1.013 at 15°/15°;  $\alpha_D - 8^\circ 40'$  in a 100 mm. tube).—This fraction was equal in amount to the preceding, and it had the odour of safrole. During its distillation, a small amount was separately collected at 240°, when the temperature was most constant. This was analysed and its physical constants determined:

0.0846 gave 0.2361 CO<sub>2</sub> and 0.0664 H<sub>2</sub>O. C = 76.1; H = 8.7 per cent.

Sp. gr. = 1.009 at 16°/16°;  $\alpha_D - 11^\circ 41'$  in a 100 mm. tube.

This fraction consisted to a large extent of the constituent of the following fraction.

*Identification of Eugenol Methyl Ether.*

*Fraction 245—250°* (sp. gr. = 1.021 at 16°/16°;  $\alpha_D - 2^\circ 22'$  in a 100 mm. tube).—This was a large fraction, which had a slightly yellow

colour and was nearly odourless. The greater portion was observed to boil at 248—250°, and a quantity was therefore separately collected at this point for the purpose of analysis and the determination of its physical constants:

0.1035 gave 0.2846 CO<sub>2</sub> and 0.0796 H<sub>2</sub>O. C = 75.0; H = 8.5.

C<sub>11</sub>H<sub>14</sub>O<sub>2</sub> requires C = 74.2; H = 7.9 per cent.

This fraction was shown to consist of eugenol methyl ether by the fact that it readily afforded an excellent yield of bromoeugenol methyl ether dibromide, C<sub>6</sub>H<sub>2</sub>Br(O·CH<sub>3</sub>)·C<sub>3</sub>H<sub>5</sub>Br<sub>2</sub>, which, after crystallisation from ethyl alcohol, melted at 78—79° (compare Power and Lees, *Trans.*, 1902, 81, 68). Furthermore, on oxidation with potassium permanganate, it yielded veratric acid, melting at 177°.

### *Summary.*

The results of this investigation have shown that the essential oil of Californian laurel contains the following substances:

	Approximate percentage amount.
1. Eugenol ... ..	1.7
2. <i>l</i> -Pinene ... ..	6.0
3. Cineol ... ..	20.0
4. <i>Umbellulone</i> , C <sub>10</sub> H <sub>14</sub> O ... ..	60.0
5. Safrole ... ..	A very small amount.
6. Eugenol methyl ether ... ..	10.0
7. A mixture of fatty acids containing formic acid ... ..	A very small amount.

THE WELLCOME CHEMICAL RESEARCH LABORATORIES,  
LONDON, E.C.

## LXIV.—*Some Derivatives of Umbellulone.*

By FREDERIC HERBERT LEES.

IN the preceding paper, it was shown that the new unsaturated ketone, umbellulone, C<sub>10</sub>H<sub>14</sub>O, as compared with the majority of ketones, behaves abnormally in its interactions with hydroxylamine and with semicarbazide, for not only does its carbonyl group undergo the usual transformation by reacting with one molecule of the respective

base, but, in each case, the elements of a second molecule of the latter become attached to the molecule of the ketone. The products, therefore, represent the interaction of one molecule of umbellulone with two molecules of hydroxylamine or semicarbazide.

A behaviour of this kind in respect to the interaction of hydroxylamine or semicarbazide with certain unsaturated ketones has been previously observed in many instances, particularly by Harries and his pupils (*Ber.*, 1899, 32, 1317), by Tiemann, and quite recently with regard to the action of semicarbazide, by Rupe and Schlochoff (compare this vol., p. 635).

It has been shown by these authors that the abnormal behaviour under consideration is common to those ketones which contain an ethylenic linking in an  $\alpha\beta$ -position with respect to the carbonyl group.

In the hope of ultimately elucidating the constitution of umbellulone, its behaviour towards a number of reagents is being studied, and some of the results obtained are recorded in this paper.

Umbellulone combines directly, in the cold, with only two atomic proportions of bromine, forming *umbellulone dibromide*,  $C_{10}H_{14}OBr_2$ ; it would therefore seem to contain only one ethylenic linking. From its formula,  $C_{10}H_{14}O$ , and the foregoing considerations, umbellulone would appear to be an  $\alpha\beta$ -unsaturated cyclic ketone, containing two closed rings.

When umbellulone dibromide is slowly heated under diminished pressure, it rapidly becomes decomposed with evolution of hydrogen bromide. The product of this decomposition is an *unsaturated bromoketone*, having the formula  $C_{10}H_{13}OBr$  (b. p. 140—145°/20 mm.); but, besides this, *dibromodihydroumbellulone*,  $C_{10}H_{14}OBr_2$  (m. p. 119—119.5°) is also formed, the latter being probably the result of the subsequent combination of the unsaturated bromoketone with the elements of hydrogen bromide.

The unsaturated bromoketone,  $C_{10}H_{13}OBr$ , on reduction with zinc dust and acetic acid, becomes converted into a *saturated ketone*,  $C_{10}H_{16}O$  (b. p. 214—217°).

When dibromodihydroumbellulone is reduced with zinc dust and acetic acid, it is only found possible to eliminate one bromine atom with the formation of *bromodihydroumbellulone*,  $C_{10}H_{15}OBr$  (m. p. 58—59°). When the latter, however, is reduced by means of sodium and alcohol, *tetrahydroumbellulol*,  $C_{10}H_{19}OH$ , is produced (b. p. 207—208°/760 mm.).

Both dibromodihydroumbellulone and bromodihydroumbellulone behave as saturated substances, since they do not decolorise a solution of bromine in chloroform, even on boiling. In view of this fact, the formation of tetrahydroumbellulol,  $C_{10}H_{20}O$ , from bromodihydro-

umbellulone,  $C_{10}H_{15}OBr$ , can only be explained on the assumption that one of the two closed rings present in umbellulone, dibromodihydroumbellulone, and bromodihydroumbellulone becomes resolved by reduction in passing to the alcohol.

Umbellulone is readily oxidised by cold permanganate, yielding a lactone,  $C_9H_{12}O_2$  (b. p.  $217-221^\circ$ ), together with several acids which, on account of insufficiency of material, have not yet been investigated.

#### EXPERIMENTAL.

##### *Action of Bromine on Umbellulone. Formation of Umbellulone Dibromide, $C_{10}H_{14}OBr_2$ .*

Twenty grams of umbellulone were dissolved in 100 c.c. of dry chloroform, and the solution cooled in a freezing mixture. A solution of 25 grams of dry bromine in 100 c.c. of dry chloroform was then run in, drop by drop; the bromine was instantaneously absorbed, and without any evolution of hydrogen bromide. When all the bromine had been added, the colour of the solution was red, and on this remaining permanent for some minutes, the slight excess of bromine was removed by shaking the liquid with a solution of sodium hydrogen sulphite. The nearly colourless liquid, after washing several times with water, was dried with calcium chloride, and the chloroform removed by allowing the liquid to boil under diminished pressure, without the application of external heat. The resulting dibromide was a somewhat dark, heavy oil, the amount obtained being approximately equal to the combined weights of the umbellulone and bromine originally taken for its formation, thus showing that the process is one of addition and not of substitution. A portion was exposed in a vacuum desiccator over paraffin wax, and then analysed:

0.4554 gave 0.528 AgBr.  $Br = 49.3$ .

$C_{10}H_{14}OBr_2$  requires  $Br = 51.6$  per cent.

Umbellulone dibromide is very unstable, readily losing hydrogen bromide even when kept at the ordinary temperature.

##### *Action of Heat on Umbellulone Dibromide. Formation of an Unsaturated Bromoketone, $C_{10}H_{13}OBr$ , and Dibromodihydroumbellulone, $C_{10}H_{14}OBr_2$ .*

A quantity of umbellulone dibromide was slowly heated in a distilling apparatus under 20 mm. pressure. An energetic evolution of hydrogen bromide commenced almost immediately, and a small amount of a colourless liquid passed over into the receiver while the temperature was

below  $100^{\circ}$ . The temperature gradually rose to  $160^{\circ}$ , when the evolution of hydrogen bromide ceased; in the meantime, a large fraction ( $\alpha$ ) had collected in the receiver (pressure = 20 mm.). The residual liquid was then rapidly distilled, and the last distillate, which passed over between  $160^{\circ}$  and  $190^{\circ}/20$  mm., was collected separately from the first fraction, which distilled below  $160^{\circ}$ . A quantity of dark, resinous, undistillable residue remained in the distilling flask. The less volatile fraction, on cooling, became for the most part crystalline, and on diluting with an equal volume of light petroleum, a further amount of the crystalline substance separated. It was collected at the pump and washed with light petroleum. After the removal of the petroleum from the filtrate, the residual oil, together with the more volatile fraction ( $\alpha$ ), when fractionated under diminished pressure yielded a further quantity of the  $\alpha$ -fraction ( $160$ — $190^{\circ}/20$  mm.), which, on treatment with petroleum, afforded more of the crystalline substance, and also two other principal fractions, one of which distilled below  $130^{\circ}/80$  mm., and the other at  $140$ — $145^{\circ}/20$  mm.

*Fraction boiling below  $130^{\circ}/80$  mm.*—This was nearly insoluble in 70 per cent. alcohol, and consisted chiefly of a hydrocarbon; it was distilled repeatedly under the ordinary pressure, and finally twice over sodium, being thus obtained as a colourless, limpid liquid, which boiled at  $175$ — $177^{\circ}$ , had the odour of cymene, and was evidently a hydrocarbon having the formula  $C_{10}H_{14}$ .\*

0.1184 gave 0.3873  $CO_2$  and 0.1125  $H_2O$ .  $C = 89.2$ ;  $H = 10.6$ .  
 $C_{10}H_{14}$  requires  $C = 89.6$ ;  $H = 10.4$  per cent.

*The Unsaturated Bromoketone,  $C_{10}H_{13}OBr$ .*

*Fraction  $140$ — $145^{\circ}/20$  mm.*—This fraction was a heavy, light yellow oil, the vapour of which had a very irritating effect on the eyes. It contained bromine, and was unsaturated, since it instantaneously decolorised a solution of bromine in chloroform.

0.2134 gave 0.4090  $CO_2$  and 0.1168  $H_2O$ .  $C = 52.3$ ;  $H = 6.1$ .  
 0.1593 „ 0.3029  $CO_2$  and 0.0875  $H_2O$ .  $C = 51.9$ ;  $H = 6.1$ .  
 $C_{10}H_{13}OBr$  requires  $C = 52.4$ ;  $H = 5.7$  per cent.

*Action of Zinc Dust and Acetic Acid.*—Fifteen grams of the unsaturated bromoketone were dissolved in 100 c.c. of glacial acetic acid,

\* Sufficient of this hydrocarbon to admit of purification was only obtained by the employment of a large amount of the umbellulone fraction (b. p.  $217$ — $222^{\circ}$ ) (compare this vol., p. 634), afforded by direct fractional distillation of the essential oil of Californian laurel. The formation of a hydrocarbon,  $C_{10}H_{14}$ , would be explained on the assumption that there was associated with the umbellulone a small amount of a substance having the formula  $C_{10}H_{16}O$ .

and 50 grams of zinc dust introduced. A vigorous reduction took place, which was moderated by immersing the flask in cold water. When the reaction had become less energetic, the mixture was heated on the water-bath during 3 hours; the product was then ground up with water and the oil extracted with ether. The ethereal solution was washed successively with water, aqueous sodium carbonate, and water, dried over calcium chloride, and the ether removed. The residual yellow oil was fractionated under the ordinary pressure, when it nearly all passed over between  $212^{\circ}$  and  $218^{\circ}$ , but principally at  $214$ — $217^{\circ}$ , as a nearly colourless liquid, which had an odour closely resembling that of pulegone. A portion of that which distilled at  $214$ — $217^{\circ}$  was analysed:

0.1156 gave 0.3342  $\text{CO}_2$  and 0.1099  $\text{H}_2\text{O}$ .  $\text{C}=78.8$ ;  $\text{H}=10.6$ .

0.1234 „ 0.356  $\text{CO}_2$  „ 0.1174  $\text{H}_2\text{O}$ .  $\text{C}=78.7$ ;  $\text{H}=10.6$ .

$\text{C}_{10}\text{H}_{16}\text{O}$  requires  $\text{C}=79.0$ ;  $\text{H}=10.5$  per cent.

It was thus shown that the action of zinc dust and acetic acid on the unsaturated bromoketone,  $\text{C}_{10}\text{H}_{13}\text{OBr}$ , is to form a ketone having the formula  $\text{C}_{10}\text{H}_{16}\text{O}$ . This new ketone was shown to be saturated, since it did not decolorise a very dilute solution of bromine in chloroform even after some time.

The *semicarbazone*, when prepared in the ordinary way, was first obtained as a viscid oil, which, however, soon became crystalline. It was drained on a porous plate, and then crystallised several times from dilute methyl alcohol, from which it separated in fine, white needles melting at  $171$ — $172^{\circ}$ .

0.051 gave 0.0118  $\text{CO}_2$  and 0.043  $\text{H}_2\text{O}$ .  $\text{C}=63.1$ ;  $\text{H}=9.4$ .

$\text{C}_{10}\text{H}_{19}\text{ON}_3$  requires  $\text{C}=63.1$ ;  $\text{H}=9.1$  per cent.

The semicarbazone is soluble in dilute sulphuric acid (25 per cent.), and on warming the solution it is decomposed, regenerating the pure ketone.

*Dibromodihydroumbellulone*,  $\text{C}_{10}\text{H}_{14}\text{OBr}_2$ .

The crystalline substance which was separated from the less volatile fraction ( $160$ — $190^{\circ}/20$  mm.), obtained as a product of the action of heat on umbellulone dibromide (p. 642), after washing with petroleum, melted at  $118^{\circ}$ ; when recrystallised from warm, light petroleum (b. p.  $40$ — $50^{\circ}$ ), it formed beautiful, white, glistening leaflets melting at  $119$ — $119.5^{\circ}$  without decomposition:

0.123 gave 0.1754  $\text{CO}_2$  and 0.0525  $\text{H}_2\text{O}$ .  $\text{C}=38.9$ ;  $\text{H}=4.7$ .

0.1909 „ 0.2744  $\text{CO}_2$  „ 0.0785  $\text{H}_2\text{O}$ .  $\text{C}=39.2$ ;  $\text{H}=4.6$ .

0.3489 „ 0.4225  $\text{AgBr}$ .  $\text{Br}=51.5$ .

$\text{C}_{10}\text{H}_{14}\text{OBr}_2$  requires  $\text{C}=38.7$ ;  $\text{H}=4.5$ ;  $\text{Br}=51.6$  per cent.

A solution containing 0.5232 gram in 25 c.c. of chloroform gave  $\alpha_D + 0.8'$  in a 1 dm. tube, whence  $[\alpha]_D + 6.4^\circ$ .

Dibromodihydroumbellulone can also be conveniently recrystallised from hot ethyl alcohol; it separates from the solution on cooling in glistening, prismatic needles. It is a saturated substance, since its solution in chloroform containing bromine can be boiled without the colour of the latter becoming discharged. It is also very stable towards boiling nitric acid, for its bromine is not eliminated on boiling with this reagent in the presence of silver nitrate. It does not interact with hydroxylamine even in boiling alcoholic solution.

*Bromodihydroumbellulone*,  $C_{10}H_{15}OBr$ .

Twenty grams of dibromodihydroumbellulone were dissolved in 100 c.c. of glacial acetic acid, and 40 grams of zinc dust added. The mixture was heated on a water-bath during five hours, and then ground up with more glacial acetic acid. The insoluble mixture of zinc salts was then removed by filtration at the pump, and the bromo-derivative precipitated from the filtrate by the addition of water. The crystalline precipitate, when washed, and dried on a porous plate, weighed 13 grams, and then melted at  $58-59^\circ$ . It was recrystallised from dilute methyl alcohol, from which it separated in well-defined, transparent, prismatic needles melting at  $58-59^\circ$ .

0.2042 gave 0.3885  $CO_2$  and 0.1181  $H_2O$ .  $C = 51.9$ ;  $H = 6.4$ .

0.2046 „ 0.3912  $CO_2$  „ 0.1224  $H_2O$ .  $C = 52.1$ ;  $H = 6.6$ .

$C_{10}H_{15}OBr$  requires  $C = 51.9$ ;  $H = 6.5$  per cent.

A solution containing 0.4163 gram in 25 c.c. of chloroform gave  $\alpha_D - 1.10'$  in a 1 dm. tube, whence  $[\alpha]_D - 70.1^\circ$ .

Bromodihydroumbellulone is readily soluble in cold ethyl and methyl alcohols, ethyl acetate, benzene, chloroform, and petroleum. When it is melted and warmed somewhat, its vapour has an odour resembling that of  $\alpha$ -bromocamphor. It is a saturated substance, since its solution in chloroform containing bromine can be boiled without decolorising the latter. Like the dibromo-derivative, bromodihydroumbellulone does not interact with hydroxylamine.

*Tetrahydroumbellulol*,  $C_{10}H_{19}OH$ .

Thirteen grams of bromodihydroumbellulone were dissolved in 150 c.c. of ethyl alcohol, and 10 grams of sodium gradually introduced in small pieces. The solution was not cooled, but was allowed to boil vigorously. When all the sodium had dissolved, the liquid was cooled and diluted with water in order to precipitate the oil, which was then

taken up with ether, the ethereal solution washed with water, dried with calcium chloride, and the ether removed. The residual oil was first distilled under 60 mm. pressure, when it nearly all passed over between  $125^{\circ}$  and  $130^{\circ}$ ; when finally fractionated under the ordinary pressure, the oil passed over for the most part at  $205\text{--}209^{\circ}$ , but boiled most constantly at  $207\text{--}208^{\circ}$  (corr.)/760 mm.; it was thus obtained as a colourless liquid, which had a camphoraceous odour resembling that of borneol.

0.1317 gave 0.3696  $\text{CO}_2$  and 0.1521  $\text{H}_2\text{O}$ .  $\text{C} = 76.5$ ;  $\text{H} = 12.8$ .

0.1305 „ 0.3672  $\text{CO}_2$  „ 0.1512  $\text{H}_2\text{O}$ .  $\text{C} = 76.7$ ;  $\text{H} = 12.9$ .

$\text{C}_{10}\text{H}_{20}\text{O}$  requires  $\text{C} = 76.9$ ;  $\text{H} = 12.8$  per cent.

Sp. gr. = 0.9071 at  $15^{\circ}/15^{\circ}$ .  $[\alpha]_{\text{D}} - 6.6^{\circ}$ .

*Oxidation of Umbellulone with Potassium Permanganate. Formation of a Lactone,  $\text{C}_9\text{H}_{12}\text{O}_2$ .*

Thirty grams of umbellulone were mixed with 500 c.c. of water and the mixture cooled by introducing a few pieces of ice. A 3 per cent. solution of potassium permanganate was then added, with vigorous shaking, so long as the colour of the latter was discharged. It was found that, working in this way, 80 grams of potassium permanganate, which is the equivalent of 4 atomic proportions of oxygen, were required. The liquid, after the removal of the manganese dioxide precipitate, was evaporated to a small volume, acidified with the calculated amount of sulphuric acid, and distilled in steam. The distillate contained a very small amount of an insoluble oil, which had a pleasant, lactonic odour. The cooled acid residue was then saturated with ammonium sulphate, whereupon a quantity of viscid oil separated; this was taken up with ether, the ethereal solution washed once with water, dried with calcium chloride, and the ether removed. The residual viscid oil was then fractionated under 20 mm. pressure. With the exception of a small fraction which passed over below  $170^{\circ}/20\text{ mm.}$ , the whole distilled between  $170^{\circ}$  and  $220^{\circ}$  as a light yellow oil. It was found to be only partly soluble in sodium carbonate solution. Consequently, the whole of the fraction  $170\text{--}220^{\circ}$  was shaken with cold aqueous sodium carbonate and the undissolved portion then taken up with ether. The ethereal solution, after shaking several times with sodium carbonate solution, was washed with water, dried with potassium carbonate, and the ether removed. The residual oil, when fractionally distilled under the ordinary pressure, was ultimately obtained as a nearly colourless liquid boiling at  $217\text{--}221^{\circ}$  and having a pleasant, sweetish, lactonic odour.

0.1269 gave 0.3284  $\text{CO}_2$  and 0.0926  $\text{H}_2\text{O}$ .  $\text{C} = 70.6$ ;  $\text{H} = 8.1$ .

$\text{C}_9\text{H}_{12}\text{O}_2$  requires  $\text{C} = 71.1$ ;  $\text{H} = 7.9$  per cent.

This substance was evidently a lactone, and this conclusion was confirmed by converting it into the barium salt of the corresponding hydroxy-acid. For this purpose, the pure lactone was digested with a concentrated solution of barium hydroxide until all the oil had disappeared. The excess of barium was then removed by means of carbon dioxide. The filtered solution was then evaporated, and finally left in a vacuum desiccator over sulphuric acid. The barium salt was thus obtained as a hard, white cake, which was powdered, dried at  $110^{\circ}$ , and then analysed.

0.2118 gave 0.1033  $\text{BaSO}_4$  instead of 0.1039, which is the calculated amount for  $(\text{C}_9\text{H}_{13}\text{O}_3)_2\text{Ba}$ .

The barium salt is extremely soluble in cold water, and on the addition of silver nitrate to the solution, the silver salt is not precipitated.

The author particularly wishes to reserve the further study of umbellulone and its derivatives.

THE WELLCOME CHEMICAL RESEARCH LABORATORIES,  
LONDON, E.C.

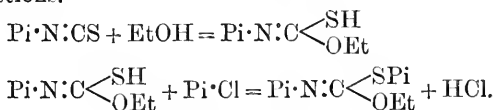

## LXV.—*Picryl Derivatives of Urethanes and Thiourethanes.*

By JAMES CODRINGTON CROCKER, B.A., and FRANK HAROLD LOWE, B.Sc.

In a paper by one of the authors (Trans., 1902, 81, 436), it was shown that picryl chloride reacted readily with ammonium thiocyanate and alcohols, with the production of the alkyl picryl picriminothiocarbonates.

The formation of these compounds was explained by the interaction of an intermediate additive compound of picrylthiocarbimide and picryl chloride with the alcohols. Another explanation of the reaction which, at the time, seemed less probable, when viewed in the light of other researches on the thiocyanates and the work in this paper, seems, however, to be the true one. It was shown by Dixon (Trans., 1899, 75, 375) that the acidic thiocarbimides,  $\text{R}\cdot\text{CO}\cdot\text{N}:\text{C}:\text{S}$ , easily react with the alcohols to form additive compounds, the thiourethanes. When the potassium salts of these substances are treated with alkyl halides, they behave as the tautomeric *pseudothiourethanes*,  $\text{R}\cdot\text{CO}\cdot\text{N}:\text{C}(\text{SH})\cdot\text{OX}$ , and pass into acyl iminothiocarbonic esters,  $\text{R}\cdot\text{CO}\cdot\text{N}:\text{C}(\text{SX}')\cdot\text{OX}$ , the

second alkyl group becoming attached to the sulphur. This explains the formation of the picriminothiocarbonic esters from picryl chloride, thiocyanate, and alcohols. The first formed picrylthiocarbimide unites with the alcohol to form the thiourethane, the tautomeric form of which is again acted on by the picryl chloride, with the production of the picriminothiocarbonate and the liberation of hydrochloric acid—the second molecule of picryl chloride taking the place of the alkyl halide in the foregoing example. According to this explanation, the formation of ethyl picryl picriminothiocarbonate is represented by the following reactions.

The results obtained with *isopropyl*, *tert.*-butyl, and amyl alcohols are described in the present paper.

The reaction with *isopropyl* alcohol is not so complete as in the previous cases. There was a considerable amount of unchanged picryl chloride, and the yield was less than usual. This is probably due to the spatial influence of the two methyl groups in preventing the formation of the thiourethane. With *tert.*-butyl alcohol, this effect is very marked. Even after boiling for an hour under a reflux apparatus, most of the picryl chloride was unchanged, and the sole products isolated were picryl sulphide and picryl thiocyanate, both in rather small quantity. This behaviour of *tert.*-butyl alcohol is very similar to that noticed by Lewis (Proc., 1903, 19, 41) in the case of the reaction between *tert.*-butyl chloride and sodium phenoxide, which gives rise to *tert.*-butylphenol and not the phenyl *tert.*-butyl ether. The amyl compound was obtained by boiling together lead thiocyanate, picryl chloride, benzene, and amyl alcohol. The reaction proceeded normally and gave a moderate yield. Attempts were made to produce the capryl compound, but without result. The bulk of the picryl chloride remained unchanged and very small quantities of picryl thiocyanate and picryl sulphide were isolated.

It seemed of interest to try whether cyanate would react in an analogous manner. The results obtained are quite in accordance with the foregoing explanation of the thiocyanate reaction.

When potassium cyanate is boiled with an alcoholic solution of picryl chloride, two substances are formed.

(1) A substance sparingly soluble in alcohol, having a high melting point, and resembling the picriminothiocarbonates except in colour, which proved to be ethyl picryl picriminocarbonate,  $\text{PiN} : \text{C}(\text{OPi}) \cdot \text{OEt}$ .

(2) A much more fusible substance, moderately easily soluble in alcohol, which was found to be the urethane,  $\text{PiN} : \text{C}(\text{OH}) \cdot \text{OEt}$ .

The ethoxy-group was estimated by Zeisel's method, and the substance was shown to give picramide on hydrolysis. Moreover, it was identical with the compound, melting at 144°, obtained by Romburgh (*Rec. trav. chim.*, 1891, 10, 138) on nitrating phenylurethane. This leaves no doubt as to its constitution.

The formation of these substances is represented by the following equations :  $\text{Pi}\cdot\text{N}:\text{C}:\text{O} + \text{EtOH} = \text{Pi}\cdot\text{N}:\text{C} \begin{smallmatrix} \text{OEt} \\ \text{OH} \end{smallmatrix}$  ;  $\text{Pi}\cdot\text{N}:\text{C} \begin{smallmatrix} \text{OEt} \\ \text{OH} \end{smallmatrix} + \text{Pi}\cdot\text{Cl} = \text{Pi}\cdot\text{N}:\text{C} \begin{smallmatrix} \text{OEt} \\ \text{OPi} \end{smallmatrix} + \text{HCl}$ .

Methyl alcohol under similar conditions also yielded two compounds, the red potassium picrylmethylurethane,  $\text{PiN}:\text{C}(\text{OK})\cdot\text{O}\cdot\text{CH}_3$  (soluble with difficulty in alcohol), and also the free urethane; the former was transformed into the urethane by crystallisation from a mixture of acetic acid and alcohol. This again was identical with Roxburgh's compound melting at 192° (*loc. cit.*).

In addition to these compounds, similar urethanes were prepared from *n*-propyl, *isopropyl*, *isobutyl*, and *amyl* alcohols. *tert*.-Butyl alcohol again behaved abnormally. Picramide was obtained in comparatively large quantities and there was some unchanged picryl chloride, but no urethane was isolated.

The behaviour of these picrylurethanes in solution is rather interesting. The substances themselves and their petroleum, chloroform, and carbon tetrachloride solutions are colourless, but when dissolved in water or alcohol the solutions are intensely yellow. One drop of dilute acid makes the weak solutions colourless, and in the case of water the substance is at once "salted out." When carbon dioxide is passed into a weak alcoholic solution, the colour gradually changes, but is not completely destroyed. On boiling and cooling, the yellow colour again becomes more intense. These marked colour changes, combined with the fact that the substances are excessively weak acids, and therefore not appreciably ionised, seem to indicate that the substances are tautomeric, the solid substances and the petroleum solutions probably containing the urethane proper,  $\text{Pi}\cdot\text{NH}\cdot\text{CO}\cdot\text{OX}$ , whilst other solvents, such as water, alcohol, ether, contain the *pseudourethane*,  $\text{Pi}\cdot\text{N}:\text{C}(\text{OH})\cdot\text{OX}$ .

The production of these urethanes as intermediate compounds between picrylcarbimide and the iminocarbonates confirms the foregoing view with regard to the analogous reaction in the case of thiocyanates.

#### EXPERIMENTAL.

##### *isoPropyl Picryl Picriminothiocarbonate.*

Five grams of picryl chloride and 1.6 grams of ammonium thiocyanate were separately dissolved in the smallest possible amount of

isopropyl alcohol and the hot solutions mixed. Precipitation took place immediately with violent frothing, and an oil which separated became solid on cooling and was collected, washed with water, and then with alcohol; it was then extracted with 20 c.c. of boiling alcohol and the residue crystallised from 40 c.c. of a mixture of alcohol and acetic acids (1:2), filtering from a small quantity of insoluble impurity, the yield of partially purified product being 2.5 grams. After a second crystallisation, it was obtained pure.

0.2299 gave 0.3016  $\text{CO}_2$  and 0.0430  $\text{H}_2\text{O}$ .  $\text{C} = 35.78$ ;  $\text{H} = 2.08$ .

0.2064 „ 31.2 c.c. moist nitrogen at  $16.5^\circ$  and 770 mm.  $\text{N} = 17.83$ .

$\text{C}_{10}\text{H}_{11}\text{O}_{13}\text{N}_7\text{S}$  requires  $\text{C} = 35.49$ ;  $\text{H} = 2.03$ ;  $\text{N} = 18.11$  per cent.

The substance forms light yellow, glistening plates melting at  $147^\circ$ , which are insoluble in water, somewhat sparingly so in alcohol and in ether, and easily dissolve in benzene or glacial acetic acid.

#### *Amyl Picryl Picriminothiocarbonate.*

Ten grams of picryl chloride were mixed with 14 grams of lead thiocyanate and boiled on the water-bath for one hour with a mixture of 80 c.c. of amyl alcohol and 120 c.c. of benzene. The solution was filtered from lead chloride and excess of thiocyanate and the solid residue extracted with benzene, the extracts being mixed with the filtered solution of the product, and the whole liquid then diluted and distilled in steam. The residual solid was washed with alcohol and dried, the yield of the crude product being 9.5 grams. After crystallisation from acetic acid and alcohol (1:1), 6 grams of pure substance were obtained.

0.1795 gave 0.2497  $\text{CO}_2$  and 0.0450  $\text{H}_2\text{O}$ .  $\text{C} = 37.93$ ;  $\text{H} = 2.78$ .

0.1871 „ 27.0 c.c. moist nitrogen at  $17^\circ$  and 772 mm.  $\text{N} = 17.03$ .

$\text{C}_{18}\text{H}_{15}\text{O}_{13}\text{N}_7\text{S}$  requires  $\text{C} = 37.97$ ;  $\text{H} = 2.64$ ;  $\text{N} = 17.23$  per cent.

The compound consists of minute, light yellow, glistening plates melting constantly at  $138.5^\circ$ ; the melting point remaining unchanged after several crystallisations; it is insoluble in water, rather sparingly soluble in alcohol or ether, easily so in acetic acid or benzene.

#### *Picryl Thiocyanate.*

Fifteen grams of picryl chloride and 4.8 grams of ammonium thiocyanate were dissolved separately in the least possible quantity of *tert.*-butyl alcohol and the hot solutions mixed; the precipitate which immediately separates was found to consist, for the most part, of unchanged picryl chloride. It was boiled with water, washed with

alcohol, and then extracted carefully with about 30 c.c. of alcohol and acetic acid (1 : 1). As soon as the melted substance gave place to a light, powdery material, it was filtered off rapidly. The residual crude product, which melted at  $221^{\circ}$ , was a mixture of picryl sulphide and picryl thiocyanate and weighed 3.5 grams. This mixture was now extracted repeatedly with small quantities of alcohol and acetic acid, until the extracts yielded no crystals on cooling. The residue was purified by dissolution in excess of benzyl alcohol and reprecipitation by alcohol. It weighed one gram, and consisted of an almost white powder with a faint yellow tinge, insoluble in water or ether and practically insoluble in acetic acid, benzene, or alcohol. It dissolves readily in acetone or benzyl alcohol, separating from the latter in microscopic, needle-shaped crystals. The substance does not melt, but darkens at about  $285^{\circ}$ .

0.1607 gave 0.1837  $\text{CO}_2$  and 0.0162  $\text{H}_2\text{O}$ .  $\text{C} = 31.18$ ;  $\text{H} = 1.12$ .

0.1741 „ 31.0 c.c. moist nitrogen at  $20^{\circ}$  and 760 mm.  $\text{N} = 20.61$ .

0.2145 „ 0.1992  $\text{BaSO}_4$ .  $\text{S} = 12.18$ .

$\text{C}_7\text{H}_2\text{O}_6\text{N}_4\text{S}$  requires  $\text{C} = 31.11$ ;  $\text{H} = 0.74$ ;  $\text{N} = 20.74$ ;  $\text{S} = 11.85$  per cent.

The crystals obtained by extracting the crude product were found to be picryl sulphide; when recrystallised, they melted at  $226^{\circ}$ , and did not depress the melting point of the substance prepared according to Willgerodt's method. It was rather remarkable that, when boiled with caustic potash, picryl sulphide yielded ammonia and also alkali nitrite. The production of ammonia was found to be due to the interaction of nitrite and potassium picrate formed in the reaction, as these substances, when boiled with potash, were found to yield ammonia.

### *Picrylmethylurethane.*

Nine grams of picryl chloride and 3 grams of potassium cyanate were mixed with 90 c.c. of methyl alcohol, heated on the water-bath for 3 hours in a reflux apparatus, and filtered hot; the filtrate, on cooling, deposited yellow crystals, which were washed with water and recrystallised from ethyl alcohol and acetic acid (2 : 1). The long needles obtained, which were almost colourless, melted at  $192^{\circ}$  and seemed to be identical with Romburgh's compound (*loc. cit.*).

The red residue was insoluble in alcohol, but dissolved easily in glacial acetic acid, changing colour, and depositing the same colourless crystals, the yield being 7 grams. As it was important to demonstrate that this really was the picrylurethane, it was analysed and the methoxy-group determined by Hewitt's modification of Zeisel's method (*Trans.*, 1902, 81, 319).

- 0.2004 gave 0.2476  $\text{CO}_2$  and 0.0400  $\text{H}_2\text{O}$ .  $\text{C} = 33.71$ ;  $\text{H} = 2.18$ .  
 0.1909 „ 33.8 c.c. moist nitrogen at  $25^\circ$  and 750 mm.  $\text{N} = 19.75$ .  
 $\text{C}_8\text{H}_6\text{O}_8\text{N}_4$  requires  $\text{C} = 33.57$ ;  $\text{H} = 2.09$ ;  $\text{N} = 19.58$  per cent.  
 0.2236 gave 0.1671 AgI.  $\text{OMe} = 9.86$ .  
 $\text{C}_8\text{H}_6\text{O}_8\text{N}_4$  requires  $\text{OMe} = 10.08$  per cent.

Hydrolysis of the substance by hydrochloric or acetic acid yielded picramide melting at  $188^\circ$ .

The red residue, which was insoluble in alcohol, was recrystallised from water; it was found to contain potassium, the analysis corresponding with the mono-potassium salt described by Romburgh (*loc. cit.*).

- 0.3595 gave 0.0975  $\text{K}_2\text{SO}_4$ .  $\text{K} = 12.16$ .  
 $\text{C}_8\text{H}_5\text{O}_8\text{N}_4\text{K}$  requires  $\text{K} = 12.04$  per cent.

This salt was partially hydrolysed by water, and was distinctly alkaline to litmus.

The conductivity of the methylurethane was determined. Owing to the small solubility at the ordinary temperature, the indications were too small to be of value. It was therefore taken in saturated solution at  $75.6^\circ$ . This gave  $\mu_{580} = 4.33$ , whilst a solution of the potassium salt in a saturated solution of the methyl compound under the same conditions gave  $\mu_{110} = 207.2$ . This indicates that the acid is weaker than carbonic acid, giving  $\mu_\infty = 590$ , and  $\text{K} = 0.0793$ .

*Ethyl Picryl Picriminocarbonate and Picrylethylurethane.*

Nine grams of picryl chloride were mixed with 3 grams of potassium cyanate and 70 c.c. of absolute alcohol, the whole being boiled in a reflux apparatus for 3 hours and then filtered while hot. The residue, which amounted to 0.6 gram, was washed with alcohol and water in order to remove potassium cyanate; it was practically insoluble in alcohol, ether, or water; easily soluble in benzene, and also in glacial acetic acid, from which it crystallised in minute, heavy, almost colourless crystals melting at  $222^\circ$ .

- 0.1972 gave 0.2560  $\text{CO}_2$  and 0.0342  $\text{H}_2\text{O}$ .  $\text{C} = 35.40$ ;  $\text{H} = 1.93$ .  
 $\text{C}_{15}\text{H}_9\text{O}_{14}\text{N}_7$  requires  $\text{C} = 35.23$ ;  $\text{H} = 1.76$  per cent.

The hot filtrate deposited the picrylethylurethane (*loc. cit.*) either in plates or needles, which were shown to be dimorphous, both forms of crystals melting at  $147^\circ$ ; the yield was 6 grams. The needles separate from dilute alcoholic solution, and the plates from concentrated solutions. As with the other urethanes, the aqueous and alcoholic solutions are intensely coloured, but are decolorised by the addition of one drop of dilute acid.

0.2076 gave 0.2764  $\text{CO}_2$  and 0.0521  $\text{H}_2\text{O}$ .  $\text{C} = 36.30$ ;  $\text{H} = 2.79$ .

0.1694 ,, 26.8 c.c. moist nitrogen at  $14^\circ$  and 770 mm.  $\text{N} = 18.46$ .

$\text{C}_9\text{H}_8\text{O}_8\text{N}_4$  requires  $\text{C} = 36.00$ ;  $\text{H} = 2.66$ ;  $\text{N} = 18.66$  per cent.

0.1399 gave 0.1101  $\text{AgI}$ .  $\text{OEt} = 15.19$ .

$\text{C}_9\text{H}_8\text{O}_8\text{N}_4$  requires  $\text{OEt} = 15.00$  per cent.

### *Picryl-n-propylurethane.*

Five grams of picryl chloride, 1.6 grams of potassium cyanate, and 17 c.c. of *n*-propyl alcohol with 20 c.c. of benzene were boiled together for 3 hours. The benzene and *n*-propyl alcohol were distilled off in steam, and the solid residue recrystallised from a mixture of ethyl alcohol and glacial acetic acid (3:1). Well-defined, almost colourless needles melting at  $139^\circ$  were obtained, the yield being 3 grams. The substance is slightly soluble in water or light petroleum, moderately so in alcohol or ether, easily so in benzene, glacial acetic acid, or alcohol.

0.3356 gave 0.4682  $\text{CO}_2$  and 0.0979  $\text{H}_2\text{O}$ .  $\text{C} = 38.06$ ;  $\text{H} = 3.24$ .

0.2245 ,, 33.8 c.c. moist nitrogen at  $15^\circ$  and 760.5 mm.  $\text{N} = 17.63$ .

$\text{C}_{10}\text{H}_{10}\text{O}_8\text{N}_4$  requires  $\text{C} = 38.23$ ;  $\text{H} = 3.19$ ;  $\text{N} = 17.83$  per cent.

### *Picrylisopropylurethane.*

A mixture of 2.5 grams of picryl chloride, 0.8 gram of potassium cyanate, and 20 c.c. of *isopropyl* alcohol was boiled for two hours in a reflux apparatus and then cooled; the crystalline product, which was collected, washed with hot water and alcohol, weighed 2.2 grams. When crystallised from a mixture of acetic acid and alcohol (1:1) and then from dilute acetic acid, it forms long, white, lustrous needles melting at  $177.5^\circ$ , which are slightly soluble in hot water, forming a yellow solution. The substance is easily soluble in acetic acid and in benzene, moderately so in alcohol or ether, somewhat sparingly so in light petroleum. When boiled with caustic potash, ammonia is evolved. If to the yellow aqueous solution a drop of dilute acid is added, it is immediately decolorised and the substance is salted out.

0.1907 gave 0.2673  $\text{CO}_2$  and 0.0574  $\text{H}_2\text{O}$ .  $\text{C} = 38.22$ ;  $\text{H} = 3.34$ .

0.2070 ,, 31.6 c.c. moist nitrogen at  $16.5^\circ$  and 754 mm.  $\text{N} = 17.62$ .

$\text{C}_{10}\text{H}_{10}\text{O}_8\text{N}_4$  requires  $\text{C} = 38.22$ ;  $\text{H} = 3.19$ ;  $\text{N} = 17.84$  per cent.

### *Picrylisobutylurethane.*

Five grams of picryl chloride and 1.6 grams of potassium cyanate were boiled on the water-bath for two hours with a mixture of 20

c.c. of *isobutyl* alcohol and 20 c.c. of benzene. The mixture was then distilled in steam and the residue crystallised from a mixture of alcohol and acetic acid. On cooling, the solution became nearly solid. The product when collected and washed with alcohol, weighed 2·3 grams; it was crystallised from dilute acetic acid, and separated in nearly colourless, lustrous needles with a faint yellow tinge (m. p.  $134^{\circ}$ ). It is moderately soluble in hot water, giving a yellow solution, and dissolves easily in acetic acid, alcohol, or benzene. It is moderately soluble in light petroleum or ether. When boiled with caustic potash solution, ammonia and *isobutyl* alcohol are evolved, but the substance may be crystallised practically unchanged from sodium carbonate solution. The solutions in water, alcohol, ether, acetic acid, and benzene are all somewhat yellow, particularly the aqueous and alcoholic solutions. The solution in light petroleum, however, is quite colourless. On the other hand, the addition of one drop of hydrochloric or acetic acid to the alcoholic or aqueous solution removes the colour. Carbon dioxide also produces this effect, but the colour returns on expelling the gas.

0·2396 gave 0·3530  $\text{CO}_2$  and 0·0842  $\text{H}_2\text{O}$ .  $\text{C} = 40\cdot18$ ;  $\text{H} = 3\cdot90$ .

0·1955 „ 29·0 c.c. moist nitrogen at  $15^{\circ}$  and 752 mm.  $\text{N} = 17\cdot20$ .

$\text{C}_{11}\text{H}_{12}\text{O}_8\text{N}_4$  requires  $\text{C} = 40\cdot25$ ;  $\text{H} = 3\cdot66$ ;  $\text{N} = 17\cdot08$  per cent.

#### *Picrylamylurethane.*

Five grams of picryl chloride and 1·6 grams of potassium cyanate were mixed with 40 c.c. of amyl alcohol and heated on the water-bath for 12 hours; on cooling, the whole mass solidified. The excess of amyl alcohol was removed by distillation in steam and the residue crystallised several times from a mixture of ethyl alcohol and glacial acetic acid (1 : 1) and finally from ethyl alcohol alone; the yield was 2·5 grams. The needle-shaped, somewhat yellow crystals, which melted at  $131^{\circ}$ , were moderately soluble in hot water or light petroleum and easily so in alcohol, benzene, ether, or acetic acid. As in the case of the other urethanes, the solution in light petroleum is colourless, whilst the other solutions are more or less yellow, particularly the aqueous and alcoholic solutions.

0·2689 gave 0·4139  $\text{CO}_2$  and 0·1088  $\text{H}_2\text{O}$ .  $\text{C} = 42\cdot11$ ;  $\text{H} = 4\cdot49$ .

0·1964 „ 28·4 c.c. moist nitrogen at  $22^{\circ}$  and 754·3 mm.  $\text{N} = 16\cdot25$ .

$\text{C}_{12}\text{H}_{14}\text{O}_8\text{N}_4$  requires  $\text{C} = 42\cdot11$ ;  $\text{H} = 4\cdot09$ ;  $\text{N} = 16\cdot38$  per cent.

*tert.*-Butyl alcohol behaved abnormally, as before; when treated in the usual way, picramide alone was obtained in somewhat large quantity.

The authors wish to take this opportunity of thanking Professor J. B. Coleman for his kindness in placing the resources of the laboratory at their disposal.

LXVI.—*Experiments on the Synthesis of the Terpenes.*  
*Part I. Synthesis of Terpin, Inactive Terpeneol,*  
*and Dipentene.*

By WILLIAM HENRY PERKIN, jun.

IN that remarkable section of chemistry which deals with the terpenes and their derivatives, there are probably few substances of greater importance than the closely related group, terpin, terpeneol, and dipentene, and this is due, not only to the great interest attached to the substances themselves, but also to their intimate connection with pinene and many other members of the same section. Terpin, as is well known, combines very readily with water to form the highly characteristic compound, terpin hydrate,  $C_{10}H_{18}(OH)_2 \cdot H_2O$ , and from the first this hydrate has been specially selected by chemists for investigation, partly because of its extraordinary facility for crystallising and the consequent ease with which it is obtained pure from oil of turpentine, and partly because there was reason to suppose that the determination of its constitution would afford a valuable clue to the nature of the terpene group as a whole. The fact that the constitution of terpin and its derivatives is now fairly well understood is due principally to the laborious researches of Baeyer, Tilden, Tiemann and Schmidt, and Wallach, and to the brilliant theoretical deductions of Wagner, and to such of this work as has a direct bearing on the present investigation some mention is made below.

It must, however, be remembered that it is impossible, within the limits of a paper of this kind, to enter into anything like a complete historical discussion of the gradual progress of the development of the formulæ of terpin, terpeneol, and dipentene, and for this reason many valuable contributions to our knowledge of the subject must unavoidably remain unnoticed.

The difficulties which early investigators of terpin and its derivatives had to encounter were of a quite unusual kind, not only owing to the fact

that the chemical behaviour of the many partially unsaturated closed chain compounds belonging to this class was, at that time, not at all understood, but also because of the unexpected fundamental intra-molecular changes which were frequently met with, and which gave rise to false deductions and the suggestion of many formulæ now known to be incorrect.

That a close relationship exists between terpin, terpineol, and dipentene was long ago evident from the work of Tilden (*Ber.*, 1879, 12, 848) and of Wallach (*Annalen*, 1885, 230, 258), who showed that when terpin is digested with dilute acids, it yields terpineol, and that the latter is converted by potassium hydrogen sulphate at 200° into dipentene, these changes being simply due to the successive elimination of water :

The first to represent terpineol as a derivative of cymene appears to have been Kanonnikoff (*J. Russ. Phys. Chem. Soc.*, 1883, 15, 472), who, mainly from physical considerations, proposed the formula

for this substance. In a remarkable paper (*Annalen*, 1893, 277, 105), which contains a careful investigation of terpineol, Wallach suggested the following modification of this formula,

and, shortly afterwards, Baeyer (*Ber.*, 1893, 26, 2558) published a research on the same subject, in which he expresses his agreement with Wallach's view of the constitution of terpineol, and at the same time suggests the formula

for terpin.

The strongest argument against the acceptance of these views was the fact that, in whichever way water is eliminated from Wallach's terpineol formula, a constitution for dipentene is arrived at which does not contain an asymmetric carbon atom, whereas it is well known that dipentene is an externally compensated mixture of the two active *d*- and *l*-limonenes. In order to get over this difficulty, Baeyer (*Ber.*, 1894, 27, 454) suggested the possibility that the activity of the limonenes was due to the asymmetry of the whole molecule, and not to the presence of an asymmetric carbon atom.

In 1894, Wagner published his classical paper "On the oxidation of

cyclic compounds" (*Ber.*, 27, 1636), in which he discusses the constitutions of some of the more important members of the terpene group. From a careful consideration of the relationship of terpineol to pinene, pinol, and sobrerol, he deduces the expression,

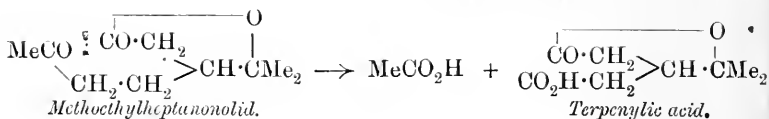

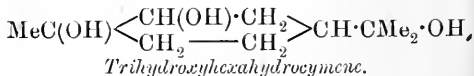

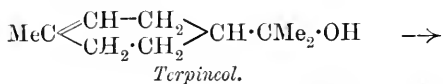

as best representing terpineol, and points out that, if this formula is adopted, the difficulty with regard to the activity of the limonenes disappears, since the constitution of limonene (dipentene) would then be represented thus :

that is to say, by a formula which contains an asymmetric carbon atom. The constitution of terpin itself, deduced from the above formula for terpineol, would then be

That the formula suggested by Wagner for terpineol is correct was rendered probable by the subsequent work of Wallach (*Ber.*, 1895, 28, 1776), who showed that this substance, on oxidation, is converted first into trihydroxyhexahydrocymene, which then breaks up further into a ketolactone, called methoethylheptanonolid, and then into acetic and terpenylic acids. With the aid of Wagner's formula, these changes may be expressed in the following simple manner :

but Wallach is careful to remark that the formation of these oxidation products cannot be accepted as a definite proof that the constitution of terpineol is that suggested by Wagner.

The present investigation was undertaken with the object of synthesising terpin, terpineol, and dipentene, not only on account of the interest which always attaches to syntheses of this kind, but also in the hope that a method of synthesis might be devised of such a

simple kind that there would no longer be room for doubt as to the constitution of these important substances.

In the synthesis described in this paper, the first step was the preparation of ethyl  $\gamma$ -cyanopentane- $\alpha\gamma\epsilon$ -tricarboxylate,

by the interaction of ethyl  $\beta$ -iodopropionate and ethyl sodiocyanoacetate. On hydrolysis with hydrochloric acid, this ester yields pentane- $\alpha\gamma\epsilon$ -tricarboxylic acid, and on digesting with acetic anhydride and distilling, this acid is decomposed, with elimination of water and carbon dioxide and formation of  $\delta$ -ketohexahydrobenzoic acid,

(compare *Trans.*, 1904, 85, 418).

The ester of this acid reacts readily with magnesium methyl iodide in ethereal solution, and the product, on hydrolysis, yields  $\delta$ -hydroxyhexahydro-*p*-toluic acid,  $\text{MeC}(\text{OH}) \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{CH}\cdot\text{CO}_2\text{H}$ , which melts at  $153^\circ$  and has already been prepared by Stephan and Helle (*Ber.*, 1902, 35, 2156) by the oxidation of  $\Delta^{(9)}$ -menthenol (I) (see p. 659). This hydroxy-acid dissolves readily in fuming hydrobromic acid, and the solution soon deposits crystals of  $\delta$ -bromohexahydro-*p*-toluic acid (m. p.  $126^\circ$ ), from which, by treatment with weak alkalis or pyridine,  $\Delta^3$ -tetrahydro-*p*-toluic acid (m. p.  $99^\circ$ ) is obtained,

The last step was to convert the unsaturated acid into its ester and to act on this with an ethereal solution of magnesium methyl iodide, when an almost quantitative yield of an oil was obtained which, on examination, proved to be *terpineol*. This synthesis is readily understood with the aid of the formulæ,

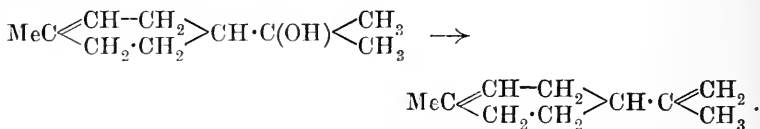

the change being simply the conversion of the  $-\text{CO}_2\text{Et}$  group into the group  $-\text{CMe}_2\cdot\text{OH}$ .

The *terpineol* thus synthesised had the pronounced odour of lilac which is so characteristic of this substance, and distilled constantly at  $135^\circ$  under 60 mm. pressure, and this was found to be exactly the temperature at which a sample of pure *terpineol*, from Schimmel & Co., distilled in the same apparatus and under the same conditions.

In order that there might be no room for doubt as to the identity of the synthetical product, it was converted into the *nitrosochloride*,

$C_{10}H_{15}O, NOCl$  (m. p.  $122^\circ$ ), and *phenylurethane*,  $C_{10}H_{17}O \cdot CO \cdot NH \cdot C_6H_5$  (m. p.  $113^\circ$ ), and these were compared with specimens prepared from ordinary terpineol, with the result that the preparations obtained from both sources were found to be absolutely identical.

The next step was to convert the synthetical terpineol into dipentene, which was readily accomplished by heating with potassium hydrogen sulphate, when water was eliminated according to the scheme,

The *dipentene* produced in this way was converted into the *tetra-bromide*,  $C_{10}H_{16}Br_4$  (m. p.  $125^\circ$ ), the *dihydrochloride*,  $C_{10}H_{16}, 2HCl$  (m. p.  $48-50^\circ$ ), and the *nitrosochloride*,  $C_{10}H_{16}, NOCl$  (m. p.  $106^\circ$ ), and these derivatives were compared with the corresponding specimens obtained from ordinary dipentene, with which they were found to be identical in all respects.

Lastly, the synthetical terpineol was agitated with dilute sulphuric acid until the oil had become converted into a mass of crystals; these, on examination, were found to consist of pure terpin hydrate,

and thus the synthesis of the three substances, terpin, terpineol, and dipentene, which have played so prominent a part in the history of the terpene group, was accomplished, and in a way which can leave no further doubt as to their constitutions.

Recently, Stephan and Helle (*Ber.*, 1902, 35, 2147) have shown that one of the products of the dehydration of terpin is that isomeric modification of terpineol,

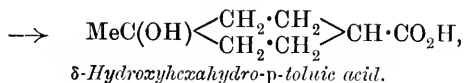

for which the name  $\Delta^{(9)}$ -menthenol (1) has been suggested (Meyer and Jacobson, *Lehrbuch*, II, 933). When this interesting substance is oxidised, it yields the following products

*Trihydroxyhexahydrocymene.*

*p-Hydroxy-p-methylhexahydroacetophenone.*

and the last of these is identical with the acid which is one of the steps in the foregoing synthesis of terpineol. For the purpose of this synthesis, this acid was prepared from ethyl  $\delta$ -keto-hexahydrobenzoate by the action of magnesium methyl iodide, the change being simply due to the conversion of the ketonic group into the group  $\text{MeC(OH)}\langle$ . The reaction does not, however, proceed entirely in this direction, for there is always produced, although in very small quantity, a neutral oil, the formation of which is due to the conversion of the  $-\text{CO}_2\text{Et}$  group into the group  $-\text{CMe}_2 \cdot \text{OH}$  :\*

The hydroxyisopropyl-*p*-keto-hexamethylene obtained in this way could only be somewhat imperfectly investigated, owing to the small amount of available material. It distils at  $177-180^\circ$  under 100 mm. pressure, and when treated with hydrobromic acid and then with alcoholic potash, is converted into isopropenyl-*p*-keto-hexamethylene (b. p.  $186^\circ$ ) :

When this ketone is left in contact with magnesium methyl iodide, a substance,  $\text{C}_{10}\text{H}_{18}\text{O}$ , is produced, which distils at  $127^\circ$  (60 mm.) and crystallises on cooling. Assuming that, during this process, the ketonic group is converted in the usual way into the group  $\text{MeC(OH)}\langle$ , the substance,  $\text{C}_{10}\text{H}_{18}\text{O}$ , should be identical with the menthenol,

of Stephan and Helle. The most characteristic derivative of this menthenol appears to be the phenylurethane which melts at  $85^\circ$ , and, on preparing this derivative from the above synthetical substance, crystals were obtained which melted at  $83-85^\circ$ , so that there is little room for doubt that the synthetical substance is identical with the above  $\Delta^{8(9)}$ -menthenol (1).

It is hoped that further experiments, which are in progress, will result in the synthesis of other important members of the terpene series.

\* This behaviour has been also observed in the case of other keto-esters, and a description of the interesting substances obtained in this way is reserved for a future communication.

*cis*- $\delta$ -Hydroxyhexahydro-*p*-toluic Acid,

and its Lactone.

The preparation of these substances may be conveniently carried out in the following way.

In a large flask, connected with a reflux condenser, magnesium (12 grams) is covered with anhydrous ether \* (300 c.c.), and then methyl iodide (100 grams) added in four portions, the vigorous reaction being kept under control by means of running water. As soon as all the magnesium has dissolved, the flask is well cooled, and ethyl  $\delta$ -keto-hexahydrobenzoate † (50 grams) is then gradually run in. The decomposition is not energetic, the rise of temperature being comparatively small, and as this seemed to point to the reaction being a gradual one, the whole was always left for 24 hours.

Excess of dilute hydrochloric acid is then cautiously added in small quantities at a time, the flask being carefully cooled after each addition, the ethereal solution is separated, washed with a little water and evaporated, and the residual yellow oil mixed with a solution of caustic potash (50 grams) in methyl alcohol. After heating for a few minutes on the water-bath, water is added, and the small quantity of neutral oil (the examination of which is described on p. 670) extracted with ether.

The aqueous liquor is then evaporated until free from methyl alcohol, transferred to a flask, acidified with hydrochloric acid, and heated for half an hour on the water-bath, when the crude lactone of  $\delta$ -hydroxyhexahydro-*p*-toluic acid separates as a brown oil which has a powerful odour of peppermint. In order to extract completely the whole of the products of the reaction, the aqueous liquors must be treated at least 20 times with ether in the ordinary way or 10 times on the shaking machine: the ethereal solution is then repeatedly extracted with sodium carbonate (A, see p. 661), dried over calcium chloride, and evaporated. The residual crude lactone distils for the most part at 140—150° under 45 mm. pressure and the distillate gradually becomes semi-solid. After cooling in ice and salt, the crystals are rapidly collected at the pump, ‡ drained on porous porcelain, and purified by recrystallisation

\* The ether used in these experiments was first dehydrated over sodium and then distilled over phosphoric oxide; the methyl iodide was also distilled over phosphoric oxide.

† For the preparation of this ester, see Trans., 1904, 85, 427.

‡ The oily filtrate from these crystals may be used, without further purification, in the preparation of  $\delta$ -bromohexahydro-*p*-toluic acid (p. 663).

from light petroleum (b. p. 60—70°), from which the lactone separates in glistening leaflets.

0.1240 gave 0.3098 CO<sub>2</sub> and 0.0962 H<sub>2</sub>O. C=68.2; H=8.6.

0.1363 „ 0.3421 CO<sub>2</sub> „ 0.1061 H<sub>2</sub>O. C=68.4; H=8.7.

C<sub>8</sub>H<sub>12</sub>O<sub>2</sub> requires C=68.6; H=8.6 per cent.

The lactone of *cis*- $\delta$ -hydroxyhexahydro-*p*-toluic acid has already been described by Stephan and Helle (*Ber.*, 1902, 35, 2154); it melts at 69—70°, and possesses a penetrating odour closely resembling that of thymol. When the lactone is warmed with barium hydroxide, it readily dissolves, and the solution, after acidifying, remains clear, but if boiled with excess of hydrochloric acid, oily drops of the lactone soon separate. In order to isolate the corresponding hydroxy-acid, a considerable quantity of the lactone was hydrolysed by boiling with excess of barium hydroxide, the acidified solution being then extracted 10 times with ether. After drying over calcium chloride and evaporating to a small bulk, the ethereal solution gradually deposited a crystalline crust, which was collected, washed with a little ether, and re-crystallised from the same solvent.

0.1395 gave 0.3099 CO<sub>2</sub> and 0.1143 H<sub>2</sub>O. C=60.5; H=9.1.

C<sub>8</sub>H<sub>14</sub>O<sub>3</sub> requires C=60.8; H=8.8 per cent.

*cis*- $\delta$ -Hydroxyhexahydro-*p*-toluic acid melts at about 153°, and is readily soluble in hot water, from which it crystallises, on cooling, in colourless, glistening leaflets.

#### *Examination of the Sodium Carbonate Extract A* (see p. 660).

After the lactone of  $\delta$ -hydroxyhexahydro-*p*-toluic acid had been separated as described above, the extract (A) was acidified, saturated with ammonium sulphate, and extracted 10 times with ether; the ethereal solution was dried over calcium chloride and evaporated, when a brown syrup was obtained, which, when left over sulphuric acid in a vacuum desiccator, became semi-solid. In contact with porous porcelain, the dark, oily impurity was soon absorbed, and the residual yellow, crystalline mass was readily purified by crystallisation from water with the aid of animal charcoal. The colourless, glistening crystals thus obtained melted at 153°, and consisted of pure  $\delta$ -hydroxyhexahydro-*p*-toluic acid.

0.1401 gave 0.3112 CO<sub>2</sub> and 0.1140 H<sub>2</sub>O. C=60.6; H=9.0.

C<sub>8</sub>H<sub>14</sub>O<sub>3</sub> requires C=60.8; H=8.8 per cent.

The amount of hydroxy-acid obtained in this way was considerable (p. 662), and it is therefore evident that only a portion of this acid is

converted into its lactone when it is digested with dilute hydrochloric acid under the conditions described on p. 660.

The porous porcelain, which had been used to absorb the dark, oily mother liquors of the hydroxy-acid (see above), was broken up and extracted with ether in a Soxhlet apparatus, and the extract dried over calcium chloride and evaporated. On distilling the residue under 15 mm. pressure, water was eliminated, and, with the exception of a small quantity of a dark brown, resinous substance, the whole passed over below  $210^{\circ}$ , and most of it distilled at  $140-150^{\circ}$ . The distillate was dissolved in ether, the ethereal solution extracted with sodium carbonate, dried over calcium chloride, and evaporated, and the residue fractionated under 100 mm. pressure, when the whole passed over at  $175-185^{\circ}$  as a colourless oil, which gradually became semi-solid, and on examination was found to consist of the lactone of  $\delta$ -hydroxyhexahydro-*p*-toluic acid.\*

The sodium carbonate extract was acidified and extracted, when, after drying and evaporating to a small bulk, small hexagonal plates were deposited which melted at  $65-67^{\circ}$ , and consisted of  $\delta$ -keto-hexahydrobenzoic acid, which had escaped the action of the magnesium methyl iodide, and in some experiments a good deal of this valuable acid was recovered in this way. In order to obtain an approximate estimate of the yields obtained in the above preparation of  $\delta$ -hydroxyhexahydro-*p*-toluic acid and its lactone, two special experiments were made, and the average of these gave the following results. After treatment with magnesium methyl iodide, 100 grams of ethyl keto-hexahydrobenzoate were found to yield 21 grams of lactone (obtained direct), and, from the sodium carbonate extract (A), 12 grams of the same lactone, 10 grams of the hydroxy-acid, and 8 grams of unchanged keto-hexahydrobenzoic acid. No doubt the considerable loss shown by these numbers is partly accounted for by the formation of resinous substances which remain in the distilling flasks, but it is also due largely to the great difficulty experienced throughout this research in extracting completely the products of the reactions, even when the solutions were treated on the shaking machine with large quantities of ether.

The  $\delta$ -hydroxyhexahydro-*p*-toluic acid described in this section is evidently the *cis*-modification, since it readily yields a lactone, and, in spite of very careful search, no trace of the corresponding *trans*-acid, which it was thought should also have been present, could be detected.

\* Stephan and Helle (*loc. cit.*, p. 2153) state that pure  $\delta$ -hydroxyhexahydro-*p*-toluic acid distils unchanged under 10-15 mm. pressure, but yields the lactone when distilled under the ordinary pressure.

The above experiment shows that the crude acid is completely converted into its lactone on distillation under 15 mm. pressure.

Attention has already been directed (Trans., 1904, 85, 421) to the fact that in many cases where stereoisomeric modifications should be capable of existence it sometimes happens either that, as in the above case, only one of the modifications is actually obtained, or more frequently that the one is found to be present in very much larger quantities than the other.

*δ-Bromohexahydro-p-toluic Acid*,  $\text{MeCBr} \begin{smallmatrix} \text{CH}_2 \cdot \text{CH}_2 \\ \text{CH}_2 \cdot \text{CH}_2 \end{smallmatrix} \text{CH} \cdot \text{CO}_2\text{H}$ , and

*Δ<sup>3</sup>-Tetrahydro-p-toluic Acid*,  $\text{MeC} \begin{smallmatrix} \text{CH} - \text{CH}_2 \\ \text{CH}_2 \cdot \text{CH}_2 \end{smallmatrix} \text{CH} \cdot \text{CO}_2\text{H}$ , and its

*Derivatives.*

When the finely powdered lactone of *δ*-hydroxyhexahydro-*p*-toluic acid (p. 661) was mixed with aqueous hydrobromic acid (saturated at 0°) it dissolved, and almost immediately the liquid became clouded and an oil separated which rapidly solidified. After two hours, water was added, the crystalline precipitate of the bromo-acid collected, and left in contact with porous porcelain until quite dry; it was then dissolved in boiling light petroleum (b. p. 70–80°), from which it separated in groups of glistening needles. The dry substance has a satiny lustre, and closely resembles benzoic acid in appearance.

0.1368 gave 0.1156 AgBr. Br = 36.0.

$\text{C}_8\text{H}_{13}\text{O}_2\text{Br}$  requires Br = 36.2 per cent.

*δ-Bromohexahydro-p-toluic acid* softens at 122° and melts at about 126°; it is readily soluble in alcohol, but almost insoluble in water; it dissolves readily in boiling light petroleum, but sparingly in the cold. Much of the bromo-acid which was required for this research was prepared direct from *δ*-hydroxyhexahydro-*p*-toluic acid itself. This acid dissolves in concentrated hydrobromic acid, but the solution soon begins to deposit crystals, and, after two hours, water is added and the bromo-acid purified as described above. Again, in preparing the bromo-acid from the lactone, it should be mentioned that it is not at all necessary to use the recrystallised lactone; the semi-solid fraction boiling at 140–150° (45 mm.) was always employed with excellent results (compare p. 660 and footnote).

*Action of Sodium Carbonate on δ-Bromohexahydro-p-toluic Acid.*—In studying this decomposition, the pure bromo-acid was ground with water to a fine paste, excess of a warm saturated solution of sodium carbonate was then added, and, after the acid had dissolved, the whole was heated to boiling for a few minutes. On acidifying the cold liquid, a crystalline precipitate separated at once and was collected, washed well, and purified by recrystallisation from much water, from which the substance separated in needles resembling benzoic acid.

0.1258 gave 0.3162  $\text{CO}_2$  and 0.0980  $\text{H}_2\text{O}$ .  $\text{C} = 68.5$ ;  $\text{H} = 8.6$ .

0.1513 „ 0.3795  $\text{CO}_2$  „ 0.1179  $\text{H}_2\text{O}$ .  $\text{C} = 68.4$ ;  $\text{H} = 8.7$ .

$\text{C}_8\text{H}_{12}\text{O}_2$  requires  $\text{C} = 68.6$ ;  $\text{H} = 8.6$  per cent.

This  $\Delta^3$ -tetrahydro-*p*-toluic acid has already been obtained by Stephan and Helle (*Ber.*, 1902, 35, 2154) from  $\Delta^{8(9)}$ -menthenol (1) by the action of oxidising agents. It softens at  $95^\circ$  and melts at  $99$ – $100^\circ$ ; it is almost insoluble in cold water, and very sparingly so even on boiling; it dissolves readily in acetic acid, and dilute acetic acid appears to be the most convenient solvent from which to crystallise it.

The aqueous mother liquors from which this acid had separated on acidifying were extracted repeatedly with ether, the ethereal solution dried over calcium chloride and evaporated, when a considerable quantity of a solid acid was obtained which crystallised from water in glistening needles and melted at  $153^\circ$ . This substance on analysis proved to be  $\delta$ -hydroxyhexahydro-*p*-toluic acid, which had evidently been produced from the bromo-acid by simple hydrolysis.

*Action of Pyridine on  $\delta$ -Bromohexahydro-*p*-toluic Acid.*—As the yield of the tetrahydro-acid produced in the above experiment was only about 60 per cent. of the theoretical (nearly 40 per cent. being converted into the hydroxy-acid), the action of pyridine as an agent for eliminating hydrogen bromide was investigated, and excellent results were obtained. The bromo-acid dissolves readily in pyridine, and if, after boiling for 5 minutes, the excess of pyridine is removed by evaporation and the residue decomposed by dilute sulphuric acid, a white, crystalline deposit of nearly pure tetrahydro-acid is obtained at once, the yield being almost quantitative. After recrystallising from dilute acetic acid, a sample of the acid prepared in this way was analysed with the following result:

0.1390 gave 0.3489  $\text{CO}_2$  and 0.1082  $\text{H}_2\text{O}$ .  $\text{C} = 68.5$ ;  $\text{H} = 8.7$ .

$\text{C}_8\text{H}_{14}\text{O}_2$  requires  $\text{C} = 68.6$ ;  $\text{H} = 8.6$  per cent.

*Ethyl  $\Delta^3$ -Tetrahydro-*p*-toluate.*—This ester could not be prepared from the acid by treatment with alcohol and hydrogen chloride in the ordinary way, owing to the great ease with which it unites with hydrogen chloride; it was, however, obtained pure in the following manner. The pure acid (25 grams) was digested for three hours on the water-bath with 100 c.c. of a mixture of 1 volume of sulphuric acid and 10 volumes of alcohol, and, after remaining overnight, water was added and the oily ester extracted with ether. The ethereal solution was washed well with water and dilute sodium carbonate, dried over calcium chloride, and evaporated, the residual oil being fractionated under 100 mm. pressure.

Almost the whole distilled at 155—157° as a colourless oil having a pungent and unpleasant odour.

0.1109 gave 0.2893 CO<sub>2</sub> and 0.0949 H<sub>2</sub>O. C = 71.0; H = 9.5.

C<sub>10</sub>H<sub>16</sub>O<sub>2</sub> requires C = 71.4; H = 9.5 per cent.

*γδ-Dibromohexahydro-p-toluic Acid*.—Tetrahydro-*p*-toluic acid shows all the properties of an unsaturated acid, since its solution in sodium carbonate rapidly decolorises permanganate, and the powdered acid is at once attacked by bromine with considerable development of heat and evolution of some hydrogen bromide. In order to prepare the dibromo-additive product, the acid was dissolved in dry chloroform, the solution cooled to -10°, and bromine added drop by drop until the colour just remained permanent. The solution was then exposed in a shallow basin and, when the chloroform had evaporated, a solid residue was obtained which crystallised from formic acid (sp. gr. 1.22) in satiny plates.

0.1396 gave 0.1754 AgBr. Br = 53.4.

C<sub>8</sub>H<sub>12</sub>O<sub>2</sub>Br<sub>2</sub> requires Br = 53.3 per cent.

*γδ-Dibromohexahydro-p-toluic acid* melts at about 104°, but it softens a few degrees below this temperature. It dissolves readily in sodium carbonate, and the solution is stable to permanganate in the cold and, even on warming, reduction takes place only gradually.

*Conversion of Δ<sup>3</sup>-Tetrahydro-p-toluic Acid into p-Toluic Acid by Oxidation with Sulphuric Acid*.—In carrying out this oxidation, the tetrahydro-acid (1 gram) dissolved in concentrated sulphuric acid (10 grams) was heated on the water-bath until the evolution of sulphur dioxide was complete, which was the case after about 10 minutes. The dark brown liquid was diluted with water, the solid mass which separated was collected, washed with water, dried on porous porcelain, and distilled. The distillate was then recrystallised from dilute acetic acid, and the colourless mass of crystals dried at 100°.

0.1385 gave 0.3575 CO<sub>2</sub> and 0.0748 H<sub>2</sub>O. C = 70.4; H = 6.0.

C<sub>8</sub>H<sub>8</sub>O<sub>2</sub> requires C = 70.6; H = 5.9 per cent.

This acid melted sharply at 179°, and consisted of pure *p*-toluic acid.

*Action of Magnesium Methyl Iodide on Ethyl Δ<sup>3</sup>-Tetrahydro-p-toluate.*

*Synthesis of Inactive Terpeneol.*

In carrying out this synthesis, magnesium (21 grams) was covered with pure dry ether (500 c.c.) and then gradually treated with an

excess of methyl iodide (120 grams),\* the vigorous reaction being kept under control by cooling in running water. As soon as the magnesium had dissolved, ethyl tetrahydro-*p*-toluate (30 grams) was added in one portion, since the reaction takes place apparently only gradually, and with evolution of very little heat. After 24 hours, the product was cautiously decomposed by adding water and dilute hydrochloric acid, the ethereal solution was separated, washed with dilute hydrochloric acid, and evaporated. In order to remove any unchanged ester which might have escaped the action of the magnesium methyl iodide, the yellow, oily residue was mixed with a solution of caustic potash (10 grams) in methyl alcohol and heated on the water-bath for 15 minutes; water was then added and the oil again extracted with ether.

The ethereal solution was carefully freed from methyl alcohol by washing with water, dried over anhydrous sodium sulphate, and the residue, after evaporation, distilled under 60 mm. pressure.

With the exception of a small quantity of a more volatile fraction which had the odour of dipentene, almost the whole quantity distilled at 134—135° as a viscid, colourless oil† which proved to be *inactive terpeneol*. After a second fractionation, the following analytical results were obtained:

0.1592 gave 0.4536 CO<sub>2</sub> and 0.1670 H<sub>2</sub>O. C=77.7; H=11.7.

0.1431 „ 0.4086 CO<sub>2</sub> „ 0.1529 H<sub>2</sub>O. C=77.8; H=11.9.

C<sub>10</sub>H<sub>18</sub>O requires C=77.9; H=11.7 per cent.

That the boiling point given above is that of *terpeneol* was proved by distilling a specimen of pure *terpeneol* in the same apparatus and under the same conditions, when a boiling point identical with that given above was observed. Furthermore, the synthetical substance possessed in a marked degree the odour of lilac, which is so characteristic of *terpeneol*. In order, however, that there should be no doubt as to the identity of the synthetical substance, it was converted into the crystalline nitrosochloride and phenylurethane, which were then compared, and found to be identical with specimens prepared from ordinary *terpeneol*.

*Terpeneolnitrosochloride*, C<sub>10</sub>H<sub>15</sub>O, NOCl.

This derivative was obtained by mixing synthetical *terpeneol* (1.5 grams) with glacial acetic acid (1.5 c.c.) and *isoamyl nitrite* (1.5 c.c.);

\* See footnote, p. 660.

† When this oil was cooled in a freezing mixture, it became very viscid, but did not crystallise even on rubbing with a glass rod, and the same behaviour was noticed in the case of a carefully fractionated sample of liquid *terpeneol*. Subsequently, a specimen of solid *terpeneol* was obtained from Schimmel & Co., and, on adding a minute crystal of this to the synthetical *terpeneol* and cooling in ice, the whole became quite solid.

hydrochloric acid (0.7 c.c.) was then added drop by drop, the whole being carefully cooled in ice and salt during the operation. After 2 hours, the pale green liquid was poured on to powdered ice, when an oil separated which gradually solidified.

In contact with porous porcelain, traces of oily mother liquor were rapidly absorbed, and the residue, after recrystallisation from ethyl acetate, melted at about 119—122°, whereas a specimen of the nitrosochloride, prepared from crystallised terpineol in the same way, melted at 121—123°. The identity was further proved by the fact that the mixture of the two specimens melted at 120—122°.

The specimen from synthetical terpineol was analysed with the following result:

0.1129 gave 0.0724 AgCl. Cl = 15.9.

$C_{10}H_{18}O_2NCl$  requires Cl = 16.1 per cent.

*Terpineolphenylurethane*,  $C_{10}H_{17}O \cdot CO \cdot NH \cdot C_6H_5$ .

In preparing this substance, synthetical terpineol (1.5 grams) was mixed with phenylcarbimide (1.2 grams), and the whole heated at 60° for one hour and then at 90° for half an hour. On pouring the product on to a watch glass, it soon solidified completely, and was easily purified by recrystallisation from dilute methyl alcohol, from which it separated in colourless needles melting at 113° (compare Wallach, *Annalen*, 1893, 275, 104).

0.1406 gave 6.2 c.c. of nitrogen at 16° and 760 mm. N = 5.2.

$C_{17}H_{23}O_2N$  requires N = 5.1 per cent.

A quantity of the phenylurethane was prepared from crystallised terpineol, and found to melt at the same temperature; moreover, on mixing this with the specimen obtained from synthetical terpineol, no alteration in the melting point could be observed.

*Conversion of Synthetical Terpineol into Terpin Hydrate.*

Tiemann and Schmidt have made the interesting observation (*Ber.*, 1895, 28, 1781) that when terpineol is shaken with dilute sulphuric acid it is slowly converted into terpin hydrate, and as this change is highly characteristic, it was thought important to endeavour to bring it about in the case of the synthetical substance.

Synthetical terpineol (10 grams) was therefore mixed with benzene (5 grams) and shaken in a stoppered bottle, partly by hand and partly on the machine, with 1500 c.c. of 5 per cent. sulphuric acid.

After three days, crystals began to appear on the sides of the bottle, and when the formation of these seemed to be complete (in about 10 days), the whole was filtered and the pasty mass left in contact with porous porcelain until quite dry. The residue, together with a further crop of crystals which were obtained from the sulphuric acid mother liquors by saturating with ammonium sulphate, was then slowly recrystallised from water, and in this way magnificent crystals of *terpin hydrate* were obtained, which, after remaining exposed to the air for 2 days, were analysed.

0.1545 gave 0.3578  $\text{CO}_2$  and 0.1607  $\text{H}_2\text{O}$ .  $\text{C} = 63.1$ ;  $\text{H} = 11.6$ .

$\text{C}_{10}\text{H}_{22}\text{O}_3$  requires  $\text{C} = 63.2$ ;  $\text{H} = 11.6$  per cent.

When rapidly heated, this substance melted at  $120^\circ$  with vigorous decomposition,\* due to evolution of steam, and, when kept in a water oven at  $90^\circ$ , the glistening crystals gradually became opaque and partially sublimed, and the *anhydrous terpin* thus obtained melted at  $105^\circ$ , which is the melting point of ordinary terpin (Wallach, *Annalen*, 1885, 230, 248). Furthermore, an intimate mixture of synthetical and ordinary terpin hydrate melted at exactly the same point as the components, so that there can be no doubt that the synthetical substance is identical in all respects with ordinary terpin hydrate.

*Conversion of Synthetical Terpeneol into Dipentene,*

It is well known that when ordinary terpeneol is heated with potassium hydrogen sulphate it is readily converted, with loss of water, into dipentene, and in order to accomplish this important transformation in the case of synthetical terpeneol, the following experiment was carried out. Synthetical terpeneol (21 grams) was mixed with powdered potassium hydrogen sulphate (30 grams) and heated to boiling for 1 hour in a reflux apparatus, during which it was noticed that much water was produced. After distilling in steam, the oil was extracted with ether, dried over calcium chloride, and roughly fractionated, and the portion boiling above  $185^\circ$ , which contained unchanged terpeneol, again heated with potassium hydrogen sulphate. The dipentene obtained from both experiments was carefully fractionated, and 15 grams were obtained, which distilled at  $180-183^\circ$ , and possessed in a marked degree the characteristic odour of lemons; but this did not

\* This decomposition point is usually given as  $116-117^\circ$ , but if capillary tubes containing terpin hydrate are plunged into sulphuric acid heated in different experiments at temperatures between  $116^\circ$  and  $122^\circ$ , it will be seen that the correct point of decomposition is about  $120-121^\circ$ .

give satisfactory results on analysis. Experiments with ordinary dipentene clearly showed that it is a matter of considerable difficulty to prepare a specimen of dipentene in so pure a condition that it will give good results on analysis, and this is partly due to the rapidity with which this terpene absorbs oxygen from the air. The desired result was, however, ultimately accomplished in the case of the synthetical product by repeated distillation over sodium in a current of dry carbon dioxide, and the sample analysed distilled constantly at  $180-181^{\circ}$ .

0.1351 gave 0.3365  $\text{CO}_2$  and 0.1451  $\text{H}_2\text{O}$ .  $\text{C} = 88.1$ ;  $\text{H} = 11.9$ .

$\text{C}_{10}\text{H}_{16}$  requires  $\text{C} = 88.2$ ;  $\text{H} = 11.8$  per cent.

In order to demonstrate clearly the identity of this synthetical hydrocarbon with ordinary dipentene, the following derivatives were prepared from it, and directly compared with specimens made under exactly the same conditions from pure dipentene.

*Dipentene Dihydrochloride*,  $\text{C}_{10}\text{H}_{16} \cdot 2\text{HCl}$ .—Synthetical dipentene (2 grams) was mixed with glacial acetic acid (1 gram) in a beaker, and gaseous hydrogen chloride led over the surface for about an hour. On mixing the solution with ice and water, an oil separated which readily solidified, and after remaining in contact with porous porcelain until quite dry, the substance was further purified by dissolving in alcohol and precipitating with water as recommended by Wallach (*Annalen*, 1887, 239, 12).

0.1282 gave 0.1767  $\text{AgCl}$ .  $\text{Cl} = 34.1$ .

$\text{C}_{10}\text{H}_{18}\text{Cl}_2$  requires  $\text{Cl} = 34.0$  per cent.

This dihydrochloride melted at  $48-50^{\circ}$ , and was identical in all respects with a specimen prepared from ordinary dipentene.

*Dipentenetetrabromide*,  $\text{C}_{10}\text{H}_{16}\text{Br}_4$ .—This substance was readily obtained by dissolving synthetical dipentene in twice its volume of pure, dry chloroform, cooling to  $-10^{\circ}$ , and adding bromine drop by drop until the yellow colour persisted for 5 minutes.

The solution was freed from chloroform by aspirating a rapid current of dry air over it, and the crystalline residue was dried on porous porcelain and recrystallised from ethyl acetate, when it separated in colourless, glistening needles.

0.1344 gave 0.2213  $\text{AgBr}$ .  $\text{Br} = 70.1$ .

$\text{C}_{10}\text{H}_{16}\text{Br}_4$  requires  $\text{Br} = 70.2$  per cent.

Thus prepared, the tetrabromide melted at  $125^{\circ}$ , and when mixed with an equal quantity of ordinary dipentenetetrabromide, no alteration in the melting point could be detected.

*Dipentenitrosochloride*,  $\text{C}_{10}\text{H}_{16}\text{NOCl}$ .—This substance was prepared from synthetical dipentene by the method recommended by

Wallach (*Annalen*, 1888, 245, 268); it melted at 106°, and was identical in all respects with ordinary dipentenitrosochloride.

*Hydroxyisopropyl-p-ketohexamethylene, isoPropenyl-p-ketohexamethylene, and the Conversion of the latter into  $\Delta^{8(9)}$ -Menthenol (1),*

In describing the action of magnesium methyl iodide on ethyl  $\delta$ -ketohexahydrobenzoate (p. 660), it was mentioned that a neutral oil, unaffected by the treatment with methyl-alcoholic potash, and having an intense odour of peppermint, is always produced in small quantity.

During the course of this research, about 30 grams of this oil were gradually accumulated and then treated as follows.

It was first distilled in steam and then repeatedly fractionated under 100 mm. pressure, and thus separated into two portions boiling at 135—150° and 177—180°. The latter, which was about two-thirds of the whole, was analysed with the following result:

0.1113 gave 0.2799 CO<sub>2</sub> and 0.1048 H<sub>2</sub>O. C = 68.6; H = 10.4.  
CO(CH<sub>2</sub>·CH<sub>2</sub>)<sub>2</sub>CH·CMe<sub>2</sub>·OH or C<sub>9</sub>H<sub>16</sub>O<sub>2</sub> requires C = 69.2; H = 10.2 per cent.

As explained in the introduction (p. 659), this analysis and the method of formation of the substance leave scarcely any doubt that it is hydroxyisopropyl-*p*-ketohexamethylene. It is a viscid oil which is readily volatile in steam.

The lower fraction, boiling at 135—150° (100 mm.), was repeatedly distilled under the ordinary pressure, and about 10 grams were thus isolated, which boiled, not quite constantly, at 184—186°.

0.1507 gave 0.4286 CO<sub>2</sub> and 0.1369 H<sub>2</sub>O. C = 77.3; H = 10.1.  
CO(CH<sub>2</sub>·CH<sub>2</sub>)<sub>2</sub>CH·CMe·CH<sub>2</sub> or C<sub>9</sub>H<sub>14</sub>O requires C = 78.2; H = 10.1 per cent.

This substance evidently has the composition C<sub>9</sub>H<sub>14</sub>O, and is derived from hydroxyisopropylketohexamethylene by the elimination of water, but as it could not be completely separated from this hydroxy-compound by fractionation, it was shaken with aqueous hydrobromic acid (saturated at 0°), and the heavy bromide thus produced digested with methyl-alcoholic potash. After extracting in the usual way, the resulting oil distilled at the same temperature as before, and gave on analysis numbers agreeing rather more closely with the formula C<sub>9</sub>H<sub>14</sub>O.

0.1211 gave 0.3449  $\text{CO}_2$  and 0.1110  $\text{H}_2\text{O}$ .  $\text{C} = 77.6$ ;  $\text{H} = 10.2$ .

$\text{C}_9\text{H}_{14}\text{O}$  requires  $\text{C} = 78.2$ ;  $\text{H} = 10.1$  per cent.

This *isopropenyl-p-ketohecamethylene* is isomeric with phorone, acetophorone, camphorone, and many other similar ketones, and with these it shares the property of possessing a penetrating odour of peppermint. The conversion of this ketone into  $\Delta^{8(9)}$ -menthenol (1), which is discussed in the introduction (p. 659), was carried out as follows. Magnesium (3 grams) was covered with dry ether (100 c.c.) and converted into magnesium methyl iodide by treatment with 25 grams of methyl iodide; the ketone (6 grams), dissolved in ether (20 c.c.), was then added, and the whole left for 24 hours. The product was then decomposed by dilute hydrochloric acid, the ethereal solution separated, washed with water, evaporated, and the residual oil, after distilling in steam, fractionated under 60 mm. pressure. Almost the whole quantity distilled at  $125-127^\circ$ , or about  $8^\circ$  lower than terpineol, with which it is isomeric, and there can be no doubt that this synthetical substance is identical with the  $\Delta^{8(9)}$ -menthenol (1) of Stephan and Helle (*Ber.*, 1902, 35, 2147), and which melts at  $32^\circ$ .

0.1506 gave 0.4298  $\text{CO}_2$  and 0.1625  $\text{H}_2\text{O}$ .  $\text{C} = 77.9$ ;  $\text{H} = 11.9$ .

$\text{C}_{10}\text{H}_{18}\text{O}$  requires  $\text{C} = 77.9$ ;  $\text{H} = 11.7$  per cent.

The viscid oil thus obtained had a very pronounced odour of hyacinths, and when cooled in ice and well stirred, it crystallised; but owing to the small amount of material available no attempt could be made to recrystallise it and determine its melting point.

On treatment with *isoamyl* nitrite and hydrochloric acid in acetic acid solution, it yielded a crystalline nitrosochloride, and phenylcarbimide converted it into a phenylurethane, which, after crystallisation from dilute methyl alcohol, melted at  $85-87^\circ$ , whereas Stephan and Helle give  $85^\circ$  as the melting point of the phenylurethane of  $\Delta^{8(9)}$ -menthenol (1).

The author wishes to express his thanks to Mr. S. S. Pickles, B.Sc., for his valuable assistance in carrying out this difficult investigation, and to state that much of the expense incurred has been met by repeated grants from the Government Grant Fund of the Royal Society.

THE OWENS COLLEGE,  
MANCHESTER.

LXVII.—*Ammoniacal Double Chromates and Molybdates.*

By SAMUEL HENRY CLIFFORD BRIGGS.

In a previous paper (Trans., 1903, 83, 391), a number of double chromates were described belonging to a series having the general formula  $M_2^I M^{II} (RO_4)_2, 2NH_3$ .

Since the majority of the comparatively small number of ammoniacal double salts which have been prepared are halides or cyanides, it seemed worth while to make a more complete examination of this series, and compounds have been obtained in which  $M^I$  represents  $NH_4$  or K;  $M^{II}$  is Cu, Zn, Cd, Ni, or Co; and R is Cr or Mo. Numerous attempts to prepare the corresponding tungstates were unsuccessful.

The double salts are characterised by considerable stability. They may be heated at  $150^\circ$  without undergoing any change, and in some cases ammonia is not given off at temperatures above  $200^\circ$ . Decomposition always occurs below  $300^\circ$ , the ammonia being partially oxidised at the expense of the acid radicle.

The stability of the double salts is in marked contrast to the readiness with which ammonia is evolved from many ammonio-metallic compounds, such as  $CuCrO_4, 3\frac{1}{2}NH_3, \frac{1}{2}H_2O$ ,  $CuMoO_4, 2NH_3, H_2O$ , and  $CuWO_4, 4NH_3$ , which are described in the present paper. A further distinction between the two classes of substances is presented in their respective colours. The double salt  $(NH_4)_2Cu(MoO_4)_2, 2NH_3$  is bright blue, similar in tint to hydrated copper sulphate, whereas the compound  $CuMoO_4, 2NH_3, H_2O$  has the deep blue shade usually associated with cuprammonium compounds. Again, although ammonio-nickel compounds are generally blue or violet, the double salt  $(NH_4)_2Ni(MoO_4)_2, 2NH_3$  is green.

*Chromates.*

*Ammonio-copper potassium chromate*,  $K_2Cu(CrO_4)_2, 2NH_3$ , crystallises out when an ammoniacal solution of copper chromate to which a large amount (3 to 4 equivalents) of potassium chromate has been added is allowed to lose its free ammonia by exposure to the air.

Copper carbonate (12.5 grams) was dissolved in a small quantity of water containing 25 grams of chromium trioxide, and the solution added to a mixture of 75 c.c. of water and 125 c.c. of concentrated aqueous ammonia. A second solution containing 20 grams of potassium hydroxide and 150 grams of potassium chromate in 280 c.c. of water was then added, and the liquid filtered. The function of the potassium hydroxide was to diminish the concentration of the

ammonium ions, and thus prevent as far as possible the formation of an isomorphous mixture of potassium and ammonium salts.

After the filtrate had remained for a few days in an open dish, the compound separated in large, hard rosettes of thin, brown plates closely set together. These were broken up, washed by decantation with the mother liquor to remove any basic salt, then with dilute ammonia, and finally dried with alcohol and ether.

	Found.	Required.
CuO .....	19.34	19.44 per cent.
CrO <sub>3</sub> .....	49.06	49.16 „
NH <sub>3</sub> .....	8.8	8.4 „

The compound was decomposed by water and dissolved readily in dilute ammonia. When heated at 250° it gave off a little ammonia and decomposed rapidly at 280°.

*Ammonio-copper chromate*,  $\text{CuCrO}_4 \cdot 3\frac{1}{2}\text{NH}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$ , was obtained from the same solution in large, greenish-black crystals, when the potassium chromate present was insufficient for the formation of the double salt  $\text{K}_2\text{Cu}(\text{CrO}_4)_2 \cdot 2\text{NH}_3$ . Its preparation was accomplished by dissolving 14 grams of copper carbonate and 25 grams of chromium trioxide in a small amount of water, pouring the solution into a mixture containing 125 c.c. of concentrated ammonia, 50 c.c. of water, and 15 grams of potassium hydroxide, and exposing the filtered liquid to the air.

	Found.		Required.
	I.	II.	
CuO .....	31.95	32.23	32.01 per cent.
CrO <sub>3</sub> .....	40.16	40.10	40.30 „
NH <sub>3</sub> .....	23.86	23.72	24.01 „

The crystals, which readily evolve ammonia at the ordinary temperature, are easily soluble in dilute ammonia, but are decomposed by water. Although several ammoniacal copper chromates have been previously described, this is the first one known containing the acidic and basic oxides in equivalent proportion (1 : 1).

### *Molybdates.*

The double salts of ammonium molybdate belonging to this series, like the chromates, are well-defined, crystalline substances, readily obtained in a state of purity; they are decomposed by water but dissolve easily in dilute ammonia, in which they appear to be resolved to some extent into their components.

*Ammonio-copper ammonium molybdate*,  $(\text{NH}_4)_2\text{Cu}(\text{MoO}_4)_2 \cdot 2\text{NH}_3$ .—Fifty grams of ammonium molybdate in 60 c.c. of water were added

to a solution of 20 grams of ordinary copper sulphate in 50 c.c. of water and 70 c.c. of concentrated ammonia, the liquid being then made up to 210 c.c. After leaving the solution in an open dish for five days, the large, bright blue crystals were collected, washed with dilute ammonia, and dried with alcohol and ether.

	Found.	Required.
CuO .....	17.46	17.49 per cent.
MoO <sub>3</sub> .....	63.58	63.52 „
NH <sub>3</sub> .....	15.12	15.02 „

*Ammonio-copper molybdate*,  $\text{CuMoO}_4 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$ , crystallises in deep blue prisms on exposing to the air an ammoniacal solution of copper sulphate and ammonium molybdate which contains too small an amount of molybdate or is too dilute for the formation of the double salt. For its preparation, 24 grams of copper sulphate in 30 c.c. of water were added to 13 grams of ammonium molybdate in 15 c.c. of water and 40 c.c. of strong ammonia, the whole solution being made up to 350 c.c.

	Found.		Required.
	I.	II.	
CuO.....	28.75	28.74	28.87 per cent.
MoO <sub>3</sub> .....	52.66	52.53	52.29 „
NH <sub>3</sub> .....	—	12.53	12.37 „

The habit of the crystals varies greatly with the proportion of copper sulphate and ammonium molybdate present in the solution, an excess of the latter being accompanied by a large development of certain faces which remain insignificant when a considerable amount of the former is used. The compound evolves ammonia at the ordinary temperature; it is soluble in dilute ammonia, from which it may be re-crystallised either by allowing a warm saturated solution to cool, or by exposing a more dilute solution to the air.

*Ammonio-cadmium ammonium molybdate*,  $(\text{NH}_4)_2\text{Cd}(\text{MoO}_4)_2 \cdot 2\text{NH}_3$ , was prepared in the same way as the corresponding copper compound.

	Found.	Required.
CdO .....	25.69	25.49 per cent.
MoO <sub>3</sub> .....	57.72	57.36 „
NH <sub>3</sub> .....	13.47	13.56 „

When heated quickly, the colourless crystals evolved ammonia and water giving 78.6 per cent. of a black residue, whereas  $2\text{CdMoO}_4 \cdot \text{Mo}_2\text{O}_3$  requires 78.1 per cent. The black residue containing molybdenum sesquioxide on further heating in the air was oxidised, becoming white (residue found = 81.3;  $\text{CdMoO}_4 \cdot \text{MoO}_3$  requires 82.8 per cent.). This decomposition is similar to, but not so complete as, that of the salt

$(\text{NH}_4)_2\text{Cd}(\text{CrO}_4)_2, 2\text{NH}_3$ , which on heating gave  $\text{CdO}, \text{Cr}_2\text{O}_3$  (*loc. cit.*). At a higher temperature a molecule of molybdic anhydride sublimed, leaving cadmium molybdate (found  $\text{CdMoO}_4 = 54.4$ , required  $54.2$  per cent.).

*Ammonio-nickel ammonium molybdate*,  $(\text{NH}_4)_2\text{Ni}(\text{MoO}_4)_2, 2\text{NH}_3$ .—Twenty grams of hexahydrated nickel chloride dissolved in 15 c.c. of water were added to 50 grams of ammonium molybdate in 70 c.c. of strong ammonia and 50 c.c. of water. The deep blue liquid when left in an open dish deposited green crystals of the double salt.

	Found.	Required.
NiO .....	16.79	16.70 per cent.
MoO <sub>3</sub> .....	64.24	64.14 „
NH <sub>3</sub> .....	15.00	15.18 „

*Ammonio-cobalt ammonium molybdate*,  $(\text{NH}_4)_2\text{Co}(\text{MoO}_4)_2, 2\text{NH}_3$ .—A solution made up from 20 grams of cobalt sulphate, 50 grams of ammonium molybdate, 50 c.c. of strong ammonia, and 90 c.c. of water oxidised rapidly in the air; and consequently in order to obtain the cobaltous double salt it was placed over sulphuric acid in a vacuum desiccator connected with a water-pump, which was kept in action until the excess of ammonia had been evolved. The double salt was deposited in small, violet crystals, which were collected, washed with dilute ammonia, and dried with alcohol and ether.

	Found.	Required.
CoO.....	17.03	16.70 per cent.
MoO <sub>3</sub> .....	64.30	64.14 „
NH <sub>3</sub> .....	14.8	15.2 „

If the solution was allowed to oxidise in the air, it deposited a large quantity of brilliant crimson needles, which dissolved in dilute ammonia, but were slightly decomposed by water; they were easily soluble in potassium hydroxide, and the solution on boiling evolved ammonia, the cobalt being precipitated. An analysis gave  $\text{CoO} = 14.85$ ,  $\text{MoO}_3 = 55.65$  and  $55.72$ ,  $\text{NH}_3 = 19.66$ , these figures corresponding with ammonium aquopentamminocobaltic molybdate,

which requires  $\text{CoO} = 14.47$ ,  $\text{MoO}_3 = 55.57$ , and  $\text{NH}_3 = 19.73$  per cent., but the examination of the compound was not sufficiently complete to justify any conclusions with regard to its constitution.

### *Tungstates.*

The following new substances were obtained during the unsuccessful experiments made with the object of preparing ammoniacal double tungstates.

The copper compound  $\text{CuO}, 4\text{WO}_3, 6\text{NH}_3, 8\text{H}_2\text{O}$  separated as a dirty-blue, microcrystalline mass when an ammoniacal solution of copper sulphate and ammonium tungstate gave off its excess of ammonia. If the evolution of ammonia was very slow, the compound was obtained in small, bright blue needles.

Tungstic acid corresponding with 20 grams of tungstic anhydride, obtained by precipitating a solution of sodium tungstate,  $\text{Na}_2\text{WO}_4$ , with nitric acid, was dissolved in 20 c.c. of cold concentrated ammonia, 5 grams of copper sulphate in 7.5 c.c. of water and 7.5 c.c. of concentrated ammonia were added, and the filtered solution placed in an open vessel. The large crystals were used for analysis.

	Found.	Required.
$\text{CuO}$ .....	6.43	6.35 per cent.
$\text{WO}_3$ .....	73.93	74.01 „
$\text{NH}_3$ .....	8.18	8.15 „
$\text{H}_2\text{O}$ .....	11.46 (by difference)	11.48 „

The crystals were almost insoluble in dilute ammonia and insoluble in water.

*Ammonio-copper Tungstate,  $\text{CuWO}_4, 4\text{NH}_3$ .*

(1) Copper sulphate (7.5 grams) was precipitated in hot solution with 10 grams of dihydrated sodium tungstate,  $\text{Na}_2\text{WO}_4, 2\text{H}_2\text{O}$ , the precipitated copper tungstate washed by decantation and thoroughly drained, after which it was dissolved in 20 c.c. of cold concentrated ammonia.

(2) Dihydrated sodium tungstate (13 grams) was precipitated with nitric acid, and the washed tungstic acid, after being drained, was dissolved in 20 c.c. of strong ammonia, the solution being added to the ammoniacal solution of copper tungstate. The mixture was then filtered into a bottle, and a layer of alcohol allowed to diffuse slowly into it during several weeks, the bottle remaining tightly stoppered. The experiment was arranged in this way with the object of preventing the ammonia from being given off to such an extent as would result in the formation of polytungstates. This end was achieved, only the normal tungstate being obtained, but no double salt was observed even when three times as much ammonium tungstate was present as in the experiment under consideration. The compound  $\text{CuWO}_4, 4\text{NH}_3$  separated in both cases.

	Found.	Required.
$\text{CuO}$ .....	20.80	20.96 per cent.
$\text{WO}_3$ .....	61.16	61.09 „
$\text{NH}_3$ .....	18.15	17.95 „

The deep blue crystals, which dissolved in a small amount of water and were easily soluble in dilute ammonia, gave off ammonia very readily at the ordinary temperature.

*Ammonio-zinc tungstate*,  $\text{ZnWO}_4 \cdot 4\text{NH}_3 \cdot 3\text{H}_2\text{O}$ , crystallised in large, transparent tetrahedra often exhibiting twinning; it readily evolved ammonia at the ordinary temperature.

	Found.	Required.
ZnO .....	18.49	18.66 per cent.
WO <sub>3</sub> .....	54.0	53.3   ,,
NH <sub>3</sub> .....	15.61	15.65   ,,

It was prepared like the foregoing copper salt, the zinc tungstate being precipitated in the cold, since that which comes down from hot solutions is not easily soluble in ammonia.

### LXVIII.—*The Hexahydrated Double Chromates. Magnesium and Nickel Compounds.*

By SAMUEL HENRY CLIFFORD BRIGGS.

THE double chromates  $\text{M}_2\text{M}^{\text{II}}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ , which are of some interest on account of their analogy with the corresponding double sulphates, have been but slightly investigated, only two members of the series having been hitherto prepared, namely, magnesium ammonium chromate,  $(\text{NH}_4)_2\text{Mg}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$  (Grailich, *Sitzungsber. Akad. Wissen. Wien.*, 1857, 27, 175), and nickel ammonium chromate (Briggs, *Trans.*, 1903, 83, 391).

The continuation of the experiments described in the previous paper (*loc. cit.*) has led to the isolation of nickel potassium chromate,  $\text{K}_2\text{Ni}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ , a compound which is very efflorescent at the ordinary temperature.

It was shown by Tutton (*Trans.*, 1896, 69, 521) that, in the case of the double sulphates the stability of those compounds which contain the same bivalent metal increases with the increase in the atomic weight of the alkali metal. Thus the double salt  $\text{K}_2\text{Cd}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$  could not be prepared,  $\text{Rb}_2\text{Cd}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$  was very efflorescent, and  $\text{Cs}_2\text{Cd}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$  much less so at the ordinary temperature. Consequently, it seemed probable that a similar increase in stability from the potassium to the caesium compounds would hold good for the double chromates, and for this reason the rubidium and caesium salts were examined, with the result that the latter was found to be quite stable at 10°, whereas the former became slightly discoloured after

being kept for two months. Nickel ammonium chromate occupies an intermediate position between the two in agreement with the place in the alkali series assigned to ammonium by Tutton in a recent paper on the morphological and physical properties of ammonium sulphate (Trans., 1903, 83, 1049).

The double salts of magnesium chromate have also been prepared, and the same differences in stability observed. From the readiness with which magnesium potassium chromate and nickel potassium chromate give off their water at the ordinary temperature, it seems likely that all the potassium compounds of this group would be efflorescent if they could be obtained, since Tutton (Trans., 1896, 69, 521) found that nickel potassium sulphate was one of the most stable potassium double sulphates which he examined.

#### EXPERIMENTAL.

##### *Nickel Potassium Chromate*, $K_2Ni(CrO_4)_2 \cdot 6H_2O$ .

Eight grams of potassium chromate in 14 c.c. of water were added to 8 grams of nickel acetate in 27 c.c. of water, both solutions having been previously cooled to  $-6^\circ$  in a mixture of ice and salt. If the temperature rises much above this, basic salts separate, these substances also being deposited if the solution is left for any length of time in the freezing mixture. In order to obtain a good yield, it is therefore necessary to induce crystallisation by vigorous stirring. Working in this way, 3.2 grams of the double salt were prepared in the form of small, yellowish-green crystals; these were collected at the pump, washed with a very small quantity of cold water, and dried with alcohol and ether.

Two different preparations gave the following analytical results :

	Found.		Required.
	I.	II.	
$CrO_3$ .....	41.5	41.3	41.95 per cent.
$NiO$ .....	16.0	15.9	15.65 „

The compound, when kept in a stoppered bottle at  $10^\circ$  for a few hours, evolved water and was converted into a damp, brownish-yellow mass. After exposing a portion of each preparation to the air until the weight was constant, the residues contained 47.67 and 47.81 per cent. of chromium trioxide respectively; a loss of three molecules of water requires 47.30 per cent.

*Nickel Rubidium Chromate*,  $Rb_2Ni(CrO_4)_2 \cdot 6H_2O$ .—This double salt separated readily when a solution of rubidium chromate (5 grams in 7 c.c. of water) was added to a solution of nickel acetate (4.3 grams

in 13 c.c. of water) at 10°. The yellowish-green crystals (3·5 grams) were washed with water and dried with alcohol and ether.

	Found.	Required.
NiO .....	13·28	13·12 per cent.
CrO <sub>3</sub> .....	34·85	35·14 „

Nickel rubidium chromate is very slightly efflorescent at the ordinary temperature.

*Nickel caesium chromate*,  $\text{Cs}_2\text{Ni}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ , was prepared in the same way as the rubidium compound, 3·8 grams being obtained from 5 grams of caesium chromate and 3 grams of nickel acetate.

	Found.	Required.
NiO .....	11·30	11·26 per cent.
CrO <sub>3</sub> .....	30·25	30·11 „

The crystals were unaltered after having been kept for two months. The salt dissolves in cold water without much change, but is decomposed by warm water; nevertheless, it may be partially recrystallised from a solution saturated at 35—40°, after filtering off the precipitate of basic salt. The potassium compound is much more readily decomposed by water.

*Magnesium Potassium Chromate*,  $\text{K}_2\text{Mg}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ .—Dammer states (*Handbuch Anorg. Chem.*), on the authority of v. Hauer (*Sitzungsber. Akad. Wissen. Wien.*, 1860, 39, 440), that magnesium potassium chromate never crystallises with  $6\text{H}_2\text{O}$ . The hexahydrate appears to be formed, however, in a solution of its components, if the temperature is sufficiently low. For its preparation, very concentrated solutions of potassium chromate and magnesium chromate were cooled to -10°, and then mixed. The double salt was deposited in very small, lemon-yellow crystals, which were dried with alcohol and ether.

	Found.	Required.
MgO .....	9·42	9·12 per cent.
CrO <sub>3</sub> .....	45·36	45·25 „
H <sub>2</sub> O .....	23·93	24·39 „

The compound is efflorescent, and a portion on exposure to the air at 8—10° lost 14·92 per cent. of water, a loss of  $4\text{H}_2\text{O}$  requiring 16·25 per cent. The efflorescence did not appear to take place quite so readily as in the case of the corresponding nickel compound.

*Magnesium rubidium chromate*,  $\text{Rb}_2\text{Mg}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ , separated in brilliant lemon-yellow crystals, permanent at the ordinary temperature, when solutions of its components were mixed in the cold.

	Found.	Required.
MgO .....	7.88	7.54 per cent.
CrO <sub>3</sub> .....	37.04	37.39 „
H <sub>2</sub> O .....	20.10	20.17 „

*Magnesium caesium chromate*,  $\text{Cs}_2\text{Mg}(\text{CrO}_4)_2 \cdot 6\text{H}_2\text{O}$ , was prepared like the rubidium compound, which it closely resembled.

	Found.	Required.
MgO .....	6.80	6.40 per cent.
CrO <sub>3</sub> .....	31.64	31.75 „
H <sub>2</sub> O .....	17.26	17.15 „

### *Comparison of Stabilities.*

*Nickel Compounds.*—The potassium salt being efflorescent at the ordinary temperature, only the rubidium, ammonium, and caesium compounds were dealt with in these experiments.

(1) Approximately equal quantities of the caesium and rubidium salts were heated together for 12 hours in an air-bath at 40°, after which the rubidium compound had become slightly brown, having lost 0.5 per cent. of water, whereas the caesium compound was unchanged. After further heating for 1 hour at 60°, the caesium compound was also slightly discoloured. The temperature was therefore lowered to 50° for 4 hours, when the rubidium salt had lost 2.4 molecules of water and the caesium salt only 0.15 molecule.

(2) When the ammonium and rubidium compounds were heated together for 2 hours at 53°, the former lost 0.78 molecule and the latter 2 molecules of water. A repetition of the experiment gave exactly the same result.

(3) The ammonium and caesium salts were heated together for 1 hour at 56°. The ammonium compound lost 0.41 molecule of water, becoming brown, whereas the change in weight of the caesium compound was imperceptible.

The order of increasing stability is evidently potassium, rubidium, ammonium, and caesium; but, as is seen from the above experiments, the difference between the potassium and rubidium compounds is more marked than that between the rubidium and caesium salts.

*Magnesium Compounds.*—The caesium and rubidium salts were heated together for 12 hours at 55°. The caesium salt remained unchanged, whilst the rubidium compound lost only 0.16 per cent. of water. The heating was therefore continued for 3 hours at 65°, after which the caesium compound had lost 0.18 and the rubidium derivative 1.6 molecules of water respectively.

Here again the order of increasing stability coincides with the increase in the atomic weight of the alkali metal, the magnesium compounds being somewhat less readily decomposed than their nickel analogues.

---

## LXIX.—*Reduced Silicates.*

By CHARLES SIMMONDS, B.Sc.

IN a recent communication (Trans., 1903, 83, 1449) some experiments were recorded describing the reduction which silicates of lead, copper, iron, cobalt, and nickel undergo when heated in hydrogen. The bearing of the results on the structural formulæ of the silicates was pointed out, but the reduced silicates themselves were only alluded to very briefly. The object of the present note is to describe these products, and particularly those obtained from the simpler lead silicates, somewhat more fully.

The first point to decide was whether the substance left after the reduction of any silicate was a mixture of the metal and silica, or a compound of these two substances. Apparently no such compounds have hitherto been recognised, but in the present experiments it is shown that a substance of this nature is formed in all the cases yet examined. In some instances, however, this compound is found to be mixed with a certain proportion of the metal ; and whether this result is obtained or not depends on the composition of the original silicate.

Firstly, taking those lead silicates which do not yield metallic lead on reduction, it is found that lead metasilicate,  $\text{PbSiO}_3$ , the disilicate,  $\text{PbSi}_2\text{O}_5$ , and the trisilicate,  $\text{Pb}_2\text{Si}_3\text{O}_8$ , yield the compounds  $\text{PbSiO}_2$ ,  $\text{PbSi}_2\text{O}_4$ , and  $\text{Pb}_2\text{Si}_3\text{O}_6$  respectively. The evidence on which the conclusion is based that these are true compounds and not mixtures is as follows :

(1) No globules of metallic lead are observable in the reduced substance ; nor is the porcelain boat, in which the silicate is reduced, discoloured or attacked in any way. The residue is friable, and can be triturated to any degree of fineness without showing particles of lead.

(2) When the residue is fused with alkali carbonates no metallic lead is separated ; or, at most, insignificant traces only.

(3) Boiling nitric acid extracts from the reduced residue a relatively small fraction only of the lead present, and in some cases practically none. The following experiments are typical :

(a) Reduced residue from lead metasilicate. Percentage composi-

tion,  $\text{Pb} = 77.6$ ,  $\text{SiO}_2 = 22.4$ . 0.2 gram boiled for a quarter of an hour with 10 c.c. of nitric acid (sp. gr. 1.2). Lead dissolved = 0.0102 gram, or 5.1 per cent.

(b) A similar experiment with 0.2 gram of the reduced residue obtained from lead trisilicate, and containing 69.6 per cent. of lead.

Lead dissolved = 0.0044 gram, or 2.2 per cent.

These experiments show that the reduced silicates contained little or no metallic lead. Moreover, the reduced compound itself, although containing in one case upwards of 77 per cent. of lead, is not attacked to any considerable extent by boiling nitric acid.

Generally, the results obtained from a number of such experiments showed that long-continued boiling with nitric acid might dissolve from the reduced silicates quantities of lead varying from 2 up to about 10 per cent. But in none of these cases could any evidence be obtained that anything more than an insignificant fraction of the lead dissolved was originally present in the metallic condition.

Similar results were obtained with the complex silicates and borosilicates of lead, aluminium, calcium, and the alkali metals. For example, a specimen of complex boro-metasilicate gave a reduced residue in which lead was present to the extent of 45.7 per cent.; from this, when boiled with nitric acid, mere traces of lead were dissolved. Other specimens gave larger, but still relatively small, amounts of lead, ranging up to about 8 per cent.

It is concluded, therefore, that the reduced silicate residues in the above cases were not mixtures of lead and silica, but true compounds. These compounds may perhaps be conveniently designated "*silicites*," to denote that they contain less oxygen than the silicates from which they were derived.

*General Properties.*—Reduced lead silicates ("*silicites*") are black powders, distinctly less fusible than the original silicates. They are not readily re-oxidised: bromine has little or no action on them; and as a rule the compounds can be heated to redness in air for some hours without any considerable increase of weight or change in colour. Except for a slight solvent action, acid oxidising mixtures do not affect them. In one experiment, for instance, 0.5 gram of a complex lead "*silicite*" was boiled for some time with 50 c.c. of aqua regia, and again with nitric acid and potassium chlorate; the residue after this treatment showed no change in appearance, and only 4 per cent. of it had been dissolved. In their chemical deportment the "*silicites*" are frequently more refractory than the original silicates, for whereas the latter were in several instances found to be readily decomposable with cold dilute acids, the "*silicites*" obtained from them were practically unattacked even by hot acids of much greater concentration. A boiling solution of caustic soda extracts small quantities of lead and silica

from the compounds, but does not affect them to any considerable extent. Fusion with alkali carbonates, however, readily decomposes them, and they are also attacked, although with some difficulty, by hydrofluoric acid.

On the other hand, the residues left by the reduction of lead orthosilicate,  $\text{Pb}_2\text{SiO}_4$ , and of the basic disilicate,  $\text{Pb}_3\text{Si}_2\text{O}_7$ , differ notably from the foregoing, inasmuch as they contain, in each case, both a compound ("silicite") and a considerable proportion of metallic lead. As this fact has an important bearing on the question of the constitution of these silicates, the details of a typical experiment are now given:

0.5 gram of lead orthosilicate ( $\text{PbO} = 88.1$ ;  $\text{SiO}_2 = 11.9$  per cent.) was reduced with hydrogen as described in the previous paper (*loc. cit.*), care being taken to spread the silicate in a thin layer over the boat and to raise the temperature rather slowly, as otherwise there is a danger of a surface-coating of metallic lead being formed and protecting the subjacent portion from the action of the hydrogen. In this experiment the reduction was proved to be complete, both by the quantity of water produced and by the loss of weight shown by the reduced silicate. Visible globules of metallic lead were formed, and a thick film of the metal covered the bottom of the boat. After cooling, the boat with its contents was transferred to a beaker, and boiled with about 70 c.c. of nitric acid (sp. gr. 1.2). The solution contained lead equivalent to 57.2 per cent. of the reduced residue, in which the total lead amounted to 87.3 per cent. The insoluble portion was a black powder; it gave up practically no lead when further treated with nitric acid, and proved to be a compound having the following percentage composition:  $\text{Pb} = 68.4$ ;  $\text{SiO}_2 = 31.6$ .

Similar results were given by the basic disilicate,  $\text{Pb}_3\text{Si}_2\text{O}_7$ , except that the proportion of lead dissolved out was relatively larger. Nearly two-thirds of the total amount of lead could be extracted from the residue by boiling with nitric acid. The insoluble portion had, approximately, the percentage composition corresponding with the formula  $\text{Pb}(\text{SiO}_2)_2$ .

The lead silicates, therefore, fall into two groups: (1) those which yield a compound ("silicite") alone on reduction; and (2) those which give a mixture of "silicite" and metallic lead. The first group comprises those silicates in which the number of molecules of basic oxide is not greater than the number of molecules of acidic oxide:  $\text{PbO}, \text{SiO}_2$ ;  $2\text{PbO}, 3\text{SiO}_2$ ;  $\text{PbO}, 2\text{SiO}_2$ ; whereas in the second group the number of molecules of basic oxide is greater than that of the acidic oxide:

$2\text{PbO}, \text{SiO}_2$   
Orthosilicate.

$3\text{PbO}, 2\text{SiO}_2$ .  
Basic disilicate.

It has been pointed out in the previous communication (*loc. cit.*, p. 1462) that the elimination of metallic lead from the silicates in the second group during reduction, but not from those of the first group, is not readily explained by the ordinary formulæ :

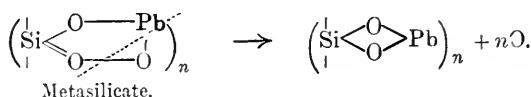

Metasilicate.

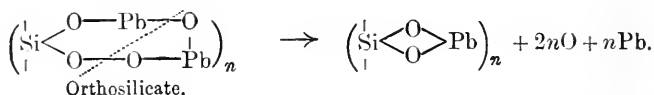

Orthosilicate.

But the elimination becomes explicable when the silicates are formulated on the system which the author has suggested :

Metasilicate.

Orthosilicate.

On this view, one-half of the lead should be eliminated in the metallic state when the orthosilicate is reduced. Treatment of the reduced residue with nitric acid should therefore dissolve out one-half the total quantity of lead, *plus* whatever amount may be dissolved by the simultaneous action of the acid on the residual compound ("silicite.") In the foregoing experiment, the total lead was 87.3 per cent., and the amount dissolved by nitric acid was 57.2 per cent., or 13.5 per cent. more than the amount required by the above expression. Since from some of the lead "silicites" alone (that is, from those containing no metallic lead) quantities of lead up to about 10 per cent. were extracted by nitric acid, it seems reasonable to assume that this quantity, 13.5 per cent., was in like manner derived from the "silicite" portion of the mixture left on reducing the orthosilicate. It was not found practicable to extract the whole of the metallic lead except by using an acid as solvent, because a portion of the metal had become slightly fused to the glaze of the porcelain boat.

Substantially similar results were obtained with various silicates of copper, iron, cobalt, and nickel. The general conclusion deduced confirmed that indicated by the study of the lead silicates, namely, that a compound of the metal and silica is always formed on reducing the silicate, but that in certain cases this compound may be mixed with more or less of the uncombined metal.

The experiments described would therefore appear to afford some evidence in favour of the theory of the structure of silicates which was put forward in the earlier communication. It may also be of interest

to note that, since flint-glass is a compound approximating to the disilicate type, it should, according to the foregoing results, give on reduction a black "silicite," and no metallic lead. Consequently the blackening which occurs when such glass is heated in a reducing flame, and which is usually attributed to the production of metallic lead, is more probably due to the formation of a film of lead "silicite." As a matter of fact, some powdered flint-glass was reduced in hydrogen and tested, but no uncombined lead could be detected in the residue.

## LXX.—*Studies on Optically Active Carbimides. Part I.*

By ALLEN NEVILLE, B.Sc. (Lond.), and ROBERT HOWSON PICKARD.

ON account of the ease with which carbimides, and particularly aromatic carbimides, react with alcohols and amines, and owing also to the well-defined crystalline nature of the products, an optically active carbimide, if obtainable, would seem to be a promising reagent to employ in effecting the resolution of synthetical asymmetric substances containing hydroxy- or amino-groups. Of the optically active amines, which are most readily obtainable, bornylamine and menthylamine appear to be best adapted for this purpose.

As the result of a series of brilliant investigations, Forster (Trans., 1898, 63, 390, &c.) has characterised pure bornylamine, so that its preparation can be readily carried out and the purity of the product ascertained.

The literature relating to the menthylamines affords evidence that the liquid described as *l*-menthylamine is in reality a mixture. Since a new asymmetric carbon atom is formed when menthoneoxime is reduced, theory indicates the production of more than one lævorotatory menthylamine. During the course of our investigations, a paper has been published by Tutin and Kipping (this vol., p. 65), in which this question is fully discussed and methods are described for the separation of some salts of four isomeric lævorotatory menthylamines. We had also obtained evidence of the existence of several lævorotatory menthylcarbimides, and the results relating to this portion of the work will be published shortly.

It has also been found that the reactions between pure *l*-menthylcarbimide and the alcohols proceed with velocities which are easily measured by means of the change in the rotations of the solutions.

The velocity of the reaction is influenced considerably by temperature, by various catalytic agents, by the solvent, and by the constitution of the alcohol. This variation affords a method of contrasting the reactivity of the alcohols in a homologous series.

*Preparation of Bornylcarbimide and 1-Menthylcarbimide.*

The carbimides,  $RN:CO$ , have been prepared by Hofmann's well-known method of distilling the corresponding ethyl carbamates,  $RNH \cdot CO_2Et$ , with phosphoric oxide, these operations being carried out under reduced pressure. At first it was feared that this method would cause racemisation. However, we have carried out over a hundred of these distillations, and have checked the specific rotations at all stages of the process of purification. The specific rotations of various preparations have been found to be uniform, and the specific rotations of the carbimides described are unaltered by repeated distillation over phosphoric oxide.

For the preparation of the following bornyl and neobornyl compounds, a mixture of bornylamine and neobornylamine hydrochlorides was first prepared by the reduction of camphoroxime by sodium in amyl-alcoholic solution; this was then fractionally crystallised until the two hydrochlorides were obtained with the specific rotations given by Forster (*loc. cit.*).

*Ethyl Bornylcarbamate,  $C_{10}H_{17} \cdot NH \cdot CO_2 \cdot C_2H_5$ .*

An aqueous solution of nineteen grams (1 mol.) of bornylamine hydrochloride is mixed with an excess of sodium hydroxide solution and extracted with light petroleum. The extract was mixed with an excess of sodium hydrogen carbonate and heated in a reflux apparatus with 10.8 grams (1 mol.) of ethyl chlorocarbonate. The mixture was then washed with water and the light petroleum extract separated and dried with calcium chloride. After distilling off the petroleum, the oily ester gradually forms a white solid, the yield being practically quantitative. The compound is volatile in steam, insoluble in water, but soluble in the ordinary organic solvents; it crystallises from light petroleum in hard, prismatic crystals or from aqueous ethyl alcohol in clusters of prismatic needles which melt at  $89^\circ$ .

0.2233 gave 12.2 c.c. moist nitrogen at  $16^\circ$  and 754 mm.  $N = 6.31$ .

$C_{13}H_{23}O_2N$  requires  $N = 6.22$  per cent.

0.5635, made up to 25 c.c. with chloroform, gave  $\alpha_D^* + 0.29^\circ$ , whence  $[\alpha]_D + 6.43^\circ$ .

\* In every case, unless otherwise specified,  $\alpha_D$  was determined in a 2 dm. tube.

0.5480, made up to 25 c.c. with benzene, gave  $\alpha_D + 0.21^\circ$ , whence  $[\alpha]_D + 4.79^\circ$ .

Some of the compound was distilled in steam, and its specific rotation taken as soon as its weight had become constant in a desiccator.

0.3775, made up to 25 c.c. with benzene, gave  $\alpha_D + 0.15^\circ$  as a mean of six concordant readings, whence  $[\alpha]_D + 4.96^\circ$ .

*Bornylcarbimide*,  $C_{10}H_{17}\cdot N:CO$ .

For the preparation of this compound, the pure ethyl bornylcarbamate is finely ground and distilled under reduced pressure in portions of three grams with twice its weight of phosphoric oxide. The slightly yellow distillate obtained after two fractionations boils at  $114-116^\circ$  under 14 mm. pressure, and on cooling solidifies to a soft, white, crystalline paste, the yield being about 70 per cent. The substance is very volatile, and has a characteristic odour, its solution in ether being particularly pungent. When dried on a porous plate, it melts at  $69^\circ$ . It is volatile in steam, and when warmed for some time with aqueous ammonia yields bornylcarbamide, melting at  $174^\circ$  (Forster gives  $175^\circ$ , *loc. cit.*).

0.1506 gave 10.6 c.c. moist nitrogen at  $21^\circ$  and 760 mm.  $N = 8.00$ .

$C_{11}H_{17}ON$  requires  $N = 7.82$  per cent.

0.2900, made up to 25 c.c. with benzene, gave  $\alpha_D + 1.14^\circ$  ( $c = 4.5$ ), whence  $[\alpha]_D + 49.14$ ; Forster and Attwell (*Proc.*, 1904, 20, 91) give  $[\alpha]_D + 46.5^\circ$ , where  $c = 2$ .

Several attempts to induce the polymerisation of the compound to the corresponding isocyanurate led to no definite result.

*Dibornylcarbamide*,  $OC:(NH\cdot C_{10}H_{17})_2$ .

When bornylcarbimide is heated with water in a rellux apparatus for several hours, carbon dioxide is evolved and the oil gradually solidifies; the latter is then collected and crystallised from aqueous alcohol. If the solution is allowed to evaporate slowly, the substance crystallises in lustrous needles often several centimetres in length; it is insoluble in water, benzene, or acetone, fairly so in ether, chloroform or in hot alcohol. It is volatile in steam, and does not melt below  $290^\circ$ , but can be sublimed at a slightly higher temperature, forming small, lustrous needles.

0.1707 gave 12.8 c.c. moist nitrogen at  $17^\circ$  and 742 mm.  $N = 8.49$ .

$C_{21}H_{36}ON_2$  requires  $N = 8.43$  per cent.

0.2724, made up to 25 c.c. with chloroform, gave  $\alpha_D + 0.35^\circ$  in a 1 dm. tube; whence  $[\alpha]_D + 32.12^\circ$ .

The neobornylamine hydrochloride was similarly treated in order to ascertain if the formation of the corresponding carbimide would facilitate the isolation of pure neo-derivatives, since there is a possibility that the neobornylamine obtained by Forster contains another isomeride, also produced in the reduction of camphoroxime.

*Ethyl Neobornylcarbamate*,  $C_{10}H_{17}\cdot NH\cdot CO_2\cdot C_2H_5$ .

The neobornylamine hydrochloride obtained in the manner indicated was treated in an exactly similar manner to the bornyl compound.

The carbamate thus produced is a white substance, which takes much longer to solidify than its isomeride; it is soluble in all organic solvents, but insoluble in water; it melts at  $36^\circ$ .

0.2419 gave 14.4 c.c. moist nitrogen at  $21^\circ$  and 758 mm.  $N = 6.75$ .

$C_{13}H_{23}O_2N$  requires  $N = 6.22$  per cent.

0.5189, made up to 25 c.c. with benzene, gave  $\alpha_D - 0.40^\circ$ ; whence  $[\alpha]_D - 9.63^\circ$ .

*Neobornylcarbimide* (?).

When the foregoing carbamate is distilled with phosphoric oxide, it yields an oil which is apparently a mixture, as it deposits a crystalline solid having  $[\alpha]_D - 13.4^\circ$ , whilst the mother liquor has  $[\alpha]_D - 1.1^\circ$ . These results seem to indicate a method of obtaining pure neobornyl derivatives, but this portion of the investigation has not been carried further.

*l-Menthylamine Derivatives*.\*

*l-Menthylcarbimide*,  $C_{10}H_{19}\cdot N\cdot CO$ .

Recrystallised menthoneoxime (from Kahlbaum's menthone,  $[\alpha]_D$  about  $-27^\circ$ ) is reduced in the usual manner with sodium and ethyl alcohol. The menthylamine (1 mol.) is dissolved in light petroleum in which an excess of sodium hydrogen carbonate is suspended, and heated in a reflux apparatus for  $1\frac{1}{2}$  hours with a solution of ethyl chlorocarbonate (1 mol.) in light petroleum, the product being worked up in the manner described under ethyl bornylcarbamate. The ethyl menthylcarbamate thus obtained melts at  $54-59^\circ$ , and various preparations dissolved in chloroform had  $[\alpha]_D$  ranging from  $-64.6^\circ$  to  $-68.9^\circ$ . The crude carbamate was distilled under reduced pressure in portions of three grams with  $1\frac{1}{2}$  times its weight of phosphoric oxide. The distillate is colourless and comes over from  $90-160^\circ$ , when the pressure varies from 20 to 40 mm. Various portions of the dis-

\* The term "*l*-menthylamine" is used for the pure *l*-menthylamine described by Tutin and Kipping (*loc. cit.*), and not for the mixture previously described in the literature under this name.

tillate vary in viscosity and in specific rotation. When fractionated under 10—13 mm. pressure, the greater portion distils at 108—110°. After three distillations, a product is obtained with a constant rotation and boiling point; this compound should be stored in sealed tubes.

The pure *l*-menthylcarbimide is a colourless, refractive, mobile liquid with a characteristic odour and the properties common to carbimides.

0.1822 gave 12.6 c.c. moist nitrogen at 16° and 742 mm.  $N = 7.87$ .

$C_{11}H_{19}ON$  requires  $N = 7.73$  per cent.

0.5544, made up to 25 c.c. with benzene, gave  $\alpha_D - 2.43^\circ$ ; whence  $[\alpha]_D - 54.79^\circ$ .

0.5548, made up to 25 c.c. with benzene, gave  $\alpha_D - 2.44^\circ$ ; whence  $[\alpha]_D - 54.97^\circ$ .

The ethyl-alcoholic solutions, when freshly prepared, gave the following values of  $[\alpha]_D$ :  $-53.83^\circ$  ( $t = 24.5^\circ$ ),  $-52.37^\circ$  ( $t = 33^\circ$ ),  $-51.71^\circ$  ( $t = 38^\circ$ ),  $-51.02^\circ$  ( $t = 50^\circ$ ).

Attempts to induce the polymerisation of the carbimide were not successful.

*Methyl l-Menthylcarbamate*,  $C_{10}H_{19} \cdot NH \cdot CO_2 \cdot CH_3$ .

This compound is easily obtained when the carbimide is heated in a reflux apparatus with an excess of methyl alcohol. After evaporating off the excess of alcohol, the residual oil soon solidifies, and is crystallised from light petroleum in long, lustrous needles. It melts at 53° and is soluble in the ordinary organic solvents.

0.1764 gave 10.6 c.c. moist nitrogen at 17° and 748 mm.  $N = 6.86$ .

$C_{12}H_{23}O_2N$  requires 6.57 per cent.

0.7840, made up to 25 c.c. with chloroform, gave  $\alpha_D - 2.33^\circ$  in a 1 dm. tube; whence  $[\alpha]_D^{16^\circ} - 74.29^\circ$ .

0.6996, made up to 25 c.c. with methyl alcohol, gave  $\alpha_D - 2.13^\circ$  in a 1 dm. tube; whence  $[\alpha]_D^{16^\circ} - 76.11^\circ$ .

*Ethyl l-Menthylcarbamate*,  $C_{10}H_{19} \cdot NH \cdot CO_2 \cdot C_2H_5$ .

The ethyl ester is prepared in exactly the same manner as the preceding compound. If molecular proportions of the carbimide and ethyl alcohol are left in a sealed tube for some weeks, hard, prismatic crystals gradually separate which, after crystallisation from aqueous alcohol, melt at 59°. This ester is volatile in steam and soluble in the ordinary organic solvents.

0.1043 gave 5.8 c.c. moist nitrogen at 18° and 752 mm.  $N = 6.35$ .

$C_{13}H_{25}O_2N$  requires  $N = 6.17$  per cent.

0.5131, made up to 25 c.c. with chloroform, gave  $\alpha_D - 2.85^\circ$ ; whence  $[\alpha]_D^{21} - 69.43^\circ$ .

0.5843, made up to 25 c.c. with ethyl alcohol, gave  $\alpha_D - 3.15^\circ$ ; whence  $[\alpha]_D - 67.39^\circ$ .

*Propyl l-Menthylcarbamate*,  $C_{10}H_{19} \cdot NH \cdot CO_2 \cdot C_3H_7$ .

This compound, which is obtained like the other esters, which it closely resembles, crystallises from petroleum in needles melting at  $57^\circ$ .

0.2013 gave 10.8 c.c. moist nitrogen at  $18^\circ$  and 750 mm.  $N = 6.11$ .  
 $C_{14}H_{27}O_2N$  requires  $N = 5.80$  per cent.

0.5889, made up to 25 c.c. with chloroform, gave  $\alpha_D - 3.23^\circ$ ; whence  $[\alpha]_D - 68.56^\circ$ .

0.5215, made up to 25 c.c. with propyl alcohol, gave  $\alpha_D - 2.82^\circ$ ; whence  $[\alpha]_D - 67.59^\circ$ .

*Di-l-menthylcarbamide*,  $OC \cdot (NH \cdot C_{10}H_{19})_2$ .

When *l*-menthylcarbimide is heated in a reflux apparatus with water, the oil gradually becomes pasty and then solid. The product can be crystallised from aqueous ethyl alcohol in long, stout needles which melt at  $258^\circ$ ; it is insoluble in water, fairly soluble in alcohol or ether, and readily so in chloroform or pyridine.

0.1392 gave 0.3805  $CO_2$  and 0.1482  $H_2O$ .  $C = 74.6$ ;  $H = 11.8$ .  
 $C_{21}H_{40}ON_2$  requires  $C = 75.0$ ;  $H = 11.9$  per cent.

0.4128, made up to 25 c.c. with ethyl alcohol, gave  $\alpha_D - 3.03^\circ$ ; whence  $[\alpha]_D - 91.75^\circ$ .

0.4595, made up to 25 c.c. with moist pyridine, gave  $\alpha_D - 3.41^\circ$ ; whence  $[\alpha]_D - 92.76^\circ$ .

TECHNICAL SCHOOL,  
 BLACKBURN.

LXXI.—*Hydrocellulose.*

By CHARLES FREDERICK CROSS and EDWARD JOHN BEVAN.

THE recent contribution of A. L. Stern (this vol., pp. 336—340) bearing the title "The so-called hydrocellulose" is based on experimental matter of obvious value, which may be taken as being beyond criticism, but the author's interpretations appear to us to be somewhat at variance with accepted facts and liable to misconstruction.

This appears in the title itself, which must be read in the light of the context supplied by one of the concluding paragraphs, where the author says :

"It is evident . . . that when cellulose is exposed to the action of hot dilute acids there is no formation of hydrocellulose . . . . The cellulose residue . . . . does not differ in elementary composition from the original, but has been converted into a fine powder . . . . A microscopic examination . . . . shows that the disintegration is due to the fact that certain portions of the fibres are more easily attacked than others, and when these portions are converted into soluble products the whole fibre falls to pieces."

We do not propose to discuss these statements in detail, but with all possible brevity to emphasise some antecedent facts, which, although of critical importance in this connection, have apparently been overlooked.

(1) The author's criticisms of the work of A. Girard are scarcely justified, because the three methods for the production of the typical hydrocelluloses carefully described by the French chemist (*Memoire sur l'Hydrocellulose et ses derivees*, Paris, 1881) are in no case followed.

(2) The question as between an empirical formula  $C_{12}H_{20}O_{10}$  or  $C_{12}H_{22}O_{11}$  for the products described by Girard as the typical hydrocelluloses is therefore not raised by the fact that the author has obtained, under other conditions, residues which have the empirical composition  $C_{12}H_{20}O_{10}$  of the original cellulose.

(3) On the other hand, we submit that these residues are constitutionally different from the original celluloses. They are attacked by dilute alkaline solutions, are largely soluble in 15—20 per cent. caustic soda solutions, are oxidised by Fehling's solution, and generally show differences in the reactivity of the typical carbonyl and hydroxyl groups. Their behaviour towards nitric acid, acetic anhydride, and esterifying reagents generally differs from that of the original cellulose, and the properties of the corresponding derivatives are also different.

Girard studied this part of the subject in detail, in regard to the typical hydrocelluloses, and his results have been frequently confirmed.

(4) The main point which Stern appears to overlook is that structure in the celluloses is bound up with chemical composition and constitution. The structural properties of cellulose and hydrocellulose persist in their esters, and also through a cycle of reactions such as is involved in the conversion into xanthate and the regeneration of the cellulose (or hydrocellulose) from this condition of combination.

This very important point has closely engaged the attention of investigators, and considerable positive evidence has already been accumulated showing that the structural properties of cellulose are a function of the actual molecular aggregate taken in the chemical sense.

Incidentally we would emphasise this point, that it is at present easily open to chemists to settle any question as to chemical changes in cellulose, independently of structure, by operating on the homogeneous, structureless forms of this compound now available.

Without extending our criticism to lesser details, we conclude that the sub-group connoted by the term "hydrocellulose" remains unaffected by Stern's investigations save as regards his useful contribution of new matter.

Finally, in order to illustrate the actual state of our knowledge of the sub-group in question, we may point out:

That the normal cellulose (anhydride) is chemically labile, as it is a structurally plastic aggregate, occupying a middle position between the two extremes, determined by treatment (*a*) with alkali hydroxides, (*b*) with halogen hydracids, both in presence of water.

These extremes are both chemical and structural; under (*a*), the carbonyl groups show no reactivity and may be assumed to occupy a ketonic or cyclo-ketonic position in the aggregate: under (*b*), they become distinctly aldehydic, and in fact the aggregate is partly resolved with the production of free aldoses.

Structurally, the maximum of integration is attained under (*a*), whilst the maximum of disintegration is reached under (*b*).

This very wide range of variation falls mainly within the limits of hydroxyl reactions; the direct effects produced are those of hydration and hydrolysis, with the complementary phenomena of reversion.

In the case of the alkali hydroxides, the reactions, including the phenomena of "mercerisation" are chiefly those of hydration, some hydrolysis probably accompanying the effects, but without resolution of the cellulose to soluble forms, at least in the case of the normal cotton cellulose.

With acids, it appears that the hydrolysis which occurs and which, in fact, proceeds to the extreme limits—since the cellulose is partly resolved into the simple aldose—is accompanied by effects of reversion. The substances described by Stern have the character of reverted products.

In either case, it is obvious that the empirical composition of a final

residue throws but little light on the changes it may have undergone. In many such reactions, the alterations in composition are fractional, but it is none the less evident that profound constitutional changes occur.

A terminology for the brief expression of these classified effects must for the present remain on a conventional basis.

It would be convenient to retain the terms which have hitherto been current, namely, hydracellulose and hydrocellulose. The former might be limited to the products of the action of alkalis on cellulose, which are certainly hydrates; hydrocellulose, on the other hand, might be applied to the products of acid reactions, which are certainly hydrolysed, although in many cases showing the empirical composition of the original anhydride.

The latter have many properties in common with the "hemicelluloses," a term which is useful in designating a group of natural, mostly cellular, celluloses, which are distinct from the fibrous celluloses in chemical constitution as well as in structure and function in plant life ("*Cellulose*," Cross and Bevan, p. 87). This term might be very well extended to include the hydrocelluloses, if the suppression of the latter designation be considered advisable.

Whatever terminology may be finally adopted, it is important that in the meantime the empirical facts should be kept clearly expressed, and our purpose in this contribution is to prevent the confusion of issues which is likely to result from the theoretical views set forth in the paper now under discussion.

---

## LXXII.—*The Slow Combustion of Ethane.*

By WILLIAM ARTHUR BONE and WILLIAM ERNEST STOCKINGS.

THE present paper contains some further results of the investigation of the slow combustion of hydrocarbons, at temperatures below their ignition points, initiated by one of us in conjunction with Mr. Wheeler (Trans., 1902, 81, 536; 1903, 83, 1074). The experimental part comprises three sections dealing respectively with: (1) the interaction of ethane and oxygen at 250–400°, under pressures of 1.75 to 2.33 atmospheres, in borosilicate glass bulbs; (2) the oxidation of ethane at 400–500°, under reduced pressure, in our "circulation apparatus"; and (3) the slow combustion of ethyl alcohol and acetaldehyde.

As will be readily understood, the case of ethane has proved more complex than that of methane; this is partly due to the greater

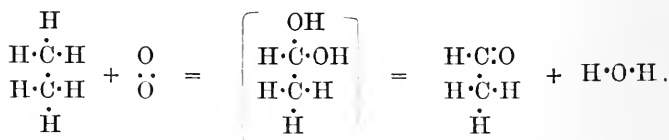

number of stages involved in the combustion of ethane, and partly also to the disturbing influences of secondary processes which were entirely absent in the methane experiments. The precise significance of the various phenomena under discussion, in relation to the general question of the combustion of hydrocarbons, can perhaps only be correctly gauged after a careful perusal of the evidence contained in our account of the actual experiments, but it may assist the reader if we now summarise our main conclusions.

(1) Under similar conditions, ethane burns much more rapidly than methane, and in borosilicate glass bulbs both hydrocarbons are oxidised at temperatures much below the limiting temperature (about  $400^{\circ}$ ) at which, under similar conditions, steam is appreciably formed from electrolytic gas.

(2) When ethane reacts with a quantity of oxygen insufficient to burn the whole of it to carbon monoxide and steam, there is no preferential combustion either of hydrogen or of carbon. In the absence of the disturbing effects of secondary processes, the interaction is always marked by a diminution in the pressure of the cold products, without any deposition of carbon or liberation of hydrogen.

(3) On the other hand, the combustion proceeds in several well-defined stages, during which the oxygen enters into, and is incorporated with the hydrocarbon molecule forming oxygenated intermediate products.

(4) The first stage we have been able to distinguish in the process involves the rapid formation of acetaldehyde and steam. It may perhaps be best represented as a process of hydroxylation, followed by the immediate decomposition of the unstable hydroxylated product, thus:

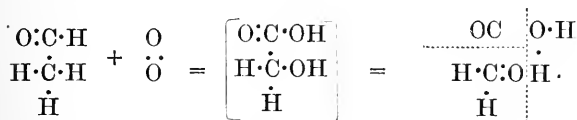

There is no direct evidence of the primary formation of any ethyl alcohol in our experiments such as would be required by the general theory of combustion recently advanced by Professor Armstrong (*Trans.*, 1903, 83, 1088). But as we find that ethyl alcohol is, under similar conditions, oxidised far more rapidly than ethane itself, we cannot attach any significance to its non-occurrence among the oxidation products of ethane.\* In this connection we would remark

\* Since the above was written, however, one of us, in conjunction with Dr. Julien Drugman, has detected ethyl alcohol among the products of the interaction of ethane and ozone at  $100^{\circ}$  (*Proc.*, 1904, 20, 127). It is therefore highly probable that ethyl alcohol is really the primary oxidation product.

that, whilst the proportions of ethane and oxygen most favourable to chemical change appear to be 1 : 1, that is, equimolecular, interaction takes place nearly as rapidly in mixtures of 2 volumes of ethane to 1 volume of oxygen.

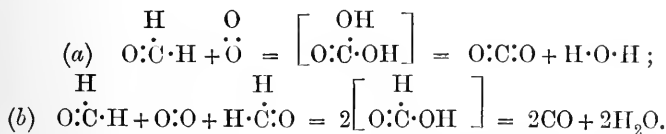

(5) The second stage, which is also a very rapid one, involves the breaking down of the original hydrocarbon structure,  $\cdot\dot{\text{C}}\cdot\dot{\text{C}}\cdot$ , and the formation of formaldehyde, carbon monoxide, and steam.

This stage may also conceivably be regarded as a process of hydroxylation, if we assume the intermediate formation of glycollic acid which immediately decomposes, thus :

That this is a very prominent stage in the sequence of the oxidation phenomena is proved by our circulation experiments. In one of these experiments (No. 5, page 720) as much as 80 per cent., and in another (No. 2, page 717) over 90 per cent., of the ethane burnt appeared in the final products as formaldehyde, carbon monoxide (or its oxidation product, carbon dioxide), and steam.

(6) The formaldehyde finally undergoes further oxidation to carbon monoxide, carbon dioxide, and steam, probably as the result of two simultaneous reactions, namely :

There was certainly some evidence of the intermediate formation of formic acid in our experiments.

This third stage appears to be somewhat slower than the two preceding stages, a circumstance which, under suitable conditions, leads to a considerable accumulation of aldehyde vapours during an experiment.

(7) Hydrogen, or methane, or both, may appear in the products, without any carbon being liberated, as the result of the purely thermal decomposition of formaldehyde and acetaldehyde vapours respectively, more particularly when there is a large accumulation of these during an experiment. Under the conditions of our bulb experiments, we have proved that acetaldehyde does decompose in accordance with the equation  $\text{CH}_3\cdot\text{CHO} = \text{CH}_4 + \text{CO}$ . Formaldehyde also yields hydrogen and carbon monoxide, although its decomposition is a more complex process than that of acetaldehyde.

(8) A little ethylene and hydrogen may appear in the products as the result of the purely thermal decomposition of ethane itself:

(9) Carbon is not liberated below the ignition points of the reacting mixtures. If, however, the experimental conditions are such that the heat liberated during the initial stages of oxidation is sufficient to raise the temperature of the reacting gases to the ignition point, an explosion occurs, during which the excess of hydrocarbon, and probably also aldehyde vapours, are decomposed with liberation of carbon and hydrogen, together with some acetylene and ethylene.

(10) The view taken of the mechanism of the combustion of ethane is supported by the experiments on the combustion of ethyl alcohol and acetaldehyde.

## EXPERIMENTAL.

### PART I.

*The Interaction of Ethane and Oxygen in Borosilicate Glass Bulbs at Temperatures between 250° and 400°.*

#### *Preparation and Composition of Original Mixtures.*

The ethane was prepared by the action of water on zinc ethide mixed with sand; the average yield was about 3 litres of gas from every 10 grams of ethide decomposed, and the purity of the gas is shown by the following explosion analysis:

					mm.
Gas taken...	...	...	...	27.8	} Total 545.2.
Oxygen and air added	...	...	...	517.4	
Ratio...	Diluents			= 3.4.*	
	Explosive mixture				
Contraction (C)	...	...	...	69.0	} C/A = 1.250.
Absorption (A)	...	...	...	55.2	
Therefore ethane = 27.6 = 99.3 per cent.					

The oxygen was obtained by heating recrystallised potassium permanganate. The mixtures of ethane and oxygen were made and stored in graduated glass holders over glycerin diluted with its own volume of water; both gases are practically insoluble in this liquid, and the composition of a particular gaseous mixture was not appreciably

\* We find it necessary in analysing ethane, or mixtures of ethane and oxygen, to dilute the explosive mixture,  $2\text{C}_2\text{H}_6 + 7\text{O}_2$ , with at least three times its own volume of excess of air or oxygen. Otherwise some of the hydrocarbon is decomposed by the shock of the explosion, carbon is deposited, and the ratio C/A may work out to 1.30, or even higher, instead of the theoretical 1.250.

altered even after prolonged contact with it. Usually, however, the mixtures were used for the experiments within 48 hours of their preparation. Most of our experiments were made with mixtures of equal volumes of the two gases, these proportions being, as we found, very favourable to rapid chemical change.

We also employed mixtures of ethane and oxygen in the ratios 2 : 1, 1 : 2, 1 : 3·5, and 1 : 3·75, and in one or two experiments we used mixtures of ethane and air. The amounts of adventitious nitrogen in our mixtures of ethane and oxygen were always very small, usually less than 0·5, and never more than 1·5 per cent. Following the rule adopted in previous papers, we propose to leave this nitrogen out of the reckoning altogether, and to express the compositions of the various gaseous mixtures, as well as pressure records, in terms of the nitrogen-free gas.\* The following table gives the exact composition of the various nitrogen-free mixtures employed, as well as the ratio C/A obtained in the analysis of each by the explosion method. We should perhaps add that the oxygen was in each case determined by absorption with a freshly prepared and strongly alkaline solution of pyrogallol, in which we found ethane to be insoluble.

TABLE I.

Mixture.	A.	B.&C.	D.	E.	F.	G.	H.	K.	L.
Ethane .....	50·6	49·8	49·5	49·7	50·3	66·65	32·2	22·8	21·05
Oxygen .....	49·4	50·2	50·5	50·3	49·7	33·35	67·8	77·8	79·95
C/A .....	1·246	1·247 1·250	1·253	1·247 1·251	1·255	1·248	1·260		

*Analysis of the Gaseous Products of Reaction.*

The products of reaction usually contained carbon dioxide, carbon monoxide, unchanged ethane, and oxygen. Occasionally also small quantities of aldehyde vapours were present, as well as some methane and free hydrogen. We found that aldehyde vapours could be removed, without appreciably affecting the relative proportions of the other products, simply by exposing the gases to a thin layer of strong sulphuric acid for about five minutes.

The carbon dioxide, carbon monoxide, and oxygen were then re-

\* Since, in analysing the various mixtures, nitrogen was always estimated "by difference," after all other constituents had been determined, the percentage composition of our nitrogen-free gases will always add up to 100.

moved and estimated in the following order, namely: (1) carbon dioxide, by means of strong caustic potash solution; (2) oxygen, by means of freshly prepared and strongly alkaline pyrogallol solution; (3) carbon monoxide, by agitating for 5 minutes with a freshly prepared ammoniacal solution of cuprous chloride previously saturated with ethane; before the final remeasurement, the gas was exposed to a layer of dilute sulphuric acid.\* The residual gas was afterwards exploded with a large excess of oxygen and air, and the ratio C/A determined. A ratio higher than 1.255 was always taken as an indication of the presence of either methane or free hydrogen in the products. In such a case, a second explosion analysis of the residual gas was usually made after it had been exposed to the action of "oxidised" palladium sponge at 100°, in order to determine the relative proportions of methane and hydrogen present.

*The Bulb Experiments at 200° to 400°.*

The mixtures of ethane and oxygen were sealed up, at atmospheric temperatures and pressures, in cylindrical borosilicate glass bulbs which were afterwards kept at constant temperatures between 200° and 400°. At the commencement of the reaction the hot gases would, therefore, be under pressures varying between 1.75 and 2.33 atmospheres, according to the temperature of the bath. The only departure from the experimental procedure described in a previous paper (Trans., 1902, 81, 535) was the adoption of a more accurate method of estimating the contraction observed when the cooled bulbs were opened under mercury. After the gaseous products had been removed for analysis through a Töpler pump, the bulbs were rinsed out with 2 or 3 c.c. of distilled water, and the rinsings tested for aldehydes and acids with Schiff's reagent and litmus respectively.

In tabulating the results of the various experiments, we shall in each case give (1) the index letter of the mixture employed; (2) the temperature and pressure at which the bulbs were filled; (3) the duration of heating; (4) the corrected change in volume (in most cases a contraction) expressed as percentage of the original volume; (5) the

\* We adopted this method for estimating carbon monoxide after a series of trial experiments on the analysis of mixtures of the monoxide and ethane in known proportions. The solubility of ethane in an ammoniacal solution of cuprous chloride, although very small, is quite appreciable.

No acetylene was ever detected in the products, except in one or two of the bulb experiments where the original mixtures of ethane and oxygen exploded. On the other hand, the products occasionally contained a small amount of ethylene, which would, of course, be removed along with the carbon monoxide by the ammoniacal cuprous chloride solution. The separate estimation of the two gases was always made in a special independent analysis.

composition of the nitrogen-free gaseous products; (6) the ratio C/A found in the explosion analysis of the residual gas after removal of carbon monoxide, carbon dioxide, and oxygen; (7) the ratio  $\text{CO}/\text{CO}_2$  in the gaseous products.

*Experiments at 200° and 225°.*

Four out of six bulbs filled with mixture D ( $\text{C}_2\text{H}_6 = 49.5$ ;  $\text{O}_2 = 50.5$ ) were kept at 200–205° for 9 days; there was no appreciable change in any one of them. The other two bulbs were then kept at 225° for a week; the formation of water was observed in one of them after four days, and in the other at the end of the experiment. The nitrogen-free gaseous products from the first bulb contained  $\text{CO}_2 = 1.5$ ,  $\text{CO} = 2.8$ ,  $\text{C}_2\text{H}_6 = 47.7$ , and  $\text{O}_2 = 48$  per cent., but no hydrogen.\*

*Experiments at 250°.*

At this temperature, no change was observed in the case of three bulbs containing a mixture of 2 volumes of ethane with 1 volume of oxygen after 48 hours. When, however, the gases were mixed in equimolecular proportions, they reacted with fair velocity, which varied considerably with the 'surface factor' of each bulb. In one out of five bulbs (No. 1, Table III) it will be seen that the whole of the oxygen disappeared within 17 hours, and in another (No. 5) after 48 hours. The reaction was characterised by the continuous formation of steam, and also of aldehydes, as was evident when we applied Schiff's test to the rinsings from the bulbs at the conclusion of each experiment. In no case was there any deposition of carbon, or liberation of hydrogen, but in all cases the cooled products showed a large contraction in volume when the bulbs were open under mercury. In bulbs Nos. 1 and 5, about 56 per cent. of the original ethane remained intact at the end of the reaction.

\* The lowest temperature at which any change could be detected in mixtures of methane and oxygen, similarly heated in borosilicate glass bulbs, was 300°, and even then the heating had to be continued for two or three weeks (Trans., 1902, 81, 546). Further, the limiting temperature at which steam is appreciably formed from electrolytic gas under similar conditions is about 400°.

TABLE II.

Bulbs 1 and 2 were originally filled with mixture B at 10° and 765 mm.  
 „ 3, 4, and 5 „ „ „ C „ 13° and 755 „

CO/CO <sub>2</sub> .....	2.60	2.23	1.97	2.19	2.08

\* The formation of condensable intermediate products is proved by the magnitude of the contractions observed in bulbs 1 and 5. For combustion to CO, CO<sub>2</sub>, and H<sub>2</sub>O only, these contractions would have been 31.7 and 31.9 per cent. respectively.

There was no acetylene in the gaseous products, but, in the case of one or two of the bulbs, possibly a small amount of ethylene (under 1 per cent.) was present; this would be included in the figures for CO.

Since it has been shown that no change occurs when the following pairs of gases are kept at 250°, or even at much higher temperatures, in borosilicate glass bulbs for very long periods of time (Trans., 1902, 81, 538—593), namely, (a) hydrogen and oxygen (electrolytic gas), (b) methane and oxygen, (c) moist carbon monoxide and oxygen, it may be concluded from the foregoing experiments:

(I) That in the primary oxidation of ethane there is no selective combustion either of carbon or of hydrogen.

(II) That no methane is liberated during the breaking down of the ethane molecule as the result of oxidation pure and simple. This, in view of some later results, is an important point.

(III) That the large quantity of carbon dioxide in the gaseous products did not arise from the secondary oxidation of carbon monoxide.

*Experiments at 300°.*

A large number of experiments were made at this temperature with mixtures in which the proportions of ethane and oxygen were varied between 2:1 and 1:3.75, and the results are extremely interesting from the point of view adopted in this paper as to the course of the oxidation. A significant feature was the surprisingly rapid oxidation always observed with the mixtures containing ethane and oxygen in the ratio 2:1 or 1:1, as compared with the much slower ratio exhibited by other mixtures containing higher proportions of oxygen.

*(1) With Mixtures of 2 Volumes of Ethane and 1 Volume of Oxygen.*

(a) Two bulbs, filled with mixture G at 18° and 760 mm., were maintained at 300° for 30 minutes. On cooling, water condensed on the inner surfaces, and soon afterwards minute oily particles appeared, due, as we afterwards found, to a rapid polymerisation of aldehyde vapours. No carbon separated. The contractions observed when the bulbs were opened under mercury were 23.6 and 29.3 per cent. respectively. The products contained hydrogen, and probably also some methane. The analytical results are shown in Table III (bulbs Nos. 6 and 7).

(b) In a second experiment, two bulbs, originally filled at 15° and 746 mm. with mixture G, were kept at 300° for 45 minutes. The appearance of the cooled bulbs was much the same as in the previous experiment, except that no separation of oily particles was observed. On opening the bulbs under mercury, we were surprised to find no contraction in volume; if anything, the gaseous products were under slight pressure. There was, however, an overpowering odour of aldehyde vapours, some of these polymerised in the connections of the Töpler pump when the gases were withdrawn from the bulbs for analysis. The rinsings from the bulbs gave a strong aldehydic reaction, but we were unable to detect any ethyl alcohol in them.

Analyses of the gaseous products, after the removal of aldehyde vapours, showed the entire absence of oxygen, and a very high ratio  $\text{CO}/\text{CO}_2$ . The ratios C/A obtained for the 'residual gas' in each case (1.616 and 1.650 resp.) indicated the presence of hydrogen, or methane, or both. On again analysing the gas after removal of hydrogen by means of oxidised palladium sponge at 100°, the ratio C/A fell to 1.343. Details of this experiment (bulbs 8 and 9) are given in Table III.

TABLE III.

	Methane .....	—	—	10·20	10·10
	Hydrogen .....	—	—	15·20	16·60
C/A for 'residual gas'.....		1·341	1·298	1·616	1·650
CO/CO <sub>2</sub> .....		4·36	4·15	19·0	14·0

The salient features of these experiments are (1) the very large formation of aldehydes (which in the case of bulbs 6 and 7 polymerised when the hot products were cooled), and (2) in the case of bulbs 8 and 9, the marked production of methane and hydrogen, accompanied as it was by an extraordinarily high ratio CO/CO<sub>2</sub>. This formation of methane and hydrogen cannot, as the experiments at 250° prove, be regarded as the result of the primary oxidation of the ethane; it is undoubtedly a secondary effect, connected, it would seem, with an excessive accumulation of aldehyde vapours during the experiment. It may, we think, be entirely ascribed to the purely thermal decomposition of acetaldehyde and formaldehyde vapours. We have proved that under the conditions of our bulb experiments at 300—400° acetaldehyde does undergo simple decomposition, at a moderate velocity, in accordance with the equation  $\text{CH}_3\cdot\text{CHO} = \text{CH}_4 + \text{CO}$ . The vapour of formaldehyde also, under similar conditions, decomposes, yielding carbon monoxide and hydrogen, but the process is not so simple as the case of acetaldehyde. As one of us is carrying out further experiments on the stabilities of these aldehydes at higher temperatures, we shall reserve details for a future communication.

(2) *With Mixtures of Equal Volumes of Ethane and Oxygen.*

In these experiments, the whole of the oxygen always disappeared within 30 to 45 minutes, and frequently even within 15 or 20 minutes, the

reaction being marked by the formation of aldehydes, steam, and carbon monoxide, together with smaller preparations of carbon dioxide. The ratio  $\text{CO}/\text{CO}_2$ , which for similar mixtures at  $250^\circ$  was 1.97 to 2.6 (see Table II), now rose to between 4 and 5. No carbon separated, neither was there any liberation of either hydrogen or methane; the rinsings from the bulbs always had a strong aldehydic reaction. More prolonged heating (see bulbs 12 and 13, Table IV) had little or no effect on the composition of the gaseous products; the ratio  $\text{C}/\text{A} = 1.260$  for the residual gas in the case of bulb 13 suggests the presence of a very small quantity of either hydrogen or methane.

TABLE IV.

Bulb No. * .....	10	11	12	13
Duration of heating.....	45 mins.	60 mins.	10½ hours.	23 hours.
Percentage contraction (corr.).....	37.6	38.6	36.8	34.4
Percentage composition of the nitrogen-free gaseous products. {

C/A for 'residual gas' .....	1.250	1.247	1.254 1.249	1.260
Ratio $\text{CO}/\text{CO}_2$ .....	4.1	4.1	4.9	4.73

\* The gases contained neither ethylene nor acetylene.

The percentage contraction for these bulbs would have been only about 31 had the hydrocarbon been burnt to  $\text{CO}$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  without the formation of intermediate condensable substances.

### (3) With Mixtures of 1 Volume of Ethane and 2 Volumes of Oxygen.

The rate of oxidation observed with these mixtures was on the whole distinctly less than in the experiments just recorded. In one experiment with five bulbs, two (Nos. 14 and 15, Table V) were removed from the air-oven after 90 minutes, the others were allowed to remain for  $16\frac{1}{2}$  hours longer.

Free oxygen still remained in the first two bulbs, but had practically all disappeared from the other three. In no case was carbon deposited or hydrogen liberated; there was an abundant formation of water,

carbon monoxide, and carbon dioxide. The rinsings from all the bulbs showed distinct aldehydic reactions.

The ratio C/A for the 'residual gas' after removal of carbon dioxide, oxygen, and carbon monoxide, was always found to be somewhat higher than 1.25, and was highest in the case of the bulb which had been heated longest. A second analysis of the 'residual gas,' after it had been exposed to the action of oxidised palladium sponge at 100°, gave ratio C/A not materially different from the corresponding values before treatment with palladium. We therefore concluded that the products contained small quantities of methane rather than hydrogen, and have interpreted the results accordingly. Probably this methane arose as the result of a purely thermal decomposition of acetaldehyde vapour.

The details for three of the above bulbs are given in Table V.

TABLE V.

Bulbs originally filled with mixture H at 12.5° and 733 mm.

Bulb No.....	14	15	16
Duration of heating .....	90 mins.	90 mins.	18 hours.

CO/CO <sub>2</sub> .....	2.75	2.35	2.10
The condensed water contained aldehydes.			

(3) *With Mixtures of 1 Volume of Ethane and 3½ Volumes of Oxygen.*

Although the mixture contained an amount of oxygen just sufficient to burn the hydrocarbon completely to steam and carbon dioxide, it is remarkable how very slowly, comparatively, the oxidation proceeded. We never, for example, detected any formation of

water within an hour, and even after two days a considerable quantity of oxygen, as well as some ethane, remained in the bulbs.

The results for two bulbs, originally filled with mixture K at 13° and 751 mm., are tabulated below.

TABLE VI.

No. of bulb .....	17	18
Duration of heating .....	17 hours.	48 hours.
Percentage contraction (corr.) .....	33·30	37·0
Percentage composition of the nitrogen-free gaseous products. {

Oxygen .....	41·40	37·50
Ethane .....	8·05	5·50
CO/CO <sub>2</sub> .....	2·16	1·74

The rinsings from these bulbs showed a faint aldehydic reaction with Schiff's reagent, and also it may be shown by calculation that the original ethane and oxygen are not wholly accounted for in the gaseous products.

(4) *With a Mixture of 1 Volume of Ethane with 3·75 Volumes of Oxygen.*

Two bulbs, filled at 13·3° and 760 mm. with mixture L (ethane = 21·05; oxygen = 78·95), were kept in the air-bath at 300° for eight consecutive days. The oxidation was very slow, but eventually all the ethane disappeared. Nearly a third of the original oxygen still remained at the end of the experiment, the ratio CO/CO<sub>2</sub> in the gaseous products being 1·28 and 1·31 respectively. The rinsings from the bulb gave a very faint aldehydic reaction. Details of the experiment are given below.

TABLE VII.

CO/CO <sub>2</sub> .....	1.31	1.28

*Experiments at 350° to 400°.*

These experiments are chiefly interesting in that they throw some light on the cause of the separation of carbon during the incomplete combustion of hydrocarbons.

(1) A series of six bulbs, filled under atmospheric pressure with mixture B ( $C_2H_6 = 49.8$ ;  $O_2 = 50.2$ ), were kept in the air-bath at 350° for 40 hours. On withdrawing them, we were somewhat surprised to find their inner surfaces covered with a thick deposit of finely-divided carbon. Some water condensed on cooling, and on opening the bulbs under mercury, we found their contents to be under considerable pressure (1000—1100 mm.). The gaseous products contained much carbon monoxide and hydrogen, as well as smaller quantities of unsaturated hydrocarbons (including some 0.1 to 0.2 per cent. of acetylene), methane, ethane, and carbon dioxide. The composition of the gaseous products from two of the bulbs is given below.

TABLE VIII.

Bulb No. ....	21. ....	22.
Carbon dioxide .....	4.80 .....	4.35
Carbon monoxide.....	33.55 .....	33.60
Unsaturated hydrocarbons	2.50 .....	1.90
Hydrogen.....	48.80 .....	50.80
Methane .....	8.75 .....	7.90
Ethane.....	1.60 .....	1.45

Evidently, therefore, either the primary oxidation of the ethane had taken a different course at 350° from that indicated by experiments

at lower temperatures, or new secondary factors were being brought into play.

(2) The true explanation became clear when the apparatus was so arranged that we could watch the bulbs during the whole time of heating. Bulbs containing mixture F ( $C_2H_6=50.3$ ;  $O_2=49.7$ ) were employed. A bulb was introduced into the bath at  $400^\circ$ ; the temperature in the vicinity of the bulb immediately sank to  $350^\circ$ , then began to rise rather quickly to about  $375^\circ$ , afterwards more slowly. Nothing in particular was observed for a time, but after about four or five minutes, a bright flash was seen, accompanied by a sharp click and the appearance of a thick cloud of solid carbon particles. The bulb was at once removed. On allowing it to cool, some water condensed, and on nipping off the sealed end of the capillary tube inside a rubber joint connected with a capillary manometer, we found the gases to be under 1290 mm. pressure. The gaseous products, which had much the same composition as those obtained in the previous experiment, are indicated in the following table.

TABLE IX.

*Bulb No. 23. Mixture F.*

	Per cent.		Per cent.
Carbon dioxide.....	3.8	Methane .....	5.0
Carbon monoxide .....	34.3	Ethane .....	0.9
Hydrogen .....	54.1	Oxygen .....	0.4
Unsaturated hydrocarbons	1.5		—
			100.0

The experiment was repeated several times with similar results, which suggested the following view. At temperatures between  $350^\circ$  and  $400^\circ$ , the velocity of the primary oxidation (or of the initial stages of oxidation) is so great that the mixture of ethane, aldehyde vapours, and oxygen, is locally heated to above its ignition point (which is probably higher than  $400^\circ$ ). The result is an explosion, during which ethane, and possibly also aldehydes, are thermally decomposed with liberation of carbon and hydrogen. If, therefore, the velocity of the initial stage, or stages, could be damped, either by admixture of inert gas, or by using a very slow bulb, the oxidation might proceed normally to its end, in which case there should be no liberation of carbon or hydrogen. This was proved in the following experiments.

(3) Three bulbs, one (No. 24) known to be a very slow one, the other two (Nos. 25 and 26) being quick ones, filled under atmospheric pressure with mixture F, were placed side by side in the same air-bath at  $375^\circ$ . The temperature in the vicinity of the bulbs at once fell to

350°, then steadily rose during the next 15 minutes to 375°. The heating was continued for an hour longer. In the case of bulbs Nos. 25 and 26, the gases had ignited, and No. 26 was smashed by the force of the explosion. The inner surface of No. 25 was covered with finely-divided carbon, and water condensed on cooling. The contained gases were under 1100 mm. pressure. In the case, however, of bulb No. 24, there had been no explosion, and consequently no deposition of carbon; on cooling it, water condensed on its inner surface, and on opening under mercury there was a contraction of 38.4 per cent. of the original volume. There was no hydrogen in the gaseous products, but the rinsings from the bulb contained aldehydes. Table X shows the details of this very suggestive experiment.

TABLE X.

Bulbs filled with mixture F at 15° and 750 mm.

Bulb No. ....	24	25	26
Percentage change in volume .....	- 38.0*	+ 46	
Percentage composition of the nitrogen-free gaseous products. {			
Carbon dioxide .....	8.15	4.75	Bulb smashed by the force of the explosion.
Carbon monoxide .....	52.35	33.30	
Ethane .....	39.50	1.35	
Hydrogen.....	nil.	50.90	
Methane .....	nil.	7.90	
Unsaturated hydrocarbons.....	nil.	1.80

Ratio CO/CO <sub>2</sub> .....	6.42		

\* For combustion to CO, CO<sub>2</sub>, and H<sub>2</sub>O only, without the formation of condensable intermediate products, this would only have been - 30.8.

(4) We now damped the velocity of oxidation by dilution with nitrogen. Two bulbs, Nos. 27 and 28, were filled with mixture B (ethane = 49.8; oxygen = 50.2) diluted with about 8 per cent. of nitrogen. Two other bulbs, Nos. 29 and 30, were filled with a special mixture of ethane and air containing C<sub>2</sub>H<sub>6</sub> = 16.95; O<sub>2</sub> = 17.40; and N<sub>2</sub> = 65.65 per cent. Bulb 27 was kept at 390—400° for an hour, and No. 28 at the same temperature for 18 hours. Bulbs Nos. 29 and 30 were kept at 380—390° for 24 hours. The oxidation proceeded normally in all cases; all the oxygen disappeared, water and aldehydes were formed, but there was

neither separation of carbon nor liberation of hydrogen. The details of the experiments with bulbs Nos. 27 and 29 are given below.

TABLE XI.

Bulb No. ....	27	29
Duration of heating .....	1 hour	24 hours
Percentage contraction (corr.) .....	35	15
Percentage composition of the gaseous products. {		
Carbon dioxide .....	7.20	5.90
Carbon monoxide .....	44.20	7.70
Oxygen .....	0.10	0.10
Ethane .....	36.10	11.50
Nitrogen .....	12.40	71.80
C/A for 'residual gas' .....	1.260	1.250
CO/CO <sub>2</sub> .....	6.14	1.30

We would draw attention to the ratios CO/CO<sub>2</sub> observed in these bulb experiments, the conditions of which precluded the possibility of the independent oxidation of carbon monoxide.

If we consider the experiments in which the combustion proceeded quite normally, that is to say without any secondary decompositions of aldehyde vapours or of the excess of hydrocarbon, we find that for one and the same original mixture of ethane and oxygen the ratio CO/CO<sub>2</sub> in the products is higher the higher the temperature, and therefore also the higher the velocity of the oxidation. Thus, for the original mixtures of equal volumes of ethane and oxygen, at 250° the ratio CO/CO<sub>2</sub> varied between 1.97 and 2.60; at 300°, between 4.1 and 4.9; and in each of the two bulbs at 350° it exceeded 6.0. These observations are quite consistent with the view of the oxidation stages set forth in the introduction of this paper, namely, that carbon monoxide arises in the second stage as the result of the oxidation of acetaldehyde,  $\text{CH}_3\cdot\text{CHO} + \text{O}_2 = \text{CH}_2\text{O} + \text{CO} + \text{H}_2\text{O}$ , as well as during the final oxidation of formaldehyde in the third stage, in which the two simultaneous reactions: (a)  $\text{CH}_2\text{O} + \text{O}_2 = \text{CO}_2 + \text{H}_2\text{O}$ , and (b)  $\text{CH}_2\text{O} + \text{O}_2 + \text{CH}_2\text{O} = 2\text{CO} + 2\text{H}_2\text{O}$ , are concerned.

Again, in the experiments at 300°, in which the proportions of ethane and oxygen in the mixtures employed varied between 2:1 and 1:3.75, the ratio CO/CO<sub>2</sub> in the products naturally decreased with

the higher proportions of oxygen originally present. But it is a significant fact, and one quite explained by our theory of the oxidation stages, that even when the oxygen in the original mixture was more than sufficient to burn all the ethane completely to carbon dioxide and steam, the ratio  $\text{CO}/\text{CO}_2$  in the products did not fall below 1.25.

PART II.—*Experiments with Mixtures of Ethane and Oxygen in the Circulation Apparatus.*

These experiments were undertaken primarily for the identification of the aldehydes, and possibly other condensable or soluble intermediate oxidation products, the formation of which had been proved in the bulb experiments. The circulation apparatus has already been fully described in a previous paper on methane (Trans., 1903, 83, 1074), and is here represented in Fig. 1. Since the experimental method with ethane was, in all essential respects, the same as with methane, we may at once proceed to the discussion of our new results. It was first of all necessary to ascertain whether ethane itself would undergo any change under our experimental conditions. Accordingly we circulated the pure gas in the apparatus for three consecutive days, the temperature of the combustion tube being kept at  $500^\circ$  throughout. A slight expansion (about 4 mm. on 500) was noticed and a subsequent analysis of the gas showed that it contained about 1 per cent. of ethylene and some hydrogen. Thus the values  $\text{C}/\text{A}$  obtained in two explosion analyses of the residual gas after removal of ethylene by means of fuming sulphuric acid were 1.267 and 1.266 respectively. There was no deposition of carbon on the white, porous porcelain with which the combustion tube was packed.

*Identification of Intermediate Products.*—Among the possible soluble and condensable products which could be caught up by the water in the worm E (Fig. 1) were ethyl alcohol, glycol, glyoxal, acet- and formaldehydes, acetic and formic acids. In all our experiments, the liquid had a strong aldehydic smell, reminiscent more of formaldehyde than of acetaldehyde; it reacted strongly with Schiff's reagent, and instantly reduced ammoniacal silver solutions. The liquid was usually quite neutral to litmus, although occasionally it had a distinct acid reaction, due to the presence of small quantities of formic acid, and possibly also of acetic acid. After dilution with an equal volume of water, it was submitted to the following tests.

(1) *The Iodoform Test.*—Ethyl alcohol or acetaldehyde would, of course, give this, but whereas the iodoform precipitated from a dilute acetaldehyde solution is always amorphous, that which separates from dilute solutions of ethyl alcohol is nearly always composed of the characteristic star-like, crystalline aggregates. Occasionally the liquid we

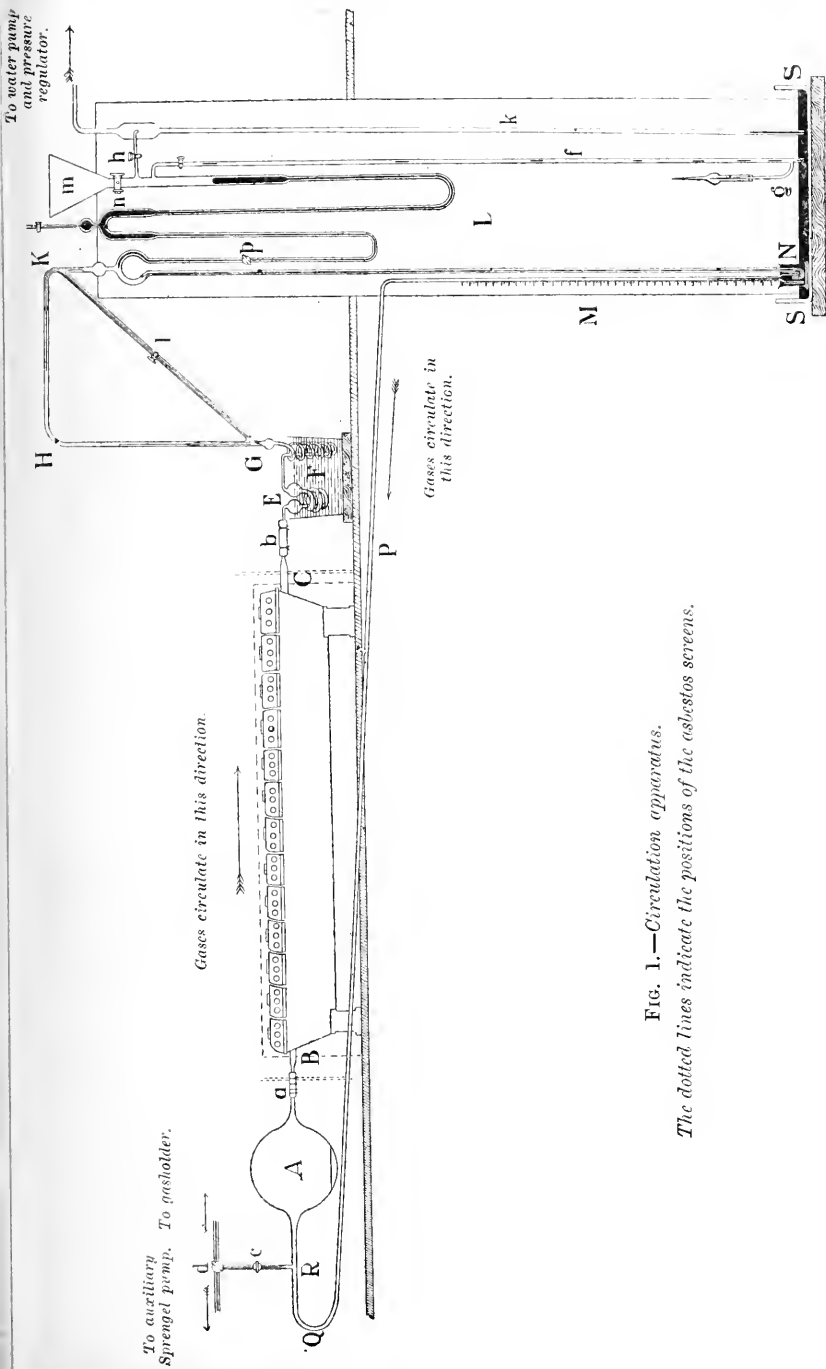

FIG. 1.—Circulation apparatus.

*The dotted lines indicate the positions of the asbestos screens.*

obtained gave amorphous iodoform, but we never got the least indication of a crystalline precipitate. When iodoform was obtained, we repeated the test with another portion of the liquid after it had remained in contact with dilute caustic soda, to polymerise the aldehydes, and subsequently distilled in steam. We never detected any ethyl alcohol in the distillate. In some cases we removed the aldehydes by careful oxidation, at the ordinary temperature, with a slight excess of an ammoniacal silver solution. The liquid was subsequently acidified with dilute sulphuric acid and distilled in steam, but alcohol was never detected in the distillates.

(2) *Reaction with an Acetic Acid Solution of p-Bromophenylhydrazine.*—The aldehydes present could generally be recognised by an examination of the resulting canary-yellow *p*-bromophenylhydrazones. In this way the presence of formaldehyde was always detected, and sometimes that of acetaldehyde also, but there was never the faintest sign of the separation of the deep-red *p*-bromohydrazone of glyoxal.

(3) *Reaction with Hydrogen Sulphide.*—The liquid, without any addition of hydrochloric acid, was saturated with hydrogen sulphide and the test-tube set aside in a warm place for several hours. By this means form- and acet-aldehydes may be distinguished with the greatest certainty (Proc., 1904, 20, 115). We invariably obtained the characteristic white flocculent precipitate of the thio-derivative of formaldehyde.

(4) In some cases, a portion of the liquid was slowly evaporated to dryness in a glass basin over a water-bath. There was never any indication of the separation of glyoxal during the process, or of any solid residue. Once or twice the faintest possible greasy film remained.

Briefly, then, the most prominent and constant intermediate product formed in these experiments was formaldehyde, which was frequently accompanied by smaller proportions of acetaldehyde and, in one or two cases, by traces of formic acid also. There was no direct evidence of the formation of any other intermediate substance such as ethyl alcohol, glycol, or glyoxal.

#### *Details of Experiments.*

Following the plan of our earlier paper on methane (*loc. cit.*, p. 1081—1087), we propose to give: (1) the pressure of the dry nitrogen-free mixture, at the temperature  $t^{\circ}$  of the room, introduced into the cold apparatus, (2) its pressure after the furnace had been lighted and the combustion tube raised to the experimental temperature,  $T^{\circ}$ , (3) the 'corrected' pressures of the dry nitrogen-free gases in the apparatus at successive regular intervals of time, (4) the pressure of the dry nitrogen-free products at the end of the experiment, after the furnace had been turned out and the apparatus

allowed to cool down to the temperature of the room, and (5) the composition of the gaseous products, together with the ratio  $C/A$ , obtained in the explosion analysis of the residual gas after removal of the oxides of carbon, oxygen, and any small amount of ethylene which might be present.

The gases were continuously circulated, day and night, over the hot surface of the porous porcelain in the combustion tube at a constant rate throughout each experiment. This rate was, of course, varied in different experiments, but it may be assumed that the time required for a complete circuit varied between 30 minutes and about 2 hours. This circumstance explains the different rates of oxidation observed with similar mixtures of ethane and oxygen.

The capacity of the whole apparatus was about 1500 c.c., that of the combustion tube was only 75 c.c. Since, however, the temperature of the combustion tube was  $450-500^{\circ}$ , whereas that of the rest of the apparatus was only  $20-25^{\circ}$ , it follows that not more than  $1/50$ th of the total gas in the apparatus was in the heated zone at any one time. But, further, since it has been proved during the research that chemical change is mainly, if not entirely, confined to the layer of gas immediately in contact with the porous surface, it follows that very much less than  $1/50$ th of the total gas was, at any one instant, actually in the sphere of reaction; at the very most not more than  $1/100$ th of the whole gas would be reacting at any given instant. Hence the rates observed in these experiments must be multiplied by at least 100 to give us even an approximate idea of the actual rates of change within the sphere of reaction. It must also be borne in mind that the conditions of these circulation experiments, unlike those of the bulb experiments, admit of the fairly rapid oxidation of free hydrogen as well as of carbon monoxide.

(1) *Experiment with Equal Volumes of Ethane and Oxygen at  $450^{\circ}$ .*

This experiment extended over 10 consecutive days, the speed of circulation was slow, the capillary tubes in GHK (Fig. 1) being in circuit throughout. Mixture E ( $C_2H_6 = 49.7$ ;  $O_2 = 50.3$ ) was used.

Pressure of cold dry nitrogen-free

original mixture at  $18.3^{\circ}$  ..... = 628.4 mm.

Pressure of cold dry nitrogen-free

final products at  $18.3^{\circ}$  ..... = 428.1 mm.

---

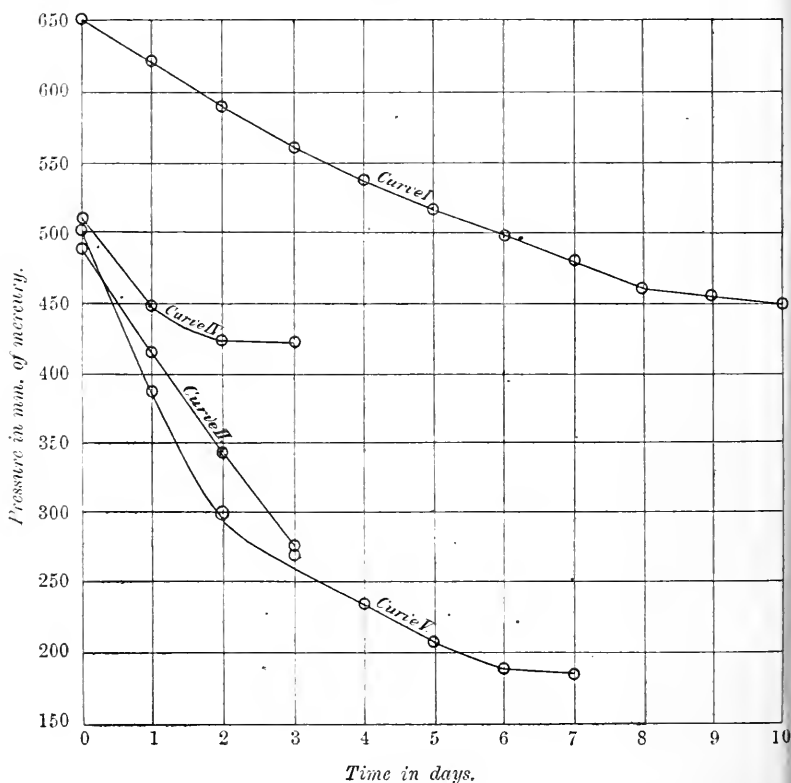

Total pressure fall = 200.3 mm. or 31.9 per cent.

The daily records were as follows :

Days.	Temperature of combustion tube $T^{\circ}$ .	Temperature of globe $t$ .	Corrected pressure of dry nitrogen-free gas.
0	450°	21°	651.3 mm.
1	452	22	622.6 „
2	460	20.8	590.0 „
3	450	20.8	561.2 „
4	447	17.7	538.8 „
5	449	19.0	516.2 „
6	451	19.3	498.7 „
7	440	19.6	480.8 „
8	446	20.0	460.8 „
9	455	18.7	455.1 „
10	450	18.0	449.3 „

The pressure curve for this experiment (Fig. 2, Curve I, ordinates = pressures, abscissæ = time in days) shows that the pressure fall was

FIG. 2.

very regular during the first 8 days, but slackened towards the end of the experiment.

There was no sign of any deposition of carbon on the white porous porcelain during the experiment; this remark applies also to all the other circulation experiments described. The gaseous products still contained some oxygen, considerable quantities of carbon monoxide and dioxide, as well as about 1 per cent. of ethylene and some hydrogen. The ratio C/A for the 'residual gas' was 1.30, which after treatment with palladium fell to 1.25. The mean of three concordant analyses gave the following as the percentage composition of the nitrogen-free gaseous products:

Carbon dioxide ...	19.90	Ethylene .....	1.00
Carbon monoxide..	24.45	Hydrogen.....	3.00
Oxygen .....	4.85	Ethane .....	46.80

The liquid in the worm had an aldehydic odour and reaction, but was quite neutral to litmus. It contained formaldehyde, some acetaldehyde, but no ethyl alcohol.

If we now compare the partial pressures of the ethane and oxygen in the original mixture with those of the various gaseous products at the end of the experiment, we obtain the following numbers:

*Original Mixture.*

Ethane.....	312.4 mm.	Oxygen.....	316.0 mm.
-------------	-----------	-------------	-----------

*Products.*

	mm.		mm.
Carbon dioxide.....	85.2	Ethane .....	200.4
Carbon monoxide.....	104.7	Ethylene .....	4.3
Oxygen.....	20.7	Hydrogen .....	12.8

The 4.3 mm. of ethylene probably arose from a thermal decomposition of a corresponding quantity of ethane; the 12.8 mm. of free hydrogen may be partly ascribed to the same cause, possibly also in part to the thermal decomposition of formaldehyde vapour. The above figures show that 107.7 mm. of ethane had reacted with 295.3 mm. of oxygen, yielding altogether 189.9 mm. of carbon monoxide and dioxide.

(2) *Experiment with Equal Volumes at 500°.*

For this, which, in respect to the amount of aldehydes removed from the sphere of action, is the most remarkable of all our experiments, mixture E ( $C_2H_6 = 49.7$ ;  $O_2 = 50.3$ ) was used.

Pressure of cold dry nitrogen-free

original mixture at 17.5° ..... = 467.6 mm.

Pressure of cold dry nitrogen-free

final products at 17.5°..... = 363.4 mm.

Fall = 204.2 mm., or 43.66 per cent.

The experiment extended over three consecutive days, the temperature of the combustion tube remaining very constant throughout. A rapid rate of circulation was kept up by throwing the capillary tubes in GHK (Fig. 1) out of circuit and allowing the Sprengel pump to work at full speed.

The daily records were as follows :—

Days.	Temperature of combustion tube.	Temperature of globe A.	Corrected pressure of dry nitrogen-free gas.
0 .....	500° .....	21.3° .....	490.7 mm.
1 .....	502 .....	20.8 .....	416.0
2 .....	500 .....	21.7 .....	344.3
3 .....	503 .....	21.5 .....	276.2

The pressure curve for this experiment (Fig. 2, Curve II) is an unbroken straight line.

The liquid in the worm had a distinctly acid reaction and a very strong aldehydic odour. It did not give the iodoform reaction, and therefore contained neither ethyl alcohol nor acetaldehyde. The *p*-bromophenyl-hydrazone prepared from it was identical with that of formaldehyde.

Besides carbon monoxide, carbon dioxide, and unchanged ethane, the gaseous products contained a considerable quantity of oxygen, some hydrogen, and ethylene. The ratio C/A for the residual gas was 1.269, and the percentage composition of the gaseous products was as follows :

	Per cent.		Per cent.
Carbon dioxide.....	20.96	Ethylene .....	2.75
Carbon monoxide ...	16.00	Hydrogen .....	1.30
Oxygen .....	8.00	Ethane.....	51.00

Comparing, again, the partial pressures of the original gases with those of the final products, we have :

*Original Mixture.*

Ethane..... 232.5 mm.      Oxygen..... 235.1 mm.

*Products.*

	mm.		mm.
Carbon monoxide .....	42.1	Ethylene .....	7.2
Carbon dioxide .....	55.2	Hydrogen .....	3.5
Oxygen .....	21.1	Ethane .....	134.4

These numbers show that whereas 90.7 mm. (that is, 232.5 *minus* 134.4 and 7.2) of ethane had been oxidised during the experiment, the sum of the pressures of carbon monoxide and dioxide in the products only amounted to 97.3 mm., a circumstance which points to a very large formation of formaldehyde according to the empirical equation :

Assuming this to have taken place, then, from the total ethane oxidised and the total oxides of carbon formed, we calculate that no less than 84.1 mm., or 92.7 per cent., of the ethane oxidised appeared in the products as formaldehyde, carbon monoxide (or dioxide), and steam, the remaining 6.6 mm. being completely oxidised to carbon dioxide and steam. Undoubtedly by far the greater part of the carbon dioxide produced in the experiment arose from the independent oxidation of carbon monoxide.

We will now show that the foregoing conclusion agrees very well with the amount of oxygen which actually disappeared during the experiment, namely 214 mm.

84.1 mm. $\text{C}_2\text{H}_6$ oxidised to $\text{CO} + \text{CH}_2\text{O} + 2\text{H}_2\text{O}$	
would require .....	168.2 mm. $\text{O}_2$ .
6.6 mm. $\text{C}_2\text{H}_6$ oxidised to $2\text{CO} + 3\text{H}_2\text{O}$	
would require .....	16.5 mm. „
55.2 mm. $\text{CO}$ oxidised to $\text{CO}_2$ would require ...	27.6 mm. „
	<hr/>
Total.....	212.3 mm.

### (3) *Experiment with Equal Volumes at 500°.*

This is interesting chiefly on account of the extremely rapid rate of oxidation observed, nearly the whole of the oxygen disappearing within 8 hours. Mixture D (ethane = 49.5 ; oxygen = 50.5) was used.

Pressure of cold dry nitrogen-free	
original mixture at 17.8° .....	= 434.6 mm.
Pressure of cold dry nitrogen-free	
final products at 17.8° .....	= 292.0 mm.
	<hr/>

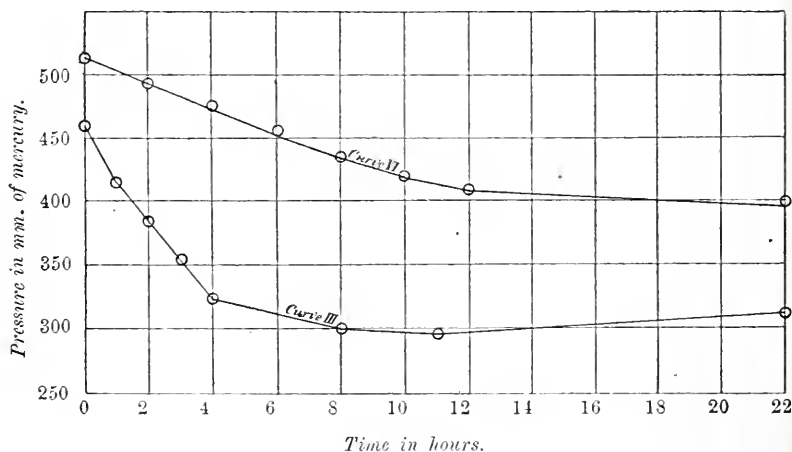

Pressure fall = 142.6 mm., or 32.8 per cent.

The pressure records were as follows :

Time in hours.	Temperature of combustion tube $T^{\circ}$ .	Temperature of the globe $t^{\circ}$ .	Corrected pressure of dry nitrogen-free gases.
0	510°	23.2°	460.3 mm
1	509	25.0	415.0
2	499	25.0	384.0
3	500	26.0	353.8 „
4	503	26.0	324.0 „
8	510	26.5	300.0 „
11	505	26.5	295.4 „
24	504	24.8	310.0 „

The pressure curve for this experiment is shown in Fig. 3, Curve III. It will be observed that a slight expansion occurred after the eleventh

FIG. 3.

hour, the pressure fall up to that time being 35.8 per cent. This expansion must be attributed to the decomposition of acetaldehyde vapour, for there was a considerable accumulation of aldehydes during the experiment, and the gaseous products contained an unusually large quantity of methane.

The liquid in the worm contained acetaldehyde and formaldehyde, but no ethyl alcohol or glyoxal.

The nitrogen-free products contained no free oxygen, and had the following composition:

	Per cent.		Per cent.
Carbon dioxide	35.1	Methane	8.8
Carbon monoxide	10.3	Hydrogen	1.8
Ethylene	2.2	Ethane	41.8

The ratio C/A for the residual gas, after removal of the oxides of carbon and ethylene, was 1.35, which after further treatment with oxidised palladium at 100° was reduced to 1.32.

(4) *Experiment with a Mixture of Ethane and Air at 500°.*

This experiment was performed in the hope that by largely diluting the reacting gases with nitrogen we might possibly detect the formation of ethyl alcohol, and also prevent any secondary decompositions of ethane and aldehyde vapours.

The mixture used contained ethane = 15.80 ; oxygen = 17.65 ; and nitrogen = 66.55 per cent. The experiment extended over three days, but the oxygen had practically all disappeared at the end of the second day.

Pressure of cold dry original mixture at 12.5°	=	467.2 mm.
"      "      "      final products      "      "	=	398.2 mm.
		Fall = 69.0 mm.

This pressure fall is 14.75 per cent., or approximately 44.5 per cent., of the pressure of the original nitrogen-free mixture. The daily records were as follows :

Days.	Temperature of combustion tube T°.	Temperature of globe t°.	Corrected pressure of dry gas at 25°.
0 .....	494° .....	22.0° .....	511.0 mm.
1 .....	500 .....	25.5 .....	449.0 "
2 .....	500 .....	25.0 .....	424.4 "
3 .....	500 .....	25.2 .....	423.4 "

The curve for this experiment is shown in Fig. 2, Curve IV.

The liquid in the worm contained acetaldehyde and formaldehyde, but no ethyl alcohol.

The gaseous products contained only carbon dioxide, carbon monoxide, unchanged ethane, and nitrogen. The ratio C/A for the residual gas was 1.249, showing the entire absence of free hydrogen or methane. Evidently, therefore, dilution with nitrogen had entirely prevented secondary decompositions of ethane and aldehydes. The percentage composition of the gaseous products was :

Carbon dioxide .....	7.00	Ethane .....	10.50
Carbon monoxide .....	4.10	Nitrogen ...	78.4

We calculate that in this experiment about 10 per cent. of the ethane changed appeared in the products as acetaldehyde and steam, 40 per cent. as formaldehyde, carbon monoxide (or dioxide), and steam and that the remainder had been completely burnt to carbon dioxide

and steam. Some of the carbon monoxide liberated in the formation of formaldehyde had undergone independent oxidation.

(5) *Experiment with Mixture of 1 Volume of Ethane to 2 Volumes of Oxygen at 500°.*

For this experiment, which extended over a week, mixture H ( $C_2H_6 = 32.2$ ;  $O_2 = 67.8$ ) was used. The speed of circulation was fairly rapid throughout.

Pressure of the cold dry nitrogen-free original mixture at 17°.....	= 468.9 mm.
Pressure of the cold dry nitrogen-free final products at 17° .....	= 176.8 mm.
	<hr/>
Fall =	292.1 mm.

This pressure fall is 62.3 per cent. of the original pressure. The curve for this experiment (Fig. 2, Curve V) indicates a fairly rapid oxidation during the first two days, followed by a much slower process. The portion of the curve for the latter part of the experiment resembles curves we have obtained for the oxidation of moist carbon monoxide, and it will be seen that carbon dioxide predominated in the gaseous products. The daily records were as follows:

Days.	Temperature of combustion tube $T^\circ$ .	Temperature of globe $t^\circ$ .	Corrected pressure of dry nitrogen-free gas.
0 .....	500° .....	18.5° .....	502.0 mm.
1 .....	499 .....	25.6 .....	387.4 „
2 .....	496 .....	26.8 .....	295.4 „
3 .....	496 .....	26.8 .....	269.9 „
4 .....	484 .....	27.5 .....	235.3 „
5 .....	494 .....	27.8 .....	207.4 „
6 .....	493 .....	27.3 .....	188.1 „
7 .....	487 .....	26.3 .....	185.7 „

The liquid in the worm had a slightly acid reaction; it contained a mere trace of acetaldehyde, but much formaldehyde. The gaseous products contained:

	Per cent.		Per cent.
Carbon dioxide.....	61.40	Ethane.....	13.40
Carbon monoxide.....	23.20	Ethylene ...	1.00
Oxygen.....	0.55	Hydrogen...	0.45

The ratio C/A for the 'residual gas' was 1.273.

Comparing now the partial pressures of the original mixture with those of the gaseous products as under:

*Original Mixture.*

Ethane..... 151.0 mm.      Oxygen..... 317.9 mm.

*Final Products.*

	mm.		mm.
Carbon dioxide.....	108.6	Ethane.....	23.70
Carbon monoxide.....	41.0	Ethylene ...	1.75
Oxygen .....	1.0	Hydrogen...	0.75

We find that whereas 125.5 mm. of ethane underwent oxidation during the experiment, the sum of the pressures of carbon monoxide and dioxide in the products amounted to 149.6 mm. only. We estimate that approximately 80 per cent. of the ethane oxidised appeared in the products as formaldehyde, carbon monoxide (or dioxide), and steam, the remainder being completely burnt to carbon dioxide and steam.

(6) *Experiments with Mixtures of 2 Volumes of Ethane to 1 Volume of Oxygen.*

Having failed to detect any ethyl alcohol among the products of the foregoing experiments, we proceeded to investigate the interaction of mixtures of ethane and oxygen in the ratio 2:1. Since rapid combination is the most favourable condition for the isolation of intermediate products, we circulated these mixtures at top speed, keeping the temperature of the combustion tube at 500°. Under these circumstances, nearly the whole of the oxygen disappeared within 12 hours, a rate hardly inferior to that observed under similar conditions with mixtures of equal volume (Expt. 3, page 717). We also tried experiments at lower temperatures (350° and 400°), but the rate of combination was much slower. In none of these experiments, however, were we able to detect any production of ethyl alcohol. As we need only give the details of one of these experiments, we will select a case in which the products were found to contain a fair quantity of hydrogen. Mixture G was used (ethane = 66.65; O<sub>2</sub> = 33.35), and pressure readings were made every two hours during the early part of the experiment.

Pressure of the cold dry nitrogen-free original mixture at 17°..... = 470.4 mm.

Pressure of the cold dry nitrogen-free final products at 17°..... = 370.0 mm.

---

Fall..... = 100.4 = 21.35 per cent.

The records were as follows :

Hours.	Temperature of the combustion tube $T^{\circ}$	Temperature of the globe $t^{\circ}$	Corrected pressure of dry nitrogen-free gas.
0 .....	480° .....	22.2° .....	514.0 mm.
2 .....	490 .....	25.2 .....	494.0 „
4 .....	493 .....	23.7 .....	476.0 „
6 .....	492 .....	24.2 .....	455.8 „
8 .....	490 .....	24.8 .....	435.0 „
10 .....	492 .....	26.3 .....	419.2 „
12 .....	494 .....	25.9 .....	409.0 „
24 .....	492 .....	26.6 .....	398.8 „

The curve for this experiment is shown in Fig. 3, Curve VI.

The liquid in the worm was quite neutral to litmus and contained acet- and form-aldehydes, but no alcohol. The gaseous products contained :

	Per cent.		Per cent.
Carbon dioxide ...	12.45	Ethane.....	57.10
Carbon monoxide...	15.00	Methane .....	2.30
Oxygen .....	0.30	Hydrogen .....	12.85

The ratio C/A for the residual gas was 1.430, which after removal of hydrogen by means of oxidised palladium sponge at 100°, was reduced to 1.265.

With regard to the other experiments with these mixtures, we may perhaps briefly refer to one in which the combustion tube was packed with fragments of fused quartz instead of the usual porous porcelain, because it illustrates in a striking manner the dependence of the velocity of oxidation on the character of the heated surface employed. In the experiment in question, although the temperature of the combustion tube was maintained at 480—500°, and the pump worked at top speed throughout, the pressure of the gases in the apparatus (measured cold and dry) only fell from 417.5 mm. to 384 mm., or by about 8 per cent., in four days, a rate of reaction only about one-tenth that observed under similar conditions with a catalytic surface of porous porcelain.

### PART III.—*Experiments on the Slow Combustion of Ethyl Alcohol and Acetaldehyde.*

#### A. *Ethyl Alcohol.*

Assuming, for the moment, that the initial stage in the oxidation of ethane involves the formation of ethyl alcohol, the non-occurrence of this compound among the soluble intermediate products in our cir-

culution experiments would be explained if it could be shown that, under similar conditions, alcohol reacts with oxygen much more rapidly than does ethane itself. It was also important to ascertain whether or not the intermediate stages of the oxidation of alcohol are of the same character and sequence as those of ethane, namely: (1), formation of acetaldehyde and steam, and (2) formation of carbon monoxide, formaldehyde, and steam.

As it was not feasible to use the circulation apparatus for these experiments, we set up a special apparatus in which air or oxygen could be passed at a constant rate (about  $1\frac{1}{2}$  litres per hour) through (1) a series of glass worms containing pure ethyl alcohol kept at a definite temperature ( $t^\circ$ ) in a large water-bath, (2) a combustion tube packed with porous porcelain, of the same dimensions as the tube used in the circulation apparatus, heated to a constant temperature ( $T^\circ$ ), and (3) two worms containing water, and externally cooled by water for the removal of soluble intermediate products. Arrangements were also made for the collection of samples of the exit gases. The conditions of these experiments were therefore fairly comparable with those of the ethane circulation experiments, except that of course in the latter the reacting gases passed many times over the heated surface. Our object was to ascertain the limiting proportion of alcohol vapour which could enter the combustion tube without any of it surviving a single passage over the heated surface.

The vapour pressures of alcohol at the various saturation temperatures employed are as follows:

$t.$	$10^\circ.$	$20^\circ.$	$30^\circ.$	$40^\circ.$	$50^\circ.$
$p.$	24.2	44.5	78.5	134.0	220.0 mm.

(a) *Experiments with Air.*

(i) With the furnace at  $300^\circ$ , traces of alcohol appeared in the products with a saturation temperature of  $20^\circ$ . The liquid in the worm contained acetaldehyde but no formaldehyde. The exit gases contained a trace of carbon dioxide and 18.7 per cent. of oxygen.

(ii) With the furnace at  $350^\circ$ , no alcohol survived the passage through the combustion tube with a saturation temperature of  $20^\circ$ , but it appeared in the exit gases with a saturation temperature of  $30^\circ$ . The products contained much acetaldehyde and also some formaldehyde, and the gases from one experiment (saturation temperature  $20^\circ$ ) contained:  $\text{CO}_2 = 1.9$ ;  $\text{CO} = 2.8$ ; and  $\text{O}_2 = 13.8$  per cent.

(iii) With the furnace at  $500^\circ$ , no alcohol survived a single passage over the heated surface at all saturation temperatures under  $35^\circ$ , but it appeared in the exit gases when the saturation temperature was  $40^\circ$ . The liquid in the worms now had a faintly acid reaction,

and contained both acetaldehyde and formaldehyde. The gaseous products from one experiment (saturation temperature =  $40^{\circ}$ ) contained  $\text{CO}_2 = 5.5$ ;  $\text{CO} = 12.0$ ;  $\text{O}_2 = \text{nil}$ ;  $\text{C}_2\text{H}_4 = 1.5$ ;  $\text{CH}_4 = 4.0$  per cent.

All the foregoing oxidation rates are far in excess of those observed with ethane at corresponding temperatures in the circulation apparatus.

(b) *With a Mixture of Oxygen = 48.6 per cent. and Nitrogen = 51.4 per cent.*

With the furnace at  $425^{\circ}$ , the ingoing gas was sometimes saturated at  $50^{\circ}$  even without alcohol appearing in the exit gases. The liquid in the worms, which was neutral to litmus, contained acetaldehyde and much formaldehyde, but no glyoxal. The gaseous products from one experiment (saturation temperature =  $40^{\circ}$ ) contained:  $\text{CO}_2 = 3.1$ ;  $\text{CO} = 8.5$ ;  $\text{O}_2 = 35.1$ ; and  $\text{CH}_4 = 0.8$  per cent.

(c) *With 95 per cent. Oxygen.*

(i) With the furnace at  $450^{\circ}$ , and the gas saturated at  $30^{\circ}$ , no alcohol escaped from the combustion tube. The liquid in the worms had a faintly acid reaction; it contained acetaldehyde and much formaldehyde, but no glyoxal. The gaseous products contained:  $\text{CO}_2 = 3.7$ ;  $\text{CO} = 13.0$ ;  $\text{O}_2 = 77.0$  per cent.

(ii) With the furnace at  $450^{\circ}$ , and the gas saturated at  $50^{\circ}$ , a mere trace of the alcohol vapour survived the passage over the heated surface. The liquid in the worms, which had a distinctly acid reaction, contained acetaldehyde and formaldehyde, but no glyoxal. The gaseous products contained:  $\text{CO}_2 = 6.0$ ;  $\text{CO} = 12.8$ ;  $\text{O}_2 = 76.4$ ;  $\text{C}_2\text{H}_4 = 0.3$ ;  $\text{CH}_4 = 0.3$ ;  $\text{N}_2 = 4.2$  per cent.

The conclusions, therefore, to be drawn from these experiments are:

(1) That ethyl alcohol reacts with oxygen far more rapidly than does ethane itself under similar conditions.

(2) That its oxidation stages, like those of ethane, involve the successive formation of (a) acetaldehyde and (b) formaldehyde, together with considerable quantities of carbon monoxide.

### B. Acetaldehyde.

It finally remained to show that acetaldehyde and oxygen react in our circulation apparatus forming formaldehyde in conformity with the views expressed in the earlier part of this paper. The experimental method was as follows.

Just sufficient water was introduced into the globe of the apparatus to keep its inner surface wet during the experiment; about 20 c.c. of

water were put into the worm. The apparatus was then completely exhausted of air, the furnace lighted, and the combustion tube raised to the desired experimental temperature. Moist oxygen was then admitted into the apparatus until the manometer recorded a pressure of about 250 mm. The oxygen supply having been cut off, connection was made with a small distillation flask containing acetaldehyde; the air in the flask had been previously completely expelled by the vapour of the boiling liquid. The vapour of the acetaldehyde was then slowly admitted to the apparatus until the manometer indicated a further fall of about 300 mm.

The mixture of aldehyde vapour and oxygen was then rapidly circulated, pressure records being taken at frequent intervals. Finally, a sample of the gaseous products was withdrawn and analysed after any aldehyde vapours present had been polymerised and removed by contact with a layer of pure sulphuric acid. The liquid in the worm was also carefully examined for formaldehyde.

### 1st Experiment.

Pressure of oxygen (dry) originally admitted	=	250 mm.
„ „ aldehyde vapour „ „	=	291 „
		—
Total	=	541 „

There was a fairly rapid pressure fall in the apparatus during the first hour and a half, but during the next hour hardly any further fall was observed. This stationary period was succeeded by a very gradual rise in pressure, which was maintained on continuing the circulation overnight.

The records obtained were as follows:

Time in hours.	Temperature of combustion tube $T^{\circ}$ .	Corrected pressure for dry mixture.
0 .....	451° .....	541 mm.
1½ .....	460 .....	462 „
2½ .....	461 .....	462 „
3½ .....	459 .....	471 „
5½ .....	460 .....	474 „
7½ .....	464 .....	481 „
21½ .....	474 .....	504 „

The liquid in the worm was nearly neutral to litmus and contained much formaldehyde; during the experiment, also, a small quantity of a white solid, apparently paraformaldehyde, appeared on the surface of the globe A.

The gaseous products had the following percentage composition :

Carbon dioxide.....	23·5	Methane.....	23·35
Carbon monoxide.....	47·1	Hydrogen.....	4·45
Oxygen.....	nil	Nitrogen... ..	1·60

From the large proportion of methane present it is evident that a considerable amount of the acetaldehyde had undergone a purely thermal decomposition during the experiment.

### *2nd Experiment.*

Pressure of aldehyde vapour introduced	=	293 mm.
„ „ oxygen (dry)	=	233 „
		<hr/>
		526 „

The mixture was circulated for 24 hours ; at first, a rapid fall of pressure was observed, followed by a slow and continuous rise. The final pressure of the dry products was 450 mm.

The liquid in the worm again contained much formaldehyde, and the gaseous products had nearly the same composition as those obtained in the first experiment, namely :

	Per cent.		Per cent.
Carbon dioxide.....	24·6	Methane.....	19·0
Carbon monoxide.....	51·4	Hydrogen.....	4·1
Nitrogen .....	0·9		

### *3rd Experiment.*

In this experiment, pressure records were taken every 15 minutes, and the furnace was turned out as soon as the pressure fall had ceased.

Pressure of aldehyde vapour introduced	=	283 mm.
„ „ oxygen (dry)	=	265 „
		<hr/>
		548 „

The records were as follows :

Time in minutes.	Temperature of combustion tube T°.	Corrected pressure of dry mixture.
0 .....	479° .....	548 mm.
15 .....	479 .....	513 „
30 .....	479 .....	496 „
45 .....	479 .....	490 „
60 .....	479 .....	490 „

The liquid in the worm again contained formaldehyde, and the gaseous products, which contained no free oxygen, had the following composition :

	Per cent.		Per cent.
Carbon dioxide.....	34·35	Methane.....	15·35
Carbon monoxide... ..	48·25	Hydrogen .....	1·00
Nitrogen.....	1·05		

The indications obtained in the above experiments of the thermal decomposition of acetaldehyde vapour in contact with the heated surface led us to try the effect of circulating acetaldehyde vapour itself in our apparatus. We have already stated (p. 695) that acetaldehyde, when heated in borosilicate bulbs at 300—350°, undergoes simple decomposition in accordance with the equation  $\text{CH}_3\cdot\text{CHO} = \text{CH}_4 + \text{CO}$ . The changes which occur when the aldehyde vapour is passed over a surface of porous porcelain maintained at 450° are, however, of a more complex character. Some polymerisation or condensation takes place, and the condensed molecules undergo thermal decomposition as well as those of the simpler acetaldehyde vapour. The gaseous products from one experiment, for instance, contained:  $\text{CO}_2 = 58\cdot5$ ;  $\text{CO} = 6\cdot7$ ;  $\text{C}_2\text{H}_4 = 0\cdot7$ ;  $\text{CH}_4 = 31\cdot0$ ; and  $\text{H}_2 = 3\cdot1$  per cent.

When, however, the aldehyde vapour was largely diluted with inert nitrogen, relatively much larger proportions of methane were formed. The whole subject of the thermal decomposition of these aldehyde vapours, which requires careful working out in detail, is now being taken in hand.

Experiments are also being carried out in these laboratories on (1) the slow combustion of acetylene and ethylene, (2) the action of ozone on the simpler hydrocarbons at the ordinary temperature, and (3) the union of hydrogen and oxygen, and of carbon monoxide and oxygen, in contact with heated surfaces of porous porcelain.

In conclusion, we desire to tender our best thanks to the Government Grant Committee of the Royal Society for repeated grants towards the expenses of this and allied researches.

THE OWENS COLLEGE,  
MANCHESTER.

LXXIII.—*Studies in the Tetrahydronaphthalene Series.*  
*Part II. Halogen Derivatives of ar-Tetrahydro- $\beta$ -naphthylamine.*

By CLARENCE SMITH, D.Sc.

WHEN  $\beta$ -naphthylamine is reduced by sodium and amyl alcohol, two isomeric tetrahydronaphthylamines are produced (Bamberger and Müller, *Ber.*, 1888, 21, 847, 1112), and it has been shown that one of these, namely, *ar*-tetrahydro- $\beta$ -naphthylamine has lost its naphthalenoid characteristics, and behaves like a benzenoid amine in forming stable diazoamines (Trans., 1902, 81, 900).

The benzenoid character of *ar*-tetrahydro- $\beta$ -naphthylamine is further exemplified by its behaviour towards the halogens. The hydrogen atom in the  $\alpha$ -position, which so readily undergoes substitution in  $\beta$ -naphthylamine, has to a great extent lost its reactivity in the tetrahydrogenated base, and is now comparable with hydrogen in the ortho-position with respect to the amino-radicle in a benzenoid amine.

Thus it is found that with one molecular proportion of bromine at the ordinary temperature, acetyl-*ar*-tetrahydro- $\beta$ -naphthylamine forms two monobromo-compounds, in one of which the halogen atom has entered the ortho-position with respect to the aminic nitrogen, whilst in the other the meta-position is assumed. With aceto- $\beta$ -naphthalide, however, the reactive hydrogen atom in the  $\alpha$ -position alone undergoes displacement, resulting in the production of aceto-1-chloro- $\beta$ -naphthalide (Cleve, *Ber.*, 1887, 20, 1989) or of aceto-1-bromo- $\beta$ -naphthalide (Cosiner, *Ber.*, 1881, 14, 59), even when the halogen is employed in excess.

The positions taken up by the bromine atoms in the two bromo-*ar*-tetrahydro- $\beta$ -naphthylamines were determined by eliminating the amino-radicle with the formation in both cases of 1-bromotetrahydronaphthalene,\* a compound which was also prepared directly from *ar*-tetrahydro- $\alpha$ -naphthylamine by the Sandmeyer reaction.

\* [In this and the two succeeding papers, the orientation of the substituent radicles (other than amidogen) in the tetrahydronaphthalene derivatives under discussion is denoted by numerals, the numbering being commenced in the aromatic ring in accordance with the following scheme :

—EDITOR.]

## EXPERIMENTAL.

The following bromotetrahydronaphthalenes were prepared in order to assist in determining the positions taken up by other substituent radicles in the tetrahydronaphthalene series.

*1-Bromotetrahydronaphthalene, C<sub>10</sub>H<sub>11</sub>Br.*

A paste consisting of 30 grams (1 mol.) of *ar*-tetrahydro- $\alpha$ -naphthylamine, 100 c.c. ( $2\frac{1}{2}$  mols.) of hydrobromic acid (sp. gr. 1.308), and 50 c.c. of water was diazotised at 2—3° with the requisite amount of sodium nitrite, the clear yellow solution of the diazonium bromide being then added slowly to a solution of cuprous bromide. With each addition of the diazonium salt, an orange-red coloration was produced, which rapidly disappeared on shaking. The contents of the flask were then distilled in steam, and *1-bromotetrahydronaphthalene* collected in the receiver as a yellow oil together with a considerable quantity of *ar*-tetrahydro- $\alpha$ -naphthol.

Sodium hydroxide was added to the distillate in order to dissolve the phenolic substance; the insoluble oil was extracted with ether, the extract being washed with water, dried over calcium chloride, and then distilled. The main portion distilled between 250° and 260° under 751 mm. pressure, and on rectification a fraction was obtained which boiled at 255—257°, and was analysed with the following result.

0.3013 gave 0.2668 AgBr. Br = 37.68.

C<sub>10</sub>H<sub>11</sub>Br requires Br = 37.91 per cent.

*1-Bromotetrahydronaphthalene* is a colourless, refractive liquid, with an aromatic odour resembling that of the halogenated benzene compounds; it darkens in colour until finally it becomes almost black. It is easily soluble in organic solvents and volatile in steam.

*2-Bromotetrahydronaphthalene, C<sub>10</sub>H<sub>11</sub>Br.*

This compound, which was obtained from *ar*-tetrahydro- $\beta$ -naphthylamine by the method described in the preceding experiment, is a colourless, highly refractive liquid which boils between 238° and 239° under 758 mm. pressure; it closely resembles the  $\alpha$ -compound in appearance, odour, and solubility.

0.2667 gave 0.2355 AgBr. Br = 37.57.

C<sub>10</sub>H<sub>11</sub>Br requires Br = 37.91 per cent.

*Action of Bromine on Acetyl-ar-tetrahydro-β-naphthylamine.*

Bromination of the acetyl compound proceeds readily at the ordinary temperature, but the best yield of *acetylbromo-ar-tetrahydro-β-naphthylamine* was obtained under the following conditions.

A solution of 5 grams of the acetylated amine in 15 grams of glacial acetic acid was maintained at 50—60°, while 4 grams of bromine dissolved in 10 grams of the same solvent were slowly added. After half an hour, during which time hydrobromic acid was evolved copiously, the mixture was heated on the water-bath for a few minutes and allowed to cool. The solid which had separated was filtered, washed with acetic acid, and crystallised from alcohol. After several crystallisations from this solvent, the substance was obtained in colourless, octahedral crystals which melted at 125·5°.

0·3220 gave 0·2264 AgBr. Br = 29·92.

$C_{12}H_{14}ONBr$  requires Br = 29·85 per cent.

The substance, which is, therefore, an *acetylbromo-ar-tetrahydro-β-naphthylamine*, dissolves only sparingly in light petroleum or cold alcohol, and is moderately soluble in hot glacial acetic acid, ethyl acetate, or hot alcohol.

The mother-liquor from which the preceding acetyl derivative had been separated was diluted with water, whereby a solid substance was precipitated. After several crystallisations from alcohol, the compound was obtained in colourless needles melting at 151°.

0·1632 gave 0·1146 AgBr. Br = 29·88.

$C_{12}H_{14}ONBr$  requires Br = 29·85 per cent.

This second *acetylbromo-ar-tetrahydro-β-naphthylamine* differs markedly from the first in its solubilities. It dissolves very easily in acetic acid, acetone, ethyl acetate, or alcohol, and is moderately soluble in light petroleum.

The yields of the two brominated acetyl derivatives melting at 125·5° and 151° are respectively 82 per cent. and 12 per cent. of the theoretical.

*The Isomeric Bromo-ar-tetrahydro-β-naphthylamines.*

From the two brominated acetyl derivatives, the bases were obtained in the usual way. Ten grams of *acetylbromo-ar-tetrahydro-β-naphthylamine* (m. p. 125·5°) were heated for thirty minutes on the water-bath with 15 c.c. of alcohol and 10 c.c. of concentrated hydrochloric acid. The *hydrochloride* of the base was obtained in long, white

needles which are moderately soluble in hot water, undergoing partial dissociation. The free *base* was precipitated, by the addition of sodium hydroxide, as an oil which slowly solidified. The dried solid, when crystallised from light petroleum, separated in colourless, silky needles melting at  $52^{\circ}$ .

The base is easily soluble in alcohol, ethyl acetate, or acetone, moderately so in light petroleum or hot water, and almost insoluble in cold water; it is easily volatile in steam.

0.3153 gave 0.2621 AgBr. Br = 35.38.

$C_{10}H_{12}NBr$  requires Br = 35.39 per cent.

The brominated acetyl derivative melting at  $151^{\circ}$  does not hydrolyse as readily as the isomeric compound.

Ten grams of the substance melting at  $151^{\circ}$  were heated for two hours in alcoholic solution with strong hydrochloric acid. The hydrochloride separated from the cold liquid in long, prismatic needles. The free *base* was obtained as an oil by adding sodium hydroxide to the aqueous solution of the hydrochloride. The oil slowly solidified, and the dried solid, when crystallised from light petroleum, separated in colourless needles which melted at  $52^{\circ}$ . The base is not volatile in steam; it dissolves readily in alcohol, chloroform, or ethyl acetate, but is only moderately soluble in light petroleum or hot water.

0.1249 gave 6.8 c.c. moist nitrogen at  $14.5^{\circ}$  and 765 mm. N = 6.43.

0.2871 „ 0.2394 AgBr. Br = 35.49.

$C_{10}H_{12}NBr$  requires Br = 35.49. N = 6.19 per cent.

Although these isomeric brominated bases resemble one another so closely in their crystalline forms and melting points, they are proved to be different compounds, not only because they yield different hydrochlorides and acetyl derivatives, but also from the fact that a mixture of equal quantities of the bases forms an oil at the ordinary temperature.

#### *1-Bromotetrahydronaphthalene Derived from the Two Brominated Bases.*

The two bromo-*ar*-tetrahydro- $\beta$ -naphthylamines are both oxidised to adipic acid by alkaline permanganate, a result which shows that the bromine atom is not situated in the hydrogenated nucleus. In order to determine the position of the halogen, the amino-group was eliminated from the brominated bases with the production of 1-bromotetrahydronaphthalene in both cases. Hence the bromine atoms in the two brominated bases must be situated in the positions 1 and 4 respectively with reference to the amino-group.

Ten grams of the hydrochloride of bromo-*ar*-tetrahydro- $\beta$ -naphthyl-

amine (m. p.  $52.5^{\circ}$ ) were suspended in 15 c.c. of cold hydrochloric acid and diluted with 30 c.c. of water, and diazotised with the requisite amount of sodium nitrite. The solution of the diazonium salt was then poured into an ice-cold solution of 20 grams of sodium hydroxide in 60 c.c. of water. To the mixture cooled by ice was added, slowly and in small quantities at a time, a concentrated solution of stannous chloride (40 grams) in sodium hydroxide. When the whole of the reducing agent had been added, and the evolution of nitrogen had ceased, the product was distilled in steam.

The yellow oil in the distillate was extracted with ether, washed with dilute sulphuric acid and water, and dried over calcium chloride. On distillation, after removing the solvent, a colourless oil passed over between  $255^{\circ}$  and  $260^{\circ}$  under 764 mm. pressure. By redistillation, the main portion was collected between  $258^{\circ}$  and  $259^{\circ}$ , and was thus recognised as 1-bromotetrahydronaphthalene (b. p.  $255-257^{\circ}/751$  mm.).

0.3179 gave 0.2813 AgBr. Br = 37.65.

$C_{10}H_{11}Br$  requires Br = 37.91 per cent.

A similar experiment was performed on the bromo-*ar*-tetrahydro- $\beta$ -naphthylamine, melting at  $52^{\circ}$ .

The colourless oil ultimately obtained distilled between  $254^{\circ}$  and  $256^{\circ}$  under 758 mm.

0.2863 gave 0.2528 AgBr. Br = 37.58.

$C_{10}H_{11}Br$  requires Br = 37.91 per cent.

The compound was identical with 1-bromotetrahydronaphthalene in its other physical properties.

LXXIV<sup>\*</sup>.—*Studies in the Tetrahydronaphthalene Series.*  
*Part III. Reaction between ar-Tetrahydro- $\beta$ -naphthylamine and Formaldehyde.*

By CLARENCE SMITH, D.Sc.

THE course of the reaction between formaldehyde and  $\beta$ -naphthylamine differs markedly from that which occurs between this aldehyde and the primary benzenoid amines. In the former case, the final product is chiefly naphthacridine (Reed, *J. pr. Chem.*, 1886, 35, 314; Morgan, *Trans.*, 1898, 73, 536). With benzenoid amines, anhydro-bases of the

type  $R \cdot N : CH_2$  are obtained ; these substances, which exist generally in the bimolecular or trimolecular state, are unsaturated compounds, forming additional products with hydrogen, the halogens, and hydrogen cyanide, and are readily hydrolysed into their generators by dilute acids (von Miller and Plöchl, *Ber.*, 1892, 25, 2020 ; Bischoff, *Ber.*, 1898, 31, 3251).

*ar*-Tetrahydro- $\beta$ -naphthylamine exhibits its benzenoid character when submitted to the action of formaldehyde. In consequence of the decreased reactivity of the hydrogen atom in the  $\alpha$ -position in *ar*-tetrahydro- $\beta$ -naphthylamine, there is no tendency towards the production of an acridine, and an anhydro-base quite analogous to methyleneaniline is formed in accordance with the equation :

Von Miller and Plöchl (*loc. cit.*) obtained two substances by the action of formaldehyde on aniline ; one of these was methyleneaniline in the trimolecular state, the other they were unable to identify, but concluded that it was a higher polymeride of methyleneaniline, since both substances gave the same reactions.

Two substances are likewise produced in the reaction between *ar*-tetrahydro- $\beta$ -naphthylamine and formaldehyde and one of these is methylene-*ar*-tetrahydro- $\beta$ -naphthylamine in the trimolecular state. In this case, however, there is no doubt that the other substance is also a polymeride of the anhydro-base, for not only do both substances exhibit the same reactions, but each can be changed into the other by the aid of solvents. The trimolecular form is partially changed into the higher polymeride by evaporating its solution in boiling alcohol ; the higher polymeride is changed almost entirely into the crystalline trimolecular form by dissolving it in boiling benzene. Methylene-*ar*-tetrahydro- $\beta$ -naphthylamine is an unsaturated substance ; it forms an unstable additive compound with bromine, and by reduction with sodium and amyl alcohol yields methyl-*ar*-tetrahydro- $\beta$ -naphthylamine, which possesses properties resembling those of the corresponding ethyl base.

#### EXPERIMENTAL.

##### *Methylene-ar-tetrahydro- $\beta$ -naphthylamine*, $(C_{10}H_{11}N : CH_2)_3$ .

Ten grams of fused *ar*-tetrahydro- $\beta$ -naphthylamine were mixed with sufficient alcohol to keep the mixture liquid at the ordinary temperature, and 9 grams of a 35 per cent. formaldehyde solution were then slowly added. Towards the end of the operation, a heavy oil suddenly separated and the temperature rose considerably. The remainder of the formaldehyde was added and the mixture was allowed to remain for

three hours. The clear, supernatant liquid containing only formaldehyde was decanted, and the extremely viscid pink product, which had a waxy appearance, was well washed with water and dried. The greater part of the substance dissolved in boiling acetone, the residue consisting of 2 grams of a white, amorphous powder (B). Eight grams of colourless needles (A) crystallised from the solution.

(A) By successive crystallisation from acetone and light petroleum, this substance was obtained as a felted mass of white needles which melted at  $121^{\circ}$ ; it was easily soluble in benzene, chloroform, or acetone, but only sparingly so in light petroleum. By gently warming the substance with glacial acetic acid, an intense blood-red coloration was produced.

0.2128 gave 0.6250  $\text{CO}_2$  and 0.1567  $\text{H}_2\text{O}$ .  $\text{C} = 83.18$ ;  $\text{H} = 8.18$ .

0.1771 „ 0.5375  $\text{CO}_2$  „ 0.1276  $\text{H}_2\text{O}$ .  $\text{C} = 82.77$ ;  $\text{H} = 8.01$ .

0.1753 „ 13.2 c.c. moist nitrogen at  $16^{\circ}$  and 767 mm.  $\text{N} = 8.86$ .

0.1116 „ 8.7 „ „ „ 748 „  $\text{N} = 8.94$ .

$\text{C}_{11}\text{H}_{13}\text{N}$  requires  $\text{C} = 83.02$ ;  $\text{H} = 8.18$ ;  $\text{N} = 8.80$  per cent.

The compound possesses properties analogous to those of methyleneaniline; it is unsaturated, forming an unstable perbromide, and is reduced to methyl-*ar*-tetrahydro- $\beta$ -naphthylamine; it does not form a benzoyl derivative, and is decomposed by dilute acids, *ar*-tetrahydro- $\beta$ -naphthylamine being regenerated.

The determination of the molecular weight by the cryoscopic method gave results which indicate that the substance, like the analogous methyleneaniline, exists in the trimolecular state.

0.2102 in 16.361 benzene gave  $\Delta t = 0.165^{\circ}$ .  $\text{M. W.} = 413$ .

0.1173 „ 13.362 „ „ 0.116 $^{\circ}$ .  $\text{M. W.} = 401$ .

$(\text{C}_{10}\text{H}_{11}\text{N}:\text{CH}_2)_3$  requires  $\text{M. W.} = 477$ .

$(\text{C}_{10}\text{H}_{11}\text{N}:\text{CH}_2)_2$  „  $\text{M. W.} = 318$ .

(B) The amorphous, white powder darkens at  $156^{\circ}$  and fuses at  $164$ – $165^{\circ}$ ; it is almost insoluble in acetone, light petroleum, or benzene, but dissolves in hot alcohol. With warm acetic acid, it gives a blood-red coloration.

0.1877 gave 0.5700  $\text{CO}_2$  and 0.1365  $\text{H}_2\text{O}$ .  $\text{C} = 82.83$ ;  $\text{H} = 8.08$ .

0.2011 „ 0.6100  $\text{CO}_2$  „ 0.1487  $\text{H}_2\text{O}$ .  $\text{C} = 82.73$ ;  $\text{H} = 8.21$ .

0.2676 „ 21 c.c. moist nitrogen at  $16^{\circ}$  and 766 mm.  $\text{N} = 9.22$ .

$\text{C}_{11}\text{H}_{13}\text{N}$  requires  $\text{C} = 83.02$ ;  $\text{H} = 8.18$ ;  $\text{N} = 8.80$  per cent.

It appears, therefore, that the substance B is a polymeric form of methylene-*ar*-tetrahydro- $\beta$ -naphthylamine.

*Action of Solvents on Compounds A and B.*—The attempt to determine the molecular weight of compound B gave the following results.

At the ordinary temperature, 0.0521 gram of this compound was insoluble in about 18 grams of benzene, but dissolved at  $40^{\circ}$ ; the clear solution did not yield the original substance, and the depression of the freezing point of 18.451 grams of benzene was  $0.035^{\circ}$ , corresponding with a molecular weight of 427.

In another experiment, 0.0976 gram dissolved at  $40^{\circ}$  depressed the freezing point of 27.27 grams of benzene by  $0.042^{\circ}$ , corresponding with a molecular weight of 421.

As the compound B, which is insoluble in cold benzene, dissolves in the warm solvent at  $40^{\circ}$  and is not reprecipitated on cooling the solution, and as the observed molecular weight of the dissolved substance is about 420, these results seem to indicate that this polymeride has been converted almost entirely into the trimolecular form  $(C_{10}H_{11}N:CH_2)_3$ .

To verify this conclusion, 2 grams of the compound B were dissolved in boiling benzene and the solution concentrated, when white needles separated, which, after crystallisation from acetone, melted at  $121^{\circ}$  and were identical with the compound A.

On the other hand, when the substance A was dissolved in boiling alcohol and the solvent allowed to evaporate, the oil, which separated slowly, solidified. This solid was boiled with 50 c.c. of acetone, and the white, amorphous, insoluble residue, when washed with acetone and dried, melted at  $164-165^{\circ}$  and was identical with the substance B.

An intimate mixture of the two substances A and B melts in a remarkable manner. Fusion does not take place until the melting point ( $121^{\circ}$ ) of A is reached; then partial fusion occurs, but the mixture does not become wholly liquid until the melting point ( $164-165^{\circ}$ ) of the substance B is attained.

*Methyl-ar-tetrahydro- $\beta$ -naphthylamine*,  $C_{10}H_{11}\cdot NH\cdot CH_3$ .—Twenty grams of methylene-ar-tetrahydro- $\beta$ -naphthylamine, dissolved in 400 c.c. of boiling amyl alcohol, were reduced by means of 50 grams of sodium until a sample of the solution did not turn red on the addition of dilute hydrochloric acid. The liquid was poured into 400 c.c. of water, the aqueous solution of sodium hydroxide drawn off, the alcoholic liquid acidified with hydrochloric acid, and evaporated to 50 c.c. and cooled. The hydrochloride which separated from the cold solution was collected and washed with ether until colourless. The base was liberated by sodium hydroxide, extracted with ether and dried over solid caustic potash. After removal of the solvent, an oil remained which boiled at  $267.5^{\circ}$  under 210 mm. pressure. The distillate was a colourless, almost odourless, highly refractive oily liquid, which turned brown on exposure to the air. It dissolves easily in organic solvents, is sparingly soluble in hot water, and possesses feebly basic properties.

0.2668 gave 0.8051  $\text{CO}_2$  and 0.2317  $\text{H}_2\text{O}$ .  $\text{C} = 82.30$  ;  $\text{H} = 9.65$ .  
 0.2284 „ 16 c.c. moist nitrogen at  $18^\circ$  and 778 mm.  $\text{N} = 8.29$ .  
 $\text{C}_{11}\text{H}_{15}\text{N}$  requires  $\text{C} = 81.99$  ;  $\text{H} = 9.32$  ;  $\text{N} = 8.69$  per cent.

The *nitrate*,  $\text{C}_{10}\text{H}_{11}\cdot\text{NH}\cdot\text{CH}_3\cdot\text{HNO}_3$ , is obtained by shaking an ethereal solution of the base with dilute nitric acid ; it separates in colourless needles, which are easily soluble in cold water.

The *hydrochloride*,  $\text{C}_{10}\text{H}_{11}\cdot\text{NH}\cdot\text{CH}_3\cdot\text{HCl}$ , produced by adding dilute hydrochloric acid to the base suspended in water, separates in white, sparingly soluble needles.

The *nitrosoamine*,  $\text{C}_{10}\text{H}_{11}\cdot\text{N}(\text{CH}_3)\cdot\text{NO}$ , is prepared by adding the requisite amount of sodium nitrite to an acidified solution of the hydrochloride. The yellow oil when extracted with ether and dried over calcium chloride, gives Liebermann's reaction, developing an intense red coloration in the acid solution, which changes to greenish-blue on the addition of sodium hydroxide.

## LXXV.—*A Study of the Substitution Products of ar-Tetrahydro- $\alpha$ -naphthylamine. 4-Bromotetrahydro- $\alpha$ -naphthylamine and ar-Tetrahydro- $\alpha$ -naphthylamine-4-sulphonic Acid.*

By GILBERT THOMAS MORGAN, FRANCES MARY GORE MICKLETHWAIT,  
 and HERBERT BEN WINFIELD.

*ar*-TETRAHYDRO- $\alpha$ -NAPHTHYLAMINE, originally obtained by Bamberger and Althausse (*Ber.*, 1888, 21, 1786) on reducing  $\alpha$ -naphthylamine with sodium and boiling amyl alcohol, was shown by these investigators to have the general properties of an aromatic amine, and in certain respects to be more closely allied to aniline and its homologues (more particularly *o*-2-xylidine) than to the original naphthalenoid amine (Bamberger, *Annalen*, 1890, 257, 11). Nevertheless, the tetrahydrogenated base resembles  $\alpha$ -naphthylamine in the facility with which it interacts with diazonium salts to yield aminoazo-derivatives, for whereas with primary amines of the benzene series this reaction usually stops at an intermediate stage, giving rise to diazoamines,  $\text{R}\cdot\text{NH}_2\cdot\text{NHX}$ , yet compounds of this type have not been isolated in the case of *ar*-tetrahydro- $\alpha$ -naphthylamine, where the formation of an aminoazo-derivative seems to take place far more readily than with the similarly constituted *o*-2-xylidine (Noelting and Forel, *Ber.*, 1885, 18, 2682).

In view of this reactivity of *ar*-tetrahydro-*a*-naphthylamine towards diazo-compounds, it seemed desirable to ascertain whether the property of forming aminoazo-compounds directly was retained by its substitution products, and accordingly an attempt has been made to obtain certain of these derivatives and, after determining the orientation of the substituent radicles, to study the action of diazonium salts on the compounds in order to compare the results with those obtained in the benzene and naphthalene series.

Preliminary experiments on the nitration and chlorination of *ar*-tetrahydro-*a*-naphthylamine and its acyl derivatives showed that the changes involved were somewhat complex, whereas the ordinary processes of bromination and sulphonation led to the production of well-defined mono-substituted derivatives, and these were therefore examined in detail.

*Bromination of the Acyl Derivatives of ar-Tetrahydro-a-naphthylamine.*

Bamberger and Althausse (*Ber.*, 1888, 21, 1895) stated that on treating acetyl-*ar*-tetrahydro-*a*-naphthylamine with bromine in chloroform solution, the colour of the halogen immediately disappeared and a colourless acetylbromo-*ar*-tetrahydro-*a*-naphthylamine was produced. In our experiments, carried out under similar conditions, we found that the first substance to separate from the chloroform solution, after a considerable proportion of the bromine had been added, was an orange-yellow, crystalline compound, which had the properties of a perbromide and liberated iodine from potassium iodide. This product appears to result from the addition of bromine to the acetylbromo-*ar*-tetrahydro-*a*-naphthylamine, for it is also produced when bromine is added to a dry chloroform solution of the brominated acetyl derivative.

When the mixture is exposed for some time at the ordinary temperature, the yellow substance slowly disappears; this change is accelerated on warming, when the coloured substance dissolves in the chloroform, and the solution on cooling yields a colourless product, consisting chiefly of the acetylbromo-*ar*-tetrahydro-*a*-naphthylamine.

Similar results were obtained with the formyl, propionyl, and benzoyl derivatives of the tetrahydrogenated base (compare footnote, p. 745).

Acetyl-*ar*-tetrahydro-*a*-naphthylamine can also be brominated by means of hypobromous acid, the intermediate bromoamine thus produced being obtained as a pale yellow precipitate, which rapidly underwent isomeric change into acetylbromo-*ar*-tetrahydro-*a*-naphthylamine.

The brominated acetyl derivative prepared by either of the foregoing methods melted at 180—181°, and was therefore identical with the product obtained by Bamberger and Althausse (*loc. cit.*). When

hydrolysed, the acetyl derivative yielded the hydrochloride of a bromotetrahydro- $\alpha$ -naphthylamine melting at  $42^\circ$ .

The orientation of the substituent bromine atom was determined in the following manner. The base was diazotised in the ordinary way and the diazonium chloride solution treated with excess of alkaline sodium stannite; the product, when distilled in steam, yielded a volatile oil which had the properties of 1-bromotetrahydro-naphthalene, obtained by C. Smith from *ar*-tetrahydro- $\alpha$ -naphthylamine by means of the Sandmeyer reaction (compare this vol., p. 729).

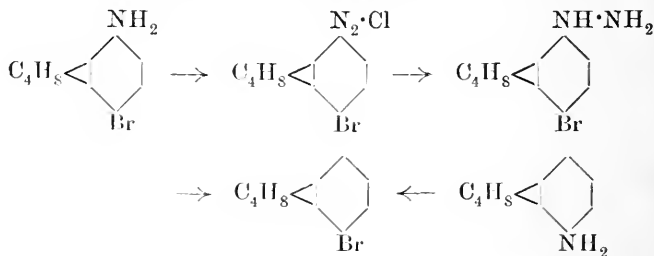

As the isomeric 2-bromotetrahydronaphthalene, prepared by the same investigator (*loc. cit.*) from *ar*-tetrahydro- $\beta$ -naphthylamine, is likewise an oil having a boiling point not far removed from that of the  $\alpha$ -compound, the two oily isomerides were nitrated with the view of obtaining, if possible, solid, crystalline nitro-derivatives.

2-Bromotetrahydronaphthalene, produced from the corresponding hydrogenated  $\beta$ -amine, when treated with a mixture of concentrated nitric and sulphuric acids, gave rise to a *dinitro*-derivative melting at  $105\text{--}106^\circ$ .

1-Bromotetrahydronaphthalene, obtained by replacing amidogen by bromine in *ar*-tetrahydro- $\alpha$ -naphthylamine by means of the Sandmeyer reaction, when similarly treated, readily yielded a *dinitro*-derivative melting at  $91^\circ$ .

Mixtures of the two dinitro-derivatives in approximately equal quantities melt at  $60\text{--}71^\circ$ , and therefore these compounds can be safely employed in identifying the two isomeric bromotetrahydronaphthalenes.

The bromo-compound, obtained by eliminating the amino-group from the new bromotetrahydro- $\alpha$ -naphthylamine, was accordingly nitrated, when it was found to give a dinitro-derivative, which melted at  $91^\circ$  and depressed considerably the melting point of the standard dinitro- $\beta$  compound (m. p.  $105\text{--}106^\circ$ ). The dinitro-compound was therefore derived from 1-bromotetrahydronaphthalene, and this result demonstrates that the bromine atom occupied the para-position with respect to the amino-group in the original bromo-base. Hence this compound is 4-bromotetrahydro- $\alpha$ -naphthylamine.

*The Action of Diazo-compounds on 4-Bromotetrahydro- $\alpha$ -naphthylamine and 4-Bromo- $\alpha$ -naphthylamine.*

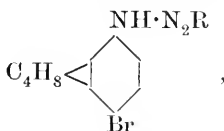

Since the bromo-base is a para-substituted compound, its reactions with diazonium salts should be compared with those of *p*-bromoaniline and 4-bromo- $\alpha$ -naphthylamine, its analogues in the benzene and naphthalene series respectively.

When two molecular proportions of 4-bromotetrahydro- $\alpha$ -naphthylamine are treated with one molecular proportion of nitrous acid, 4 : 4'-dibromo-1-diazo-1-aminotetrahydronaphthalene,

is produced. That this compound is really a diazoamine is shown by the fact that when treated with concentrated hydrochloric acid it is decomposed into a mixture of the hydrochlorides of its generators,  $\text{C}_{10}\text{H}_{10}\text{Br}\cdot\text{N}_2\cdot\text{Cl}$  and  $\text{C}_{10}\text{H}_{10}\text{Br}\cdot\text{NH}_2\cdot\text{HCl}$ . The diazonium base is detected by pouring the mixture into an alkaline solution of  $\beta$ -naphthol, when 4-bromotetrahydronaphthalene-1-azo- $\beta$ -naphthol (m. p.  $215^\circ$ ) is obtained; the regenerated amine is identified by conversion into its benzoyl derivative (m. p.  $202^\circ$ ).

4-Bromotetrahydro- $\alpha$ -naphthylamine behaves similarly towards other diazo-compounds, the product in every case being a diazoamine,

which undergoes the characteristic fission on treatment with concentrated mineral acids. The diazo-compounds employed were derived from the three nitroanilines, 6-aminocoumarin, and sulphanilic acid. In no case could the formation of an aminoazo-derivative be detected, and, moreover, it was not found possible to transform 4 : 4'-dibromo-1-diazo-1-aminotetrahydronaphthalene into its isomeric aminoazo-compound by digestion at  $70^\circ$  with a mixture of the bromo-base and its hydrochloride (compare Noetting and Witt, *Ber.*, 1884, 17, 78, and C. Smith, *Trans.*, 1902, 81, 900).

As regards its behaviour towards diazo-compounds, 4-bromotetrahydro- $\alpha$ -naphthylamine therefore resembles *p*-bromoaniline, which also gives rise to stable diazoamines.

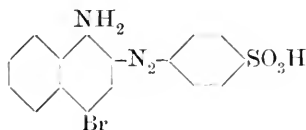

The action of nitrous acid (1 mol.) on 4-bromo- $\alpha$ -naphthylamine (2 mols.) leads to the formation of a somewhat ill-defined product which consists chiefly of an azo-compound, but although the experimental conditions were varied, it was not possible to obtain the sub-

stance in a state of purity, yet its colour, stability towards hot hydrochloric acid, and the development of an intense blue coloration with cold concentrated sulphuric acid suggest that it is an aminoazo-compound having the formula  $C_{10}H_6BrN_2 \cdot C_{10}H_5Br \cdot NH_2$ .

This view was confirmed by the preparation of more definite products by the action of other diazonium salts on the bromo-base. The compounds produced from the diazotised nitroanilines were isolated in a state of purity and were found to be dark reddish-brown substances not decomposed by hot concentrated hydrochloric acid in aqueous or alcoholic solutions; moreover, they developed characteristic colorations with cold concentrated sulphuric acid and yielded acetyl and benzoyl derivatives by the ordinary processes.

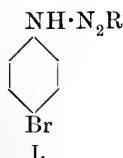

A final confirmation of the hypothesis that these compounds are azo-derivatives was furnished by the reduction of the compound  $SO_3H \cdot C_6H_4N_2 \cdot C_{10}H_5Br \cdot NH_2$ , obtained from the bromo-base and diazobenzenesulphonic acid.

This azo-colouring matter, when treated with tin and hot alcoholic hydrochloric acid, was reduced to sulphanilic acid and naphthylene-1:2-diamine (m. p. 95—96°), the destruction of the azo-linking and the elimination of bromine from the naphthalene nucleus taking place simultaneously. The latter compound was identified as an ortho-diamine by the production of its azine,  $C_{10}H_6 \begin{smallmatrix} N \\ < \\ N \end{smallmatrix} C_{14}H_8$  (m. p. 273°), with phenanthraquinone (Lawson, *Ber.*, 1885, 18, 2426), and also characterised by the formation of its diacetyl derivative (m. p. 234°). The original azo-colouring matter has therefore the constitution expressed by the following formula:

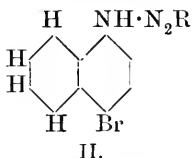

In short, the interaction of diazo-compounds and 4-bromo- $\alpha$ -naphthylamine always leads to the direct formation of azo-derivatives, the constitution of which may be indicated by the general formula III. As *p*-bromoaniline is known to give stable diazoamines which have not been hitherto transformed into the isomeric aminoazo-derivatives, it follows that 4-bromotetrahydro- $\alpha$ -naphthylamine in its behaviour towards diazo-compounds resembles the analogously constituted benzenoid bases and differs entirely from 4-bromo- $\alpha$ -naphthylamine.

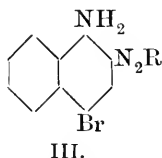

The products obtained in the three series under comparison may be therefore symbolised in the following manner:

Benzene series.

Tetrahydronaphthalene series.

Naphthalene series.

These results therefore justify Bamberger's general conclusions as to the assumption of a benzenoid character by the tetrahydronaphthylamines, owing to the hydrogenation of the unsubstituted ring (compare C. Smith, *loc. cit.*).

### *Sulphonation of ar-Tetrahydro- $\alpha$ -naphthylamine.*

The sulphonation of *ar*-tetrahydro- $\alpha$ -naphthylamine with ordinary concentrated sulphuric acid at moderate temperatures leads to the production of a monosulphonic acid, the constitution of which was established in the following manner.

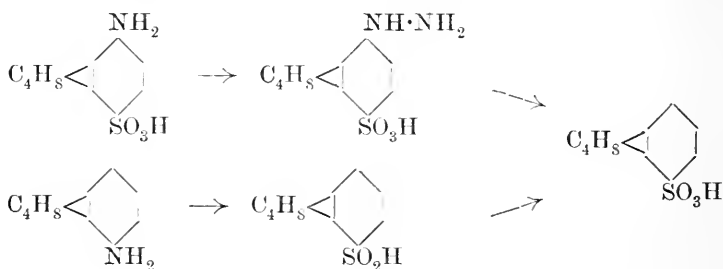

The aminosulphonic acid was successively converted into the diazo-derivative,  $C_{10}H_{10} \begin{smallmatrix} \text{N}_2 \\ \diagup \text{SO}_3 \end{smallmatrix}$ , and the hydrazine,  $NH_2 \cdot NH \cdot C_{10}H_{10} \cdot SO_3H$ , the latter being then boiled with copper sulphate solution (Baeyer and Pfizinger, *Ber.*, 1885, 18, 90, 786) in order to eliminate the hydrazino-radicle. The tetrahydronaphthalenesulphonic acid thus produced was isolated in the form of its barium salt, and from this substance the corresponding sulphonic chloride (m. p.  $70.5^\circ$ ) and sulphonanilide (m. p.  $144-145^\circ$ ) were successively prepared.

Two *ar*-tetrahydronaphthalenesulphonic acids are theoretically possible containing the sulphonic group in either the  $\alpha(=1)$ - or the  $\beta(=2)$ -position.

A sulphonic acid obtained by the direct sulphonation of tetrahydronaphthalene has been described by Graebe and Guye (*Ber.*, 1883, 16, 3031) and another by Bamberger and Kitschelt (*Ber.*, 1890, 23, 1563), but it is not possible to state with certainty from the existing data whether either of these substances is identical with the compound obtained in the foregoing experiments.

Since in the preceding bromination the entrant radicle took up the para-position with respect to the acylamino-group, it seemed likely that the sulphonic group would displace the same hydrogen atom of the aromatic nucleus, in which case the synthesised tetrahydronaphthalenesulphonic acid should be the  $\alpha$ -compound. *ar*-Tetrahydro- $\alpha$ -naphthylamine sulphate was diazotised and converted into *tetrahydronaphthalene-1-sulphinic acid* by the action of sulphurous acid and copper powder (Gatterman, *Ber.*, 1899, 32, 1136). The sulphinic

acid was oxidised with potassium permanganate to *tetrahydronaphthalene-1-sulphonic acid*, the potassium salt of which was converted successively into *tetrahydronaphthalene-1-sulphonic chloride* and *tetrahydronaphthalene-1-sulphonanilide*; these derivatives melted respectively at  $70.5^\circ$  and  $144\text{--}145^\circ$ , and were found to be identical with the chloride and anilide derived from the sulphonic acid obtained synthetically from *ar*-tetrahydro- $\alpha$ -naphthylaminesulphonic acid. Hence this amino-acid must contain its sulphonic group in the para-position with respect to the amino-radicle. The chemical changes involved in this demonstration may be thus indicated:

The fact that tetrahydronaphthalene-1-sulphonic acid may be produced by two distinct series of operations, including reactions of a somewhat dissimilar nature, tends to show that the hydrogenated residue  $\text{C}_4\text{H}_8$  does not undergo any change during the sulphonation of the *ar*-tetrahydro- $\alpha$ -naphthylamine, and confirmatory evidence was obtained by the direct comparison of tetrahydronaphthalene-1-sulphonic chloride (m. p.  $70.5^\circ$ ) with naphthalene-1-sulphonic chloride (m. p.  $66^\circ$ ), when a mixture of the two compounds was found to melt at  $45\text{--}47^\circ$ .

The sulphonic chloride and the bromodinitrotetrahydronaphthalenes obtained in the experiments recorded on p. 738 were tested with bromine in chloroform solution and were found not to decolorise this reagent, thus behaving as saturated compounds; this negative result excludes the possibility of the substances being derivatives of dihydronaphthalene and furnishes additional evidence in favour of the view that the hydrogenated ring has not undergone any change.

*ar*-Tetrahydro- $\alpha$ -naphthylamine-4-sulphonic acid,

when treated with a diazo-compound such as *p*-nitrobenzenediazonium chloride, yields a diazoamine which undergoes the characteristic fission with concentrated hydrochloric acid. In this respect, therefore, the hydrogenated amino-acid differs essentially from naphthionic acid ( $\alpha$ -naphthylamine-4-sulphonic acid), which, under these conditions, is known to give azo-colouring matters.

The foregoing study of the products of the interaction of diazo-

compounds and 4-bromotetrahydro- $\alpha$ -naphthylamine and *ar*-tetrahydro- $\alpha$ -naphthylamine-4-sulphonic acid shows that as regards this condensation the para-substituted *ar*-tetrahydro- $\alpha$ -naphthylamine derivatives differ entirely from the similarly constituted naphthalene compounds and leads to the conclusion that the reactivity of the hydrogen atom in the ortho-position adjacent to the amino-group is a characteristic feature of the naphthalene molecule which is destroyed when the non-substituted ring undergoes hydrogenation.

The azo-compounds of *ar*-tetrahydro- $\alpha$ -naphthylamine were first described by Bamberger and Bordt (*Ber.*, 1889, 22, 625), and other members of this series have been since prepared by C. Smith (*loc. cit.*). These substances, like the corresponding azo-derivatives of  $\alpha$ -naphthylamine, can be readily diazotised and the resulting diazo-compounds recombined with the sulphonic acids of the phenols or aromatic amines to yield disazo-colouring matters.

The azo-compound from diazobenzenesulphonic acid and *ar*-tetrahydro- $\alpha$ -naphthylamine, when dyed on wool in an acid bath, produces a bright orange colour, whereas the corresponding azo-derivative from  $\alpha$ -naphthylamine furnishes a dull brown shade. In order to ascertain whether these compounds, which differ so markedly in tinctorial properties, are both para-azo-derivatives, they were reduced with tin and hydrochloric acid under comparable conditions. The results obtained with  $\alpha$ -naphthylamineazobenzene-4-sulphonic acid confirm those already described by Griess (*Ber.*, 1882, 15, 2192), for the reduction products were sulphanilic acid and naphthylene-1 : 4-diamine (m. p. 120°), the latter being also characterised by the formation of its diacetyl derivative (m. p. 305°) and by its oxidation to  $\alpha$ -naphthaquinone.

The azo-acid from *ar*-tetrahydro- $\alpha$ -naphthylamine yielded on reduction sulphanilic acid and *ar*-tetrahydronaphthylene-1 : 4-diamine, the latter being identified as a para-diamine by yielding tetrahydronaphthaquinone on oxidation (Bamberger and Lengfeld, *Ber.*, 1890, 23, 1132). The azo-derivative is therefore *ar*-tetrahydro- $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic acid, and the striking contrast between its tinctorial properties and those of  $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic acid is due, not to any difference in the orientation of the azo-group with respect to the amino-radicle, but must be regarded as being the result of the profound change produced in the aromatic nucleus by the hydrogenation of the unsubstituted ring.

## EXPERIMENTAL.

*The Action of Bromine on the Acyl Derivatives of  $\alpha$ -Tetrahydro- $\alpha$ -naphthylamine.*

The tetrahydro- $\alpha$ -naphthylamine required in the following experiments was obtained by reducing batches of 45 grams of  $\alpha$ -naphthylamine, dissolved in 600 c.c. of boiling amyl alcohol, with 40 grams of sodium, the metal being added in large lumps so as to render the action as vigorous as possible. After purifying the product in the manner indicated by Bamberger and Althausse (*loc. cit.*), 321 grams of rectified tetrahydro-base, boiling at 275—277° (uncorr.), were obtained from 450 grams of crude  $\alpha$ -naphthylamine.

Acetyltetrahydro- $\alpha$ -naphthylamine was prepared by heating the tetrahydro-base for about 2—4 hours with an equal weight of glacial acetic acid containing about 8 per cent. of acetic anhydride, the crude acetyl derivative being crystallised from benzene; it then melted at 154°.

On adding 2.5 grams of bromine (1 mol.) dissolved in 15 c.c. of chloroform to a solution of 3 grams of the acetyl derivative in 25 c.c. of the same solvent, an orange-coloured, crystalline precipitate slowly separated, and the action was accompanied by a comparatively slight evolution of hydrogen bromide. This precipitate, which retained its yellow colour even after repeated washing with chloroform, was collected and found to weigh 3 grams. The filtrate was carefully evaporated to a small bulk, when a further quantity of the yellow substance was obtained, weighing 2.2 grams. The final filtrate, when evaporated to dryness, deposited a very small amount of oily matter.

The yellow compound was analysed for perbromide bromine by agitating with a mixture of chloroform and aqueous potassium iodide, and then titrating with standard thiosulphate solution. The first and second crops contained 21.0 and 20.0 per cent. of active bromine respectively. The amount of active bromine varied within 2 or 3 per cent. in different experiments, but the results seemed to indicate that approximately half the bromine combined additively with the acetyl derivative, yielding a perbromide which is fairly stable in a dry atmosphere at the ordinary temperature.

In the foregoing experiments, the materials were moderately dry, the chloroform having been distilled from calcium chloride containing a small amount of quicklime, and then kept over phosphoric oxide; the bromine had also been dried with this dehydrating agent; the recrystallised acetyl derivative was heated for 2 hours at 100° and allowed to cool in a desiccator. The reagents were mixed at the ordinary temperature. When the mixture in chloroform was

kept for several days, the precipitate gradually became colourless, and on warming on the water-bath the product was completely decolorised. The precipitate was then collected, when it was found that 14 grams were obtained from 10 grams of the original acetyl compound, only a small quantity of impure substance remaining in the filtrate. The colourless compound, when crystallised from either ethyl acetate or benzene, separated in felted needles melting at  $180-181^{\circ}$ ; it was apparently identical with the acetylbromotetrahydro- $\alpha$ -naphthylamine obtained by Bamberger and Althausse (*loc. cit.*).

The bromination was repeated with undried materials, employing glacial acetic acid as solvent, but in this case also the orange-yellow substance was first produced, and only slowly changed into the colourless compound, a few crystals of the latter being seen after three days. On heating the mixture containing the intermediate product, the latter dissolved, evolving hydrogen bromide, and the solution when cooled, yielded the colourless acetyl derivative.\*

#### *4-Bromotetrahydro- $\alpha$ -naphthylamine.*

*4-Bromotetrahydro- $\alpha$ -naphthylamine* was obtained by boiling the foregoing acetyl compound (14 grams) with 20 c.c. of concentrated hydrochloric acid and 20 c.c. of alcohol in a reflux apparatus for 2—3 hours. The hydrochloride of the base crystallised out on cooling in glistening, colourless plates, and was decomposed by ammonia, the crude base being dried and crystallised repeatedly from a mixture of equal volumes of benzene and light petroleum, when it separated in slender, colourless needles melting at  $42^{\circ}$ .

0.1895 gave 0.1574 AgBr. Br = 35.35.

0.2392 „ 13 c.c. moist nitrogen at  $18^{\circ}$  and 762 mm. N = 6.29.

$C_{10}H_{12}NBr$  requires Br = 35.40. N = 6.19 per cent.

The base is very soluble in the ordinary organic solvents excepting light petroleum; it is slightly volatile in steam.

*Formyl-4-bromotetrahydro- $\alpha$ -naphthylamine*,  $C_{10}H_{10}Br \cdot NH \cdot CHO$ , obtained by heating equal parts of the base and formic acid (sp. gr. 1.2) for half an hour, crystallised from benzene or alcohol in colourless plates melting at  $164.5^{\circ}$ .

\* It has been found that acetylbromotetrahydro- $\alpha$ -naphthylamine, and also the corresponding formyl, propionyl, and benzoyl derivatives, yield crystalline, orange-yellow perbromides when treated with bromine in chloroform solution. Moreover, acetyl-*p*-bromoaniline, under comparable conditions, gives rise to a similar additive compound. A study of these intermediate products of the action of bromine on the acyl derivatives of aromatic amines will form the subject of a separate investigation.

0.1828 gave 9.3 c.c. moist nitrogen at 18° and 752 mm.  $N = 5.81$ .  
 $C_{11}H_{12}ONBr$  requires  $N = 5.51$  per cent.

The formyl derivative, when treated with bromine in chloroform, yields a yellow additive product, which changes into a colourless substance giving an oily base on hydrolysis with alcoholic hydrochloric acid and subsequent treatment with ammonia. This oil, on treatment with acetic anhydride, yields an acetyl derivative melting at 198—199° and containing 45.65 per cent. of bromine, the calculated amount for an acetylated dibromo-base being 46.11. This compound will be further investigated.

*Propionyl-4-bromotetrahydro- $\alpha$ -naphthylamine,*

was produced on mixing together 10 grams of the bromo-base 5 grams of propionic acid, and 2 c.c. of propionic anhydride, the solid which appeared immediately being crystallised from chloroform; it separated in colourless needles melting at 185—186°.

0.1173 gave 0.0767 AgBr.  $Br = 27.83$ .

0.1554 „ 7.3 c.c. moist nitrogen at 18° and 747 mm.  $N = 5.33$ .

$C_{13}H_{16}ONBr$  requires  $Br = 28.39$ ;  $N = 4.96$  per cent.

*Benzoyl-4-bromotetrahydro- $\alpha$ -naphthylamine,*  $C_{10}H_{10}Br \cdot NH \cdot CO \cdot C_6H_5$ , prepared by the Schotten-Baumann process, crystallised from alcohol in colourless needles melting at 202—203°.

0.1199 gave 0.0668 AgBr.  $Br = 23.77$ .

$C_{17}H_{16}ONBr$  requires  $Br = 24.24$  per cent.

*Conversion of 4-Bromotetrahydro- $\alpha$ -naphthylamine into 1-Bromotetrahydronaphthalene.*

A mixture of 6.3 grams of recrystallised 4-bromotetrahydro- $\alpha$ -naphthylamine, suspended in 13 grams of concentrated hydrochloric acid diluted with 25 c.c. of water, was thoroughly cooled and treated with 2 grams of sodium nitrite in 10 per cent. aqueous solution. The diazotisation took place moderately readily, and after stirring the mixture vigorously in a mortar, the whole changed into a pale yellow solution, which was added to a cooled 30 per cent. caustic soda solution. The crimson solution thus produced was then slowly added to a solution prepared by dissolving 20 grams of crystallised stannous chloride in 30 per cent. aqueous caustic soda. At 0°, an orange-coloured solid was deposited; the mixture was left for one hour at the ordinary temperature, then warmed, and distilled in steam. About 2 c.c. of oil were obtained in the distillate accompanied by a red, tarry substance. The mixture was extracted with ether, the extract dried over calcium

chloride, the solvent then evaporated off, and the residue distilled. The residual oil boiled at 260—265° and appeared to be identical with the 1-bromotetrahydronaphthalene obtained by C. Smith on subjecting *ar*-tetrahydro- $\alpha$ -naphthylamine to the Sandmeyer reaction in the presence of hydrobromic acid and cuprous bromide; a specimen of the oily bromo-compound thus prepared also boiled at 260—265°.

The identity of the two products was further established in the following manner by the production of a definitely crystalline dinitro-compound.

*1-Bromodinitrotetrahydronaphthalene*.—Five parts of 1-bromotetrahydronaphthalene, obtained from tetrahydro- $\alpha$ -naphthylamine were suspended in 30 parts of cold concentrated sulphuric acid and treated with 3.5 parts of concentrated nitric acid (sp. gr. 1.4) mixed with 7 parts of concentrated sulphuric acid. A pale yellow substance was precipitated, the mixture was then poured on to ice, the precipitate collected, washed, and crystallised from light petroleum, when it separated in pale yellow, transparent plates or nodules; after two or three crystallisations from this solvent, the compound melted at 91°.

0.0992 gave 0.0622 AgBr. Br = 26.68.

0.2355 „ 20.1 c.c. moist nitrogen at 19° and 748 mm. N = 9.64.

$C_{10}H_9O_4N_2Br$  requires Br = 26.57; N = 9.30 per cent.

On repeating this nitration with the 1-bromotetrahydronaphthalene obtained from 4-bromotetrahydro- $\alpha$ -naphthylamine, a solid bromodinitrotetrahydronaphthalene was produced which melted at 91° and did not depress the melting point of the foregoing preparation.

As the proof of the constitution of 4-bromotetrahydro- $\alpha$ -naphthylamine depends on the foregoing results, it seemed desirable to ascertain the nature of the product obtained by nitrating the isomeric 2-bromotetrahydronaphthalene first obtained by C. Smith (this vol., p. 729).

*2-Bromodinitrotetrahydronaphthalene*.—2-Bromotetrahydronaphthalene, prepared from *ar*-tetrahydro- $\beta$ -naphthylamine by the Sandmeyer reaction in the presence of hydrobromic acid and cuprous bromide, was treated with a mixture of nitric and sulphuric acids as in the preceding experiment. The nitration appeared to take place less readily in this instance, the crude product being somewhat viscid. When repeatedly extracted with light petroleum (b. p. 40—60°), an uncrystallisable resin remained undissolved, whilst the solution deposited rosettes of well-defined, pale yellow needles which, when recrystallised from the same solvent, melted at 105—106°, softening slightly at 103°.

0.2387 gave 0.1517 AgBr. Br = 27.04.

0.0992 „ 8.3 c.c. moist nitrogen at 16° and 761 mm. N = 9.76.

$C_{10}H_9O_4N_2Br$  requires Br = 26.57; N = 9.30 per cent.

Mixtures of approximately equal parts of this dinitro-compound with its  $\alpha$ -isomeride melt at temperatures varying from 61—72°.

*Comparative Experiments on the Behaviour of 4-Bromotetrahydro- $\alpha$ -naphthylamine and 4-Bromo- $\alpha$ -naphthylamine towards Diazo-compounds.*

*Diazoamines derived from 4-Bromotetrahydro- $\alpha$ -naphthylamine.*

4:4'-Dibromo-1-diazo-1-aminotetrahydronaphthalene was obtained on condensing the hydrogenated base with its own diazonium chloride. Twelve grams of the powdered base were suspended in 19 c.c. of concentrated hydrochloric acid diluted with an equal volume of ice-cold water and treated with 3.6 grams of sodium nitrite in 10 per cent. solution. A solution of 12 grams of the base in glacial acetic acid was then added to the clear solution of the diazonium salt and the mixture treated with 18 grams of crystallised sodium acetate. The yellow diazoamine (20 grams) separated immediately and was subsequently crystallised from benzene; it separates from this solvent in orange-yellow needles and decomposes violently at 190—194°.

0.3872 gave 30.6 c.c. moist nitrogen at 17° and 757 mm.  $N = 9.14$ .

0.1949 „ 0.1562 AgBr.  $Br = 34.10$ .

$C_{20}H_{21}N_3Br_2$  requires  $N = 9.07$ ;  $Br = 34.50$  per cent.

The substance is almost insoluble in alcohol, acetone, or ethyl acetate. When treated with cold concentrated hydrochloric acid, the diazoamine slowly undergoes fission into its generators, but owing to its sparing solubility the decomposition occurs very slowly. About 0.6 gram of the substance was treated with an alcoholic solution containing 9 grams of hydrogen chloride; the solution was then diluted with water and filtered into an alkaline solution of  $\beta$ -naphthol, the insoluble azo-compound produced, when washed with acid and alkali and weighed, was found to represent 90 per cent. of the hydrolysed diazoamine, about 0.15 gram of the unchanged diazoamine being recovered.

The diazoamine does not develop a coloration with cold concentrated sulphuric acid, this result indicating the absence of any appreciable amount of the isomeric azo-compound in the substance; it is almost insoluble in this medium, and providing that the latter is kept in a dry atmosphere no fission takes place. On diluting the acid by pouring the mixture on to ice, the diazoamine is rapidly hydrolysed, yielding the soluble 4-bromotetrahydro- $\alpha$ -naphthalenediazonium sulphate and the sparingly soluble 4-bromotetrahydro- $\alpha$ -naphthylamine sulphate; the former was characterised by filtering the solution into an alkaline solution of  $\beta$ -naphthol, whilst the latter was identified by sub-

jecting the precipitate to the Schotten-Baumann reaction, when benzoyl-4-bromotetrahydro- $\alpha$ -naphthylamine was produced which melted at 202°.

4-Bromotetrahydro-1-naphthalene-1'-azo- $\beta$ -naphthol,

was also prepared from diazotised 4-bromotetrahydro- $\alpha$ -naphthylamine and  $\beta$ -naphthol in the ordinary way; it is sparingly soluble in alcohol, ethyl acetate, or acetone, and dissolves more readily in glacial acetic acid or pyridine, crystallising in red needles with a bronzy reflex.

0.1268 gave 8.4 c.c. moist nitrogen at 17° and 758 mm. N = 7.45.

0.3270 „ 0.1590 AgBr. Br = 20.70.

$\text{C}_{20}\text{H}_{17}\text{ON}_2\text{Br}$  requires N = 7.34; Br = 20.99 per cent.

This preparation, as well as those obtained from the fission products of the diazoamine, melted at 215°.

An attempt was made to transform the diazoamine into an isomeric aminoazo-compound by warming it at 70° with a mixture of 4-bromotetrahydro- $\alpha$ -naphthylamine and its hydrochloride, either alone or with pyridine as a solvent. Under these conditions, an azo-derivative could not be detected among the tarry products thus obtained.

*p*-Nitrobenzenediazo-1-amino-4-bromotetrahydronaphthalene,

was obtained by mixing a solution of *p*-nitrobenzenediazonium chloride (1 mol.), prepared in the ordinary way, with a glacial acetic acid solution of 4-bromotetrahydro- $\alpha$ -naphthylamine (1 mol.) and treating the mixture with excess of sodium acetate. The precipitated diazoamine was washed with water, dried, and crystallised from benzene; it separated in brownish-yellow leaflets and decomposed violently at about 178°.

0.1862 gave 24.3 c.c. moist nitrogen at 15° and 743 mm. N = 14.93.

0.3790 „ 0.1872 AgBr. Br = 21.02.

$\text{C}_{16}\text{H}_{15}\text{O}_2\text{N}_4\text{Br}$  requires N = 14.93; Br = 21.33 per cent.

*o*-Nitrobenzenediazo-1-amino-4-bromotetrahydronaphthalene, produced in exactly the same manner as the preceding compound, crystallised from benzene in orange-brown needles and decomposed violently at 170—175°.

0.0986 gave 13 c.c. moist nitrogen at 15° and 743 mm. N = 15.08.

0.1801 „ 0.0876 AgBr. Br = 20.70 per cent.

The isomeric *diazoamine* prepared from *m*-nitroaniline crystallised from benzene in orange-brown prisms and decomposed violently at 165—166°.

0.1666 gave 22.2 c.c. moist nitrogen at 17° and 742 mm. N = 15.09.  
 0.2052 „ 0.1016 AgBr. Br = 21.08 per cent.

The foregoing diazoamines from *o*- and *p*-nitroanilines dissolve in alcoholic alkali hydroxides to an intense bluish-crimson solution, whilst the *m*-isomeride develops a brownish-red coloration.

Diazobenzenesulphonic acid also yields with 4-bromotetrahydro-*a*-naphthylamine a pale yellow diazoamine which gives a crimson coloration in alcoholic potash.

*Coumarin-6-diazo-1-amino-4-bromotetrahydronaphthalene,*

was prepared in order to compare the action of diazotised 6-amino-coumarin on the tetrahydrogenated bromo-base with that of the same diazo-compound on 4-bromo-*a*-naphthylamine (see p. 751); on adding an excess of sodium acetate to an alcoholic solution of its generators, it is obtained as a pale yellow precipitate which is sparingly soluble in benzene and the other organic solvents. It separates in ill-defined, brownish-yellow, nodular crystals and decomposes at 165—168°.

0.1898 gave 16.5 c.c. moist nitrogen at 14° and 762 mm. N = 10.26.

$\text{C}_{19}\text{H}_{16}\text{O}_2\text{N}_3\text{Br}$  requires N = 10.55 per cent.

When warmed with concentrated hydrochloric acid, the foregoing diazoamines are all decomposed, evolving nitrogen.

#### *Azo-derivatives of 4-Bromo- $\alpha$ -Naphthylamine.*

The 4-bromo-*a*-naphthylamine required in the following experiments was prepared by brominating aceto-*a*-naphthalide with 1 molecular proportion of bromine in glacial acetic acid solution, crystallising the acetyl bromo-compound from the same solvent, and hydrolysing it by boiling with excess of 50 per cent. caustic potash solution in an open vessel until the product became quite oily. The base was then collected and crystallised from benzene and petroleum until it melted at 94—95°.

*4'-Bromo-1-naphthalene-2-azo-4-bromo- $\alpha$ -naphthylamine,*

was obtained most conveniently by diazotising 4-bromo-*a*-naphthylamine (2 grams), suspended in a mixture of 3.5 c.c. of concentrated hydrochloric acid and 75 c.c. of glacial acetic acid, the nitrite being in a 20 per cent. solution. To the clear brown solution thus obtained were added successively 2 grams of the original base dissolved in glacial acetic acid and 10 grams of hydrated sodium acetate, when the red azo-compound separated immediately. This substance does not crystallise readily from glacial acetic acid, ethyl acetate, or pyridine,

and is very sparingly soluble in alcohol; it was dissolved in benzene, and the solution, on spontaneous evaporation, deposited the azo-compound as a red powder which darkens at  $178^{\circ}$  and melts at  $181-182^{\circ}$ . Although the substance was not obtained quite pure, the analysis showed that it was an azo-derivative having the above formula. The percentages of nitrogen and bromine in the compound were found to be 10.51 and 33.81 respectively, whereas  $C_{20}H_{13}N_3Br_2$  requires  $N=9.45$  and  $Br=35.16$  per cent. The condensation was repeated in aqueous and pyridine solutions, but the results were even less favourable than the foregoing. This azo-compound develops an intense greenish-blue coloration with cold concentrated sulphuric acid.

*Coumarin-6'*: 2-azo-4-bromo-*a*-naphthylamine,

—6-Aminocoumarin (1 mol.) was diazotised in the ordinary way and the light brown solution of the diazonium chloride added to an alcoholic solution of 4-bromo-*a*-naphthylamine (1 mol.); a dark red precipitate was at once produced, and this became bright scarlet on adding excess of sodium acetate. The azo-compound is very insoluble in the ordinary solvents; it separates from glacial acetic acid in brownish-red nodules melting at  $240-241^{\circ}$ .

0.2574 gave 23.2 c.c. moist nitrogen at  $18^{\circ}$  and 762 mm.  $N=10.45$ .

0.1012 „ 0.486 AgBr.  $Br=20.44$ .

$C_{19}H_{12}O_2N_3Br$  requires  $N=10.65$ ;  $Br=20.30$  per cent.

With cold concentrated sulphuric acid, the azo-compound develops a brownish-red coloration.

*p*-Nitrobenzene-2-azo-4-bromo-*a*-naphthylamine,

when prepared by adding a dilute hydrochloric acid solution of *p*-nitrobenzenediazonium chloride (1 mol.) to a 2 per cent. alcoholic solution of the bromo-base, separates as a dark brownish-red precipitate which does not crystallise readily from the ordinary solvents. After one crystallisation from alcohol, it melted indefinitely at  $194-200^{\circ}$ , and when repeatedly crystallised from the same solvent it separated in dark reddish-brown crystals and melted sharply at  $201-202^{\circ}$ . In all probability this melting point is still too low, for both the isomerides of this azo-compound melt at higher temperatures, whereas the para-compound is usually the least fusible.

0.1470 gave 18.8 c.c. moist nitrogen at  $18^{\circ}$  and 754 mm.  $N=14.66$ .

0.1509 „ 0.0750 AgBr.  $Br=21.16$ .

$C_{16}H_{11}O_2N_4Br$  requires  $N=15.09$ ;  $Br=21.56$  per cent.

This compound develops a reddish-purple coloration with cold concentrated sulphuric acid.

*o*-Nitrobenzene-2-azo-4-bromo-*a*-naphthylamine, produced exactly like the foregoing compound, was crystallised successively from glacial acetic acid and benzene and was then obtained in well-defined, dark brown needles with a dark bronzy reflex; it melted at 219—220° and developed an intense purple coloration with cold concentrated sulphuric acid.

0.1309 gave 16.9 c.c. moist nitrogen at 13° and 762 mm.  $N = 15.30$ .

0.1902 „ 0.0952 AgBr.  $Br = 21.30$

$C_{16}H_{11}O_2N_4Br$  requires  $N = 15.09$ ;  $Br = 21.56$  per cent.

*m*-Nitrobenzene-2-azo-4-bromo-*a*-naphthylamine, was produced by diazotising *m*-nitroaniline in 15 per cent. aqueous hydrochloric acid and adding the diazo-solution to an alcoholic solution of the bromo-base (1 mol.), when the azo-compound separated at once as an amorphous, red precipitate. This product, when crystallised from pyridine, separated in minute, reddish-brown leaflets which were boiled repeatedly with alcohol to remove all traces of the basic solvent. The substance then melted at 246° and gave a brownish-red coloration with concentrated sulphuric acid.

0.2207 gave 28.6 c.c. moist nitrogen at 14° and 760 mm.  $N = 15.26$ .

0.4246 „ 0.2100 AgBr.  $Br = 21.06$ .

$C_{16}H_{11}O_2N_4Br$  requires  $N = 15.26$ ;  $Br = 21.56$  per cent.

The foregoing aminoazo-compounds are not decomposed on boiling for 1—2 hours with alcohol saturated with hydrogen chloride. The hydrochloride of the aminoazo-base is produced, and this, when separated and treated with ammonia, regenerates the original compound. The azo-derivative from *p*-nitroaniline, when subjected to this cycle of operations, still melted at 201—202°.

4-Bromo-*a*-naphthylamine-2-azobenzene-4'-sulphonic acid,

which was produced on adding diazobenzene-*p*-sulphonic acid suspended in water to an alcoholic solution of the bromo-base, separated immediately as a reddish-black precipitate, which on drying exhibits a bronzy-green reflex. A portion was converted into the sodium salt by warming with aqueous sodium carbonate, and the free acid, reprecipitated from the boiling solution, was thoroughly washed with water and dried, when it had a dark green colour. Although this substance was not further purified, an analysis of the precipitated colouring matter when dried in air, showed that it still contained bromine, and was therefore not formed by a replacement of this halogen by the diazo-group.

0.2371 gave 0.1229 AgBr.  $Br = 17.52$ .

$C_{16}H_{12}O_3N_3BrS$  requires  $Br = 19.7$  per cent.

This azo-sulphonic acid develops a red coloration with concentrated sulphuric acid, and when dyed on wool in an acid bath it furnishes a reddish-brown colour.

*Reduction of 4-Bromo- $\alpha$ -naphthylamine-2-azobenzene-4'-sulphonic Acid.*

The foregoing azo-colouring matter was dissolved in the calculated amount of sodium carbonate and the hot saturated solution of the sodium salt added gradually to a mixture of granulated tin and boiling alcoholic hydrochloric acid (1 vol. alcohol : 1 vol. concentrated acid); the azo-acid was set free and rapidly reduced, the clear brown solution being then concentrated to a small bulk and cooled. A crystalline product separated which was shaken up with excess of aqueous caustic potash and extracted with ether, the ethereal extract being decanted and filtered from the precipitated tin compounds. The ether was then removed on the water-bath, and the residual oil cooled in ice until brown crystals separated; these were extracted repeatedly with light petroleum (b. p. 40—80°). The petroleum extracts on cooling deposited light brown, nodular crystals, which did not contain bromine and melted at 94°. This substance was identified as naphthylene-1:2-diamine by the melting point, which was given by Lawson (*Ber.*, 1885, 18, 800) as 95—96°. Further confirmation was afforded by the formation of the diacetyl derivative, and the azine with phenanthraquinone. In preparing the diacetyl derivative, an excess of acetic anhydride was added to a portion of the ethereal extract from the products of reduction; the product rapidly separated in brownish-white crystals, and was recrystallised from alcohol, when it formed well-defined, colourless needles melting at 233—234°; Lawson (*loc. cit.*) gives the melting point as 234°.

The brown, nodular crystals of the diamine obtained on cooling the oily residue from the ethereal extract were mixed with a slight excess of hydrochloric acid, the dihydrochloride was partially dissolved in alcohol and boiled for 20 minutes with a glacial acetic acid solution of phenanthraquinone, the azine, which separated almost immediately as a brown, micro-crystalline deposit, was crystallised from benzene, and separated from this solvent in small, golden-yellow spangles with a brown reflex; it melted at 272—273°, this temperature being identical with the melting point given by Lawson (*Ber.*, 1885, 18, 2426). This azine dissolves in cold concentrated sulphuric acid to an intense peacock-blue solution, the colour of which is destroyed on dilution with water.

*Reduction of ar-Tetrahydro- $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic Acid.*

*ar*-Tetrahydro- $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic acid was prepared by adding an alcoholic solution of *ar*-tetrahydro- $\alpha$ -naphthylamine to diazobenzene-*p*-sulphonic acid suspended in cold water, when it separated in lustrous, yellow leaflets, which were converted into the sodium salt by the addition of sodium carbonate. The mixture was heated until the soluble sodium salt was dissolved, and then allowed to cool, when the salt crystallised in yellowish-brown leaflets. When dyed on wool in an acid bath, this azo-compound furnishes a bright orange colour quite unlike the chocolate shade produced by its analogue,  $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic acid.

A saturated solution of the sodium salt of the tetrahydronaphthalene derivative was slowly added to a mixture of tin and hot alcoholic hydrochloric acid and the reduction carried out precisely as in the preceding experiment. The crystalline product, obtained on concentrating and cooling the colourless solution, when rendered alkaline with strong aqueous caustic potash and extracted with ether, yielded a highly oxidisable base, which separated from the ethereal solution in colourless needles, rapidly turning green on exposure. The ethereal solution was accordingly treated with excess of acetic anhydride and the precipitated acetyl derivative crystallised from glacial acetic acid, from which solvent it separated in colourless needles melting at 291–292°. Bamberger and Schieffelin (*Ber.*, 1889, 22, 1377) gave 285° as the melting point of the diacetyl-*p*-diamine, and 245° as that of the diacetyl-*o*-diamine of the tetrahydronaphthalene series. The diamine obtained is in all probability the para-compound, for on oxidising a solution of its hydrochloride with warm chromic acid solution a quinone was produced; this substance was extracted with ether, the solvent evaporated, and the somewhat tarry residue extracted with light petroleum. The solution yielded yellow leaflets having the odour of benzoquinone and melting at 51°. These crystals were sublimed between watch glasses, when the quinone was obtained as a sublimate consisting of light yellow needles melting at 52–53°; the amount of material at our disposal did not admit of further purification. The melting point of tetrahydronaphthaquinone is given by Bamberger and Lengfeld as 55.5°.

A comparative reduction experiment carried out on  $\alpha$ -naphthylamine-4-azobenzene-4'-sulphonic acid confirmed the results previously obtained by Griess (*Ber.*, 1882, 15, 2192), the diamine extracted in the foregoing manner crystallised from light petroleum in grey needles and melted at 118–119°; the melting point of

naphthylene-1:4-diamine is given as  $120^{\circ}$ . The ethereal extract, when treated with acetic anhydride, yielded a precipitate of the diacetyl derivative which, after crystallisation from glacial acetic acid, separated in lenticular plates and melted at  $302-303^{\circ}$ , this being the melting point of the diacetyl derivative of the 1:4-diamine.

*ar-Tetrahydro- $\alpha$ -naphthylamine-4-sulphonic Acid,*  
 $\text{NH}_2 \cdot \text{C}_{10}\text{H}_9 \cdot \text{SO}_3\text{H}, \text{H}_2\text{O}.$

A mixture of 4 parts of *ar*-tetrahydro- $\alpha$ -naphthylamine and 5 parts of ordinary concentrated sulphuric acid were maintained at  $160-170^{\circ}$  until the dark liquid became viscid, the time required being about 30 minutes; the product was then stirred into crushed ice, the precipitated sulphonic acid being collected at the pump and washed free from sulphuric acid. A portion was crystallised from hot water, in which it is moderately soluble, the saturated solution being decolorised with animal charcoal; the acid separated from the cooled filtrate in colourless, transparent, acicular prisms which gradually assumed a pink tinge. An air-dried specimen was employed in the following analysis:

0.4264 gave 21.5 c.c. moist nitrogen at  $17^{\circ}$  and 740 mm.  $\text{N} = 5.69$ .

0.2138 „ 0.2039  $\text{BaSO}_4$ .  $\text{S} = 13.09$ .

0.6821, when dried for 5 hours at  $110^{\circ}$ , lost 0.050.  $\text{H}_2\text{O} = 7.34$ .

$\text{C}_{10}\text{H}_9\text{O}_3\text{NS}, \text{H}_2\text{O}$  requires  $\text{N} = 5.71$ ;  $\text{S} = 13.06$ ;  $\text{H}_2\text{O} = 7.34$  per cent.

The sulphonation was also effected with fuming acid containing 10 per cent. of sulphur trioxide, but no advantage is gained by the use of the stronger acid.

A portion of the sulphonic acid was suspended in warm water, treated with barium carbonate until effervescence ceased, and the filtered solution evaporated to small bulk, when the barium salt slowly separated in light brown, crystalline crusts. The analytical results for this salt were not satisfactory, but approximated to the composition of a salt  $\text{Ba}(\text{C}_{10}\text{H}_9\text{NSO}_3)_2, 3\text{H}_2\text{O}$ . The substance was accordingly converted into the sodium salt by the action of the calculated amount of sodium carbonate. The solution of the sodium amino-sulphonate after filtration from barium carbonate was carefully concentrated until crystallisation commenced. Analysis corresponded approximately with the formula  $\text{NH}_2 \cdot \text{C}_{10}\text{H}_9 \cdot \text{SO}_3\text{Na}, 2\text{H}_2\text{O}$ , but the salt was not obtained in a high state of purity.

*Diazotetrahydronaphthalene-4-sulphonic Acid.*

Four grams of the preceding aminosulphonic acid dissolved in a cold aqueous solution of sodium carbonate ( $\frac{1}{2}$  mol.) were treated suc-

cessively with 6.3 c.c. of concentrated hydrochloric acid and 1.3 grams of sodium nitrite (in 20 per cent. solution); the small, colourless crystals of the reprecipitated sulphonic acid were rapidly transferred into the opaque crystals of the diazo-compound which were collected at the pump. When freshly prepared, this diazo-acid gives a brilliant red, soluble azo-compound with sodium  $\beta$ -naphthol-3:6-disulphonate (R-salt), but when dried for several days on porous tile it loses this property and apparently undergoes some decomposition. Its reactions were accordingly studied in the moist condition. It closely resembles diazobenzenesulphonic acid, forming with  $\beta$ -naphthol an azo-colouring matter having tinctorial properties resembling those of naphthol-orange; with dimethylaniline, it yields a soluble aminoazo-compound which exhibits towards acids and alkalis the colour changes characteristic of methyl-orange. The former of the azo-compounds is produced in the ordinary way in aqueous solution, the formation of the latter takes place most readily in dilute alcohol.

*Tetrahydronaphthalene-1-sulphonic Acid from ar-Tetrahydro- $\alpha$ -naphthylamine-4-sulphonic Acid.*

The foregoing diazosulphonic acid, mixed into a paste with water, was slowly added to a cold solution of stannous chloride in equal volumes of water and concentrated hydrochloric acid; a thick, white precipitate of the corresponding hydrazo-compound was produced, the reaction being accompanied by a slight amount of frothing. The product, which was collected and washed with cold water, no longer gave an azo-colour with "R-salt," but reduced Fehling's solution even in the cold; it was then boiled with 20 per cent. copper sulphate until the blue coloration was permanent. The cuprous oxide was removed, the filtrate treated successively with hydrogen sulphide to eliminate copper, and with barium carbonate to remove sulphuric acid. The final filtrate, when concentrated considerably, yielded nodular crystals of *barium tetrahydronaphthalene-1-sulphonate*.

0.3378, when dried for  $2\frac{1}{2}$  hours at  $110^\circ$ , lost 0.0304.  $\text{H}_2\text{O} = 9.01$ .

$\text{Ba}(\text{C}_{10}\text{H}_{11}\text{SO}_3)_2 \cdot 3\text{H}_2\text{O}$  requires  $\text{H}_2\text{O} = 8.81$  per cent.

0.3076 (anhydrous salt) gave 0.1260  $\text{BaSO}_4$ .  $\text{Ba} = 24.08$ .

$\text{C}_{20}\text{H}_{22}\text{O}_6\text{S}_2\text{Ba}$  requires  $\text{Ba} = 24.50$  per cent.

*Tetrahydronaphthalene-1-sulphonic chloride*,  $\text{C}_{10}\text{H}_{11}\cdot\text{SO}_2\text{Cl}$ , was prepared by mixing the preceding barium salt with excess of phosphorus pentachloride, adding the product to cold water, and extracting the insoluble residue with light petroleum. The petroleum extracts yielded the sulphonic chloride in transparent, colourless plates melting at  $70.5^\circ$ . After hydrolysis with aqueous caustic potash:

0.1531 gave 0.095 AgCl. Cl = 15.35.

$C_{10}H_{11}O_2ClS$  requires Cl = 15.45 per cent.

A specimen of sodium naphthalene- $\alpha$ -sulphonate was likewise converted into sulphonic chloride, and the latter, after crystallisation from light petroleum, melted at 68—69° and depressed the melting point of the foregoing chloride to 45—47°, this result showing that in the sulphonation of *ar*-tetrahydro- $\alpha$ -naphthylamine, and in the subsequent reactions employed in the preparation of the sulphonic chloride, the hydrogenated nucleus does not lose its additional hydrogen atoms.

*Tetrahydronaphthalene-1-sulphonanilide*,  $C_{10}H_{11} \cdot SO_2 \cdot NH \cdot C_6H_5$ , produced on mixing warm ethereal solutions of aniline and the tetrahydronaphthalene-1-sulphonic chloride, is sparingly soluble in light petroleum, and separates in transparent, acicular crystals; it dissolves more readily in methyl alcohol, crystallising from this solvent in massive, transparent, vitreous prisms melting at 144—145°.

0.0518 gave 2.3 c.c. moist nitrogen at 16° and 767 mm. N = 5.21.

$C_{17}H_{17}O_2NS$  requires N = 4.90 per cent.

*Tetrahydronaphthalene-1-sulphonic Acid from ar-Tetrahydro- $\alpha$ -naphthylamine.*

*Tetrahydronaphthalene-1-sulphinic acid*,  $C_{10}H_{11} \cdot SO_2H$ .—Thirty grams of *ar*-tetrahydro- $\alpha$ -naphthylamine were dissolved in 150 grams of concentrated sulphuric acid and 450 c.c. of hot water, the solution rapidly cooled to -3°, and treated with 15 grams of sodium nitrite in 20 per cent. solution. The cooled mixture was rapidly filtered and thoroughly saturated with sulphur dioxide, copper powder made into a paste with water being then added. The sulphinic acid, which was partly dissolved and partly mixed with the copper precipitate, was extracted with ether, removed from the ethereal extract by means of aqueous sodium carbonate, and reprecipitated from the solution by dilute sulphuric acid. A portion was crystallised from water containing a little sulphurous acid, when it separated in colourless needles decomposing at 103—105°. The remainder (16.5 grams) was dissolved in aqueous caustic potash and the warm solution treated with 300 c.c. of 2 per cent. potassium permanganate; a little alcohol was added to reduce the excess of oxidising agent, the manganese oxides filtered off, and the filtrate evaporated to dryness.

A portion of the crude potassium salt was recrystallised and then dried at 150°, the anhydrous salt being analysed:

0.0857 gave 0.0292  $K_2SO_4$ . K = 15.28.

$C_{10}H_{11}O_3SK$  requires K = 15.60 per cent.

The remainder of the salt was converted into sulphonic chloride, the latter crystallising from light petroleum (b. p. 40—55°) in plates melting at 70·5°.

A portion was hydrolysed with aqueous caustic potash.

0·1688 gave 0·1035 AgCl. Cl = 15·16.

$C_{10}H_{11}O_2ClS$  requires Cl = 15·41 per cent.

This preparation did not depress the melting point of the sulphonic chloride obtained from *ar*-tetrahydro-*a*-naphthylamine-4-sulphonic acid after eliminating the amino-group.

A portion of the sulphonic chloride was converted into anilide, which crystallised from methyl alcohol in hard, transparent prisms with pyramidal or truncated terminations; it melted at 144—145° and did not depress the melting point of the anilide obtained in the manner indicated on p. 757.

*Action of p-Nitrobenzenediazonium Chloride on ar-Tetrahydro-a-naphthylamine-4-sulphonic Acid.*

A solution of *p*-nitrobenzenediazonium chloride prepared in the ordinary way was slowly added to a dilute aqueous solution of sodium tetrahydro-*a*-naphthylamine-4-sulphonate, a brownish-yellow precipitate separated which was filtered with some difficulty and could not be obtained crystalline. With alcoholic potash, it developed a deep purple coloration, in this respect resembling the other diazoamines derived from *p* nitroaniline. It was shown to contain diazo-nitrogen by heating with mineral acid contained in a flask fitted with an apparatus for measuring the gas evolved (compare Cain and Nicol, Trans., 1902, 81, 1412). About half a gram of the air-dried substance, when treated in this way with 50 per cent. sulphuric acid on the water-bath for 1 hour, evolved 6 per cent. of nitrogen, whereas the amount calculated from the formula  $NO_2 \cdot C_6H_4 \cdot N_2 \cdot NH \cdot C_{10}H_{10} \cdot SO_3H$  should be 7·03 per cent. As the specimen was by no means pure, and probably contained some unchanged aminosulphonic acid, this result indicates that the chief product of the action of a diazonium salt on *ar*-tetrahydro-*a*-naphthylamine-4-sulphonic acid is a diazoamine and not an aminoazo-compound.

LXXVI.—*The Action of Nitrosyl Chloride on Pinene.*

By WILLIAM AUGUSTUS TILDEN.

*Preparation of Pinene Nitrosochloride.*

IN the paper (J. Chem. Soc., N. S., 1877, 15, 554) in which, in conjunction with Mr. Shenstone, I first described the application of nitrosyl chloride to the purpose of classifying the terpenes, attention was drawn to the apparent connection between the optical activity of the hydrocarbon operated on and the yield of nitrosochloride. It was found that terpenes of high rotatory power gave a much smaller product than others apparently identical in other respects, but having less action on the polarised ray. Von Baeyer having shown (*Ber.*, 1895, 28, 648) that pinene nitrosochloride is a bimolecular compound with the formula  $(C_{10}H_{16} \cdot NOCl)_2$ , it occurred to me that the inferior yield of nitrosochloride by the more strongly rotating varieties of the hydrocarbon was due to the destructive effect of heat generated in the process of inversion of one-half of the compound as soon as formed, and that by using a mixture of *d*- and *l*-pinenes in due proportions the bimolecular compound would at once be produced by simple combination of the two semi-molecules without further change in either of them, and a larger product would result. This turns out to be the case.

When to pinene from American turpentine, diluted with half its volume of chloroform and cooled to about  $0^\circ$ , is added very gradually a solution of nitrosyl chloride in chloroform, an intense blue coloration is observed on the addition of each drop of the reagent. The colour quickly fades and a white, crystalline precipitate soon begins to form. A similar, though less intense, blue colour is produced when ethyl or amyl nitrite together with hydrochloric acid is employed, as in the process introduced by Wallach (*Annalen*, 1888, 245, 251). When the blue colour is no longer produced, the liquid diluted with about three times its volume of 84 per cent. alcohol yields a precipitate which, after being washed with alcohol and dried at about  $50^\circ$ , amounted in a series of experiments pretty uniformly to 31—32 per cent. of the pinene. The specimen used had a rotation of about  $+7^\circ$  in a 200 mm. tube.

When the *d*-pinene was replaced by *l*-pinene of greater rotatory power ( $-57^\circ 48'$  in 200 mm.), the yield was much less and never exceeded 20 per cent. of the pinene employed.

A specimen of pinene from the turpentine of *Pinus Khasyana*, which has a specially high rotatory power ( $+80^\circ 41'$  in 200 mm.), and probably

consists of nearly pure *d*-pinene, was then tried. The amount of nitrosochloride it could be made to yield was only 5.5 per cent. These results confirm the impressions derived from the experiments made in 1877.

An experiment was then made on an optically inactive mixture of the two last-named varieties of pinene, and it was found by the same process to yield 55.6 per cent. of its weight of nitrosochloride. When, in the process described, light petroleum is substituted for chloroform, no blue colour is at first produced on the addition of the nitrosyl chloride, and the yield of nitrosochloride is much smaller, but, with a view to economy, petroleum may be used in place of a portion of the chloroform. The process preferred is therefore as follows:

The pinene from ordinary American turpentine has usually a rotatory power about one-third of that of the corresponding hydrocarbon from French turpentine, but in consequence of the variation in different samples of these liquids it is necessary to distil from the commercial oils of turpentine the fraction boiling at 156—160°, to determine its rotatory power, and to mix the two liquids in exactly corresponding proportions. This inactive mixture of pinenes is then diluted with about two-thirds of its volume of petroleum (boiling at about 90—100°) and cooled to a few degrees below 0°. A solution of nitrosyl chloride in a mixture of equal volumes of chloroform and petroleum, saturated at 0° (which contains about 8 per cent. of its weight of NOCl), is then allowed to drop slowly from a tap-funnel into the liquid, which is kept in motion by a mechanical stirrer. The temperature should not be allowed to rise much above 0°. A green colour is at first developed, but this becomes bluer in shade as the chloroform accumulates in the mixture, and a white precipitate is soon copiously produced. The nitrosyl chloride is ultimately added in decided excess, and a quantity of alcohol is then added, equal to about  $1\frac{1}{2}$  times the total volume of the mixed liquids, and the whole left in the ice for half an hour. The precipitate is then collected at the pump, washed with alcohol, and dried, first by exposure to the air, then at about 50°.

The process in which amyl nitrite is mixed with the pinene diluted with glacial acetic acid and hydrochloric acid is allowed to drop into the cooled mixture is very convenient, but less productive. In my hands, using the same mixture of pinenes, it yielded only about 33 per cent. of the pinene employed. This appears to be explained by the fact that the theoretical amount of hydrochloric acid cannot be added without causing decomposition. The temperature can be kept below 0° without difficulty until about half the amount of acid has been introduced; effervescence then sets in, attended by a rapid rise of temperature.

In the course of trying variations of my process, one experiment led to a result which helps to explain this effect. Pinene was diluted with

three volumes of petroleum, and, with the object of avoiding the separate preparation of a solution of nitrosyl chloride, the gas was passed into a small quantity of ordinary strong hydrochloric acid, upon which the hydrocarbon floated as a separate layer. The whole was cooled below  $0^{\circ}$  and a white precipitate soon made its appearance. Ultimately a quantity of nitrosochloride corresponding with 14 per cent. of the pinene was collected. The aqueous acid became syrupy, and when diluted with a mixture of alcohol and water it gave a copious crystalline precipitate which, when collected, represented about one-third of the weight of the pinene, while a further quantity remained in the mother liquors. After recrystallisation from methyl alcohol, this compound was recognised as *i*-carvoxime hydrochloride (m. p.  $127-128^{\circ}$ ). Von Baeyer has observed that pinene nitrosochloride is changed into this compound by contact for three days with an ethereal solution of hydrogen chloride. In the circumstances described, however, the conversion is immediate.

In the process for the production of pinene nitrosochloride, the employment of aqueous hydrochloric acid appears to give rise to the same change. The effervescence which occurs can be accounted for by the hydrolysis of the carvoxime, whereby hydroxylamine is formed, which is immediately destroyed by the nitrosyl chloride with evolution of nitrous oxide.

#### *Properties of Pinene Nitrosochloride.*

The original statement (Tilden and Shenstone, J. Chem. Soc., N. S., 1877, 15, 556, and Wallach, *Annalen*, 1888, 245, 252) that the melting point of the nitrosochloride is  $103^{\circ}$  is incorrect. The fusion is accompanied by decomposition, and the temperature at which it occurs varies a little according to circumstances. The melting point of this compound when well washed with alcohol and thoroughly dried, but not recrystallised, is usually  $109-111^{\circ}$ . After recrystallisation from chloroform, it reaches  $115^{\circ}$ . The same compound is produced by the employment of inactive pinene regenerated from the nitrosochloride, as described later.

From whatever hydrocarbon prepared, the solution of the nitrosochloride in chloroform is optically inactive. It may be recrystallised from chloroform either by allowing the solution to evaporate at the temperature of the air, or by the addition of alcohol. It is advisable not to operate on more than a few grams at a time, and to avoid the application of heat. Fifty grams mixed with 250 c.c. of chloroform very gently warmed developed so much heat as to cause the liquid to boil, and, although cooled as quickly as possible, the whole was decomposed. The solution yielded on evaporation a red resin, together with a considerable quantity of nitrosopinene (m. p.  $129^{\circ}$ ).

If pure pinene nitrosochloride dissolved in chloroform is diluted with alcohol, the solution in a few hours assumes the orange-red colour developed in the mother liquors obtained in the ordinary process of preparation. This solution reduces Fehling's solution freely, and evidently contains hydroxylamine.

*Nitrosopinene and Pinyllamine.*

As the nitrosochloride is undoubtedly formed by the union of a dextro- and a lævo-compound, it seemed probable that nitrosopinene, which is produced from it by removal of  $2\text{HCl}$  and is monomolecular, might exist in two forms. Attention was long ago (J. Chem. Soc., N. S., 1877, 15, 557) drawn to the peculiarity of habit exhibited by the nitroso-compound prepared from certain specimens of *l*-pinene. Recent experiments, however, prove that when this variety is mixed with the same compound prepared from *d*-pinene, the melting point is not depressed, and that when the two varieties are dissolved in aqueous caustic soda, reprecipitated by acetic acid, and recrystallised from alcohol, both yield crystals of the same form as described by Maskeleyne (J. Chem. Soc., N. S., 1875, 13, 518). The nitrosopinene derived from *l*-pinene therefore probably owes the peculiarity originally observed to the presence of a trace of some unknown impurity.

Whether obtained from *d*- or from *l*-pinene, however, the crystals of nitrosopinene consist of a mixture of prisms which exhibit hemihedrism. I am indebted to Miss M. A. Whiteley, D.Sc., for kindly undertaking the task of separating a quantity of the *r*- and *l*-forms. The solution of one of them in alcohol was, however, optically inactive. Pinene benzylnitrolamine shows a similar phenomenon (Hintze, *Annalen*, 1889, 252, 131. See also Pope, *Trans.*, 1896, 69, 971, and Clare de Brereton Evans, *Trans.*, 1897, 71, 525 and 1001).

As it seemed hopeless to attempt the resolution of nitrosopinene into optically active isomerides by any process of crystallisation, it was reduced to pinyllamine and the base converted into its salts with optically active strong acids.

Reychler's *d*-camphorsulphonic acid and the *l*-oxime of the same and *d*-bromocamphorsulphonic acid, for which I am indebted to Professor Pope, were used. The camphorsulphonate was crystallised repeatedly from ethyl acetate. In another experiment, about  $2\frac{1}{2}$  molecules of pinyllamine nitrate were dissolved in water together with one molecule of ammonium camphorsulphonate, and advantage was taken of the slight solubility of pinyllamine nitrate to precipitate the base from the mixture in successive portions, leaving the elements of pinyllamine camphorsulphonate in solution.

The pinylamine *d*-bromocamphorsulphonate was recrystallised fractionally many times, first from ethyl acetate, and in another series of experiments from acetone. The base was in each case recovered from the most soluble and least soluble portions respectively, converted into hydrochloride and examined in the polarimeter, but no optical activity could be detected. As no formula has yet been proposed which will account for the disappearance of asymmetry from the molecule, ordinary pinylamine must still be regarded as probably consisting of a mixture of optical isomerides, notwithstanding that these attempts to resolve it have been unsuccessful.

*Action of Bases on Pinene Nitrosochloride.*

Wallach has already shown that primary fatty bases and benzylamine yield nitrolamines, but that aniline acting on the nitrosochloride regenerates pinene and forms aminoazobenzene. I have several times repeated this experiment, and find that the interaction with aniline proceeds slowly but completely in the cold, yielding the same products. The yield of pinene is, however, always small. I have found that methylaniline is a more advantageous reagent. Pinene nitrosochloride, heated gently together with two molecular proportions of methylaniline, diluted with about three times its volume of alcohol, dissolves quietly without any sign of the violent action which occurs when aniline is used. A slight excess of acetic acid may then be added and the liquid distilled in steam. The pinene separated from the first portions of the distillate, dried with caustic potash and distilled, amounts to about 63 per cent. of the theoretical quantity. The latter stage of the steam distillation gives phenylmethylnitrosoamine as the chief secondary product, a small quantity of a purple base remaining in the residue.

Dimethylaniline tried in similar proportions gave about the same yield of pinene. There was no spontaneous heating or evolution of gas, but the liquid assumed an intense green colour. This is due to the formation of the green hydrochloride of a purple base which gives Liebermann's reaction freely, and is not *p*-nitrosodimethylaniline.

Dimethyl-*p*-toluidine gave a similar result; the base formed gave Liebermann's reaction, but in this case no green colour was produced, the liquid assuming a deep yellow tint.

Pyridine behaves in a different way. In alcoholic solution, it produces no pinene, but only viscid products; in chloroform, it fixes hydrogen chloride and produces nitrosopinene.

The inactive pinene recovered by either of these operations from the nitrosochloride is very readily reconverted into that compound by the process I have described. It yields uniformly 55 per cent. of its

weight of nitrosochloride, an amount which is practically identical with the product obtained, as already stated, from an inactive mixture of *d*- and *l*-pinenes.

*Theoretical.*

The course of the action of nitrosyl chloride on pinene consists in the formation first of a simple nitrosochloride which, in solution, in common with nitroso-compounds in general, exhibits a blue colour. The union of two such molecules (*d* and *l*) gives rise to the colourless bimolecular or racemic compound  $(C_{10}H_{16} \cdot NOCl)_2$ , which, from its reactions with aromatic bases, evidently contains the elements of the chloride corresponding with nitrous acid.

The two semi-molecules are supposed by von Baeyer to be linked together by the two NO groups, which must be united by pentadic nitrogen,  $\begin{smallmatrix} \text{N} & \text{N} \\ | & | \\ \text{O} & \text{O} \end{smallmatrix}$ . This probably accounts for the disappearance of the blue colour when the compound is formed. Certain of the nitrolamines formed from the nitrosochloride by substitution of the basic residue for the chlorine are also stated by von Baeyer to be bimolecular.

Pinene benzylnitrolamine gave in my laboratory by the cryoscopic method the value 371 for the molecular weight, whilst the formula  $C_{10}H_{16} \cdot NO \cdot NH \cdot C_7H_7$  corresponds with 272.

On the other hand, the piperidylnitrolamine gave in one series of experiments 215, 209, and 214 as the value of the molecular weight. A second specimen gave 196 and 212. The simple formula  $C_{10}H_{16} \cdot NO \cdot NC_5H_{10}$  corresponds with 250.

Determinations of the molecular weight of the nitrosocyanide (Tilden and Burrows, Proc., 1902, 18, 161) gave 188 and 189, the formula  $C_{10}H_{16} \cdot NO \cdot CN$  requiring 192.

Hence it appears that when in the nitrosochloride the chlorine is replaced by cyanogen or by the piperidine residue, the compound becomes monomolecular and reacts as an oxime. The chlorine in the nitrosochloride therefore controls the hydrogen of the secondary carbon to which the NO group is attached, preventing the formation of the isonitroso-compound.

LXXVII.—*The Comparison of the Rotation-values of Methyl, Ethyl, and n-Propyl Tartrates at Different Temperatures.*

By THOMAS STEWART PATTERSON.

I HAVE recently had occasion to examine the rotations of methyl, ethyl, and *n*-propyl tartrates, and as the figures for these substances with reference to change of temperature present some features of interest, it seems worth while to collect the data here and briefly discuss them.

*Methyl Tartrate.*

Values for the rotation of methyl tartrate were given in a former paper (Trans., 1901, 79, 280), but the specimen used, owing to its method of preparation, was apparently contaminated either with ethyl tartrate or methyl ethyl tartrate, since the numbers given are consistently too high, as was noticed when the rotation of a fresh specimen, which had been carefully prepared and purified, was determined.

When methyl tartrate is first prepared, it is usually difficult to induce it to crystallise at all, although it may be pure so far as can be judged by its rotation or density. Indeed, for optical experiments, it is rather an advantage that it should remain liquid. When it does happen to solidify, however, it melts at 48·5—49° and can be crystallised repeatedly from benzene without any alteration of melting point. The specimen, the rotation values of which are given in the paper already cited, was prepared from ethyl tartrate by the action of methyl alcohol and hydrogen chloride, and was found to melt at 55—56°, although there was no doubt from the rotation and density that the substance was methyl tartrate.

The fresh preparation for which data are given below was made from the acid by the method of saturation with hydrogen chloride; it was distilled under diminished pressure, dissolved, when liquid, in benzene, and made to crystallise by adding a very small quantity of a specimen, the melting point of which was originally 55—56°, but which, when redetermined a year or more later, had risen to 59°. The crystals obtained were carefully dried and then redistilled under diminished pressure. The substance thus obtained melted at 61·5°, this value remaining unchanged after further crystallisation from

benzene. It may be noted too that methyl tartrate having this melting point can be crystallised from water. A specimen of methyl tartrate melting at  $48^{\circ}$  was fused on a watch glass and allowed to cool; a very minute crystal of the less fusible variety was added and stirred in with a glass rod. This caused the immediate separation of a solid, the melting point of which was  $61^{\circ}$ .

It thus appears that there are two solid forms of methyl tartrate, one of which melts at  $48^{\circ}$  and the other at  $61.5^{\circ}$ , the former, unstable, variety, as ought to be the case, being much more easily soluble in water and benzene than the latter.

The following table gives the rotation data for methyl tartrate melting at  $61.5^{\circ}$ , prepared in the foregoing manner. It solidified readily after having been fused, so that it was a little difficult to determine its rotation at the lower temperatures recorded.

*Rotation of Methyl Tartrate.*

Temperature.	$\alpha_D^{25}$ (100 mm.).	Sp. gr.	$[\alpha]_D^{25}$ .	$[M]_D^{25}$ .

\* Interpolated.

† Extrapolated.

The curve for methyl tartrate in the figure on p. 768 has been drawn from these data. It represents the variation of molecular rotation with change of temperature, and will be referred to in the sequel.

*Ethyl Tartrate.*

Data for the specific rotation of this substance have already been given in a previous paper (Trans., 1901, 79, 198), and from them the following values of molecular rotation have been calculated.

Temperature.	$[M]_D^{25}$ .	Temperature.	$[M]_D^{25}$ .
10.8°	+ 13.66°	46.1°	+ 21.10°
11.3	13.72	55.1	22.54
16	14.85	67.2	24.21
20.1	15.80	77.1	25.34
25.1	16.99	84.4	26.22
29.9	17.92	89.4	26.72
33.7	18.74	100	27.75
37.6	19.69		

The curve obtained from these data is also shown in the figure on p. 768.

#### *n*-Propyl Tartrate.

The *n*-propyl tartrate used in these experiments was prepared by mixing together tartaric acid and *n*-propyl alcohol in the proportion of one molecule to four, heating to about 70°, and passing in hydrogen chloride until all the acid had dissolved. The mixture was then allowed to cool, saturated with hydrogen chloride and the alcohol distilled off under diminished pressure. Fresh alcohol was added, saturation with hydrogen chloride repeated, the *n*-propyl tartrate distilled under diminished pressure and twice redistilled. It boiled at 171—172° (temp. of bath, 194—205°) under 17 mm. pressure.

#### *Rotation of n*-Propyl Tartrate.

Temperature .....	18.05°	39.75°	57.45°	77.96°
Sp. gr. observed.....	1.1394	1.1185	1.1013	1.0819

\* Interpolated.

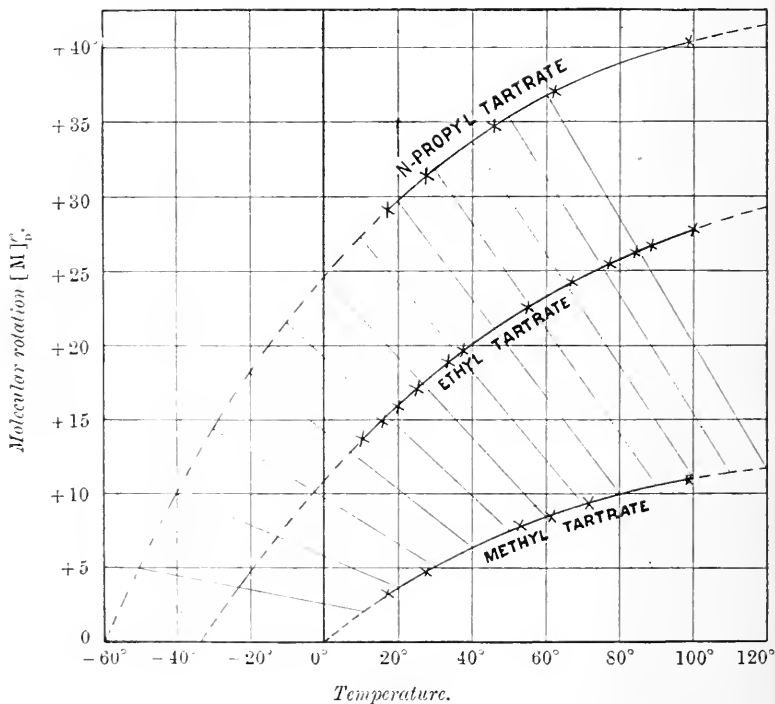

† Extrapolated.

Pictet (*Arch. phys. Nat.*, 1882, [iii], 7, 82) gives  $[\alpha]_D^{20} + 12.44^\circ$  and  $[\alpha]_D^{100} + 17.11^\circ$ , so that his preparation does not seem to have been so pure as that with which the above determinations were made.

The curve obtained from these data is also shown in the following figure.

*Comparison of Rotation Values.*

Passing now to a general consideration of these curves, we may, to begin with, confine our attention to the parts represented by full lines which cover the points experimentally determined. The rotations of these three substances all increase with rise of temperature, the gradient being greater at low temperatures than at higher ones. The increase in rotation, however, is neither the same nor regular. Thus the change in rotation of methyl tartrate between  $0^{\circ}$  and  $100^{\circ}$  is  $11^{\circ}$ , of ethyl

*Molecular rotations of methyl, ethyl, and n-propyl tartrates.*

tartrate  $16.9^{\circ}$ , and of *n*-propyl tartrate only  $15.85^{\circ}$ , whereas it might have been expected that in this respect, as in many others, the behaviour of ethyl tartrate would be intermediate between those of the methyl and *n*-propyl compounds.

Comparison of the rotations in other directions is no more satisfactory, as is at once seen when any attempt is made to discover quantitative regularities amongst the data obtained. This is obviously due to the great influence which change of temperature exerts in modifying the

rotations of the esters, and we are thus confronted with a problem of the first importance. At what temperatures may optically active substances be considered as comparable with each other as regards their rotation?

For many years the influence of change of temperature was almost completely ignored, and even at the present time rotation values are often stated without reference to this factor and in such a manner as to be quite useless for any purpose other than that immediately in hand. The importance of this variable having, however, been recognised, it is most natural as a first approximation to institute comparisons between the rotations of different compounds, the constants of which are all taken at one and the same temperature, but it should be carefully noticed that this convention is only adopted for want of some more satisfactory suggestion. Comparisons made under these circumstances—and a considerable number of data now exist for the purpose—tend chiefly to show that we have not yet hit upon the proper conditions for the discovery of regularities of any general application. This may be demonstrated by means of the following tables, the first of which gives the rotation values of the three esters at a number of different temperatures.

TABLE I.

	0°.	20°.	40°.	60°.	80°.	100°.	120°.
<i>n</i> -Propyl tartrate $[M]_D^{20} \dots$	24.65	29.66	33.73	36.80	38.97	40.57	41.65
Ethyl        ,,       ,, ...	10.80	15.95	20.00	23.25	25.80	27.70	29.20
Methyl       ,,       ,, ...	0.0	3.68	6.41	8.40	9.85	11.00	11.6

Amongst these figures we may institute, for illustration, several comparisons. By determining the ratio between the rotations of *n*-propyl and methyl tartrates, we obtain the following numbers:

TABLE II.

*Ratios of Rotations of n-Propyl and Methyl Tartrates.*

Temperature .....	0°	20°	40°	60°	80°	100°	120°
Ratio .....	$\infty$	8.06	5.26	4.38	3.96	3.69	3.58

Comparing the rotations of methyl and ethyl tartrates we have:

TABLE III.

*Ratio of Rotations of Ethyl and Methyl Tartrates.*

Temperature .....	0°	20°	40°	60°	80°	100°	120°
Ratio .....	$\infty$	4.33	3.12	2.77	2.62	2.52	2.51

For *n*-propyl and ethyl tartrates we find:

TABLE IV.

*Ratio of Rotations of n-Propyl and Ethyl Tartrates.*

Temperature .....	0°	20°	40°	60°	80°	100°	120°
Ratio .....	2.28	1.86	1.69	1.58	1.51	1.46	1.43

The above data are sufficient to show that the temperature at which any comparison of the rotations of active compounds is made is of fundamental importance, and that although some peculiarity might easily be discovered at one temperature, but little weight can be attached to it, since it is almost certain to disappear completely at some other temperature. Thus, whilst the rotation of *n*-propyl tartrate at 0° is 2.28 times as great as that of ethyl tartrate at the same temperature, it is only 1.43 times as great at 120°, the ratios in the other cases varying between much wider limits.

No greater constancy is found if, instead of seeking for a connection between the rotation values themselves, the differences between them are compared. This is shown in the following table, in which the upper line gives the differences ( $\Delta_1$ ) between the rotations of *n*-propyl and ethyl tartrates at the temperatures shown, whilst the lower one gives the differences ( $\Delta_2$ ) between those of ethyl and methyl tartrates, the ratios (*R*) between these numbers being added.

TABLE V.

	0°.	<i>R.</i>	20°.	<i>R.</i>	40°.	<i>R.</i>	60°.	<i>R.</i>
$\Delta_1$ ...	13.85°		13.71°		13.73°		13.55°	
$\Delta_2$ ...	10.80	1.282	12.27	1.117	13.59	1.010	14.85	0.913
	80°.	<i>R.</i>	100°.	<i>R.</i>	120°.	<i>R.</i>		
$\Delta_1$ ...	13.17°		12.87°		12.45°			
$\Delta_2$ ...	15.95	0.826	16.70	0.771	17.55	0.709		

It will be noticed that here  $\Delta_1$  gradually diminishes, whilst  $\Delta_2$  increases, with rise of temperature; obviously, therefore, the ratio of the differences also becomes less. At 0° then and at any temperature up to 41°, the replacement of two methyl by two ethyl groups produces a greater change of rotation than the replacement of two ethyl by two *n*-propyl groups; at higher temperatures the opposite is the case, whilst at 41° the changes thus brought about are equal.

It will be clear from what has been said that before any quantitative connection can possibly be discovered between optical activity and chemical constitution, some method must be found of eliminating the disturbing influence of change of temperature. Relationships between the rotations of active substances, to be of value, must be independent of temperature, as would be the case were specific rotation really a

constant, as originally supposed. The convention of making comparisons at identical temperatures is the only one which has hitherto been tried. It is obviously very unsatisfactory, and it remains now to consider whether any suggestion leading to better results can be made.

We may set out from the axiom that satisfactory comparisons can only be instituted between the properties of substances which are in corresponding conditions, and since it must indeed be highly exceptional that two substances, other than perfect gases, can be comparable at the same temperature and pressure, the absence of regularities dealt with above is really not surprising. That the physical properties of chemical compounds are not generally comparable at the same temperature has of course been recognised for many years. Kopp took account of this fact when he showed that greater regularity could be discovered regarding molecular volume when the constants were determined at the respective boiling points of the compounds examined, rather than at one definite temperature, and this mode of comparison has received its justification and an extended application in the general form of van der Waals' equation. Whether, in point of rotation, optically active substances would be comparable at equal fractions of the critical constants, it is difficult to say. If the suggestion made below be correct, this would probably not be so, but, however that may be, since critical constants are not easily determined, it becomes necessary in the present instance to seek for some other criterion of correspondence, and a consideration of the diagram on p. 768 furnishes an idea which may be of importance in this connection.

It is obvious from the figure that the rotation of methyl tartrate would vanish at, or near,\*  $0^{\circ}$ , whilst below this temperature it would be negative. If now the ethyl tartrate curve is similarly continued towards the left, an extrapolated value can be found for the temperature at which its rotation also would disappear, but since the extrapolation has to be carried out through a greater distance than before, the value found will be correspondingly less exact, and doubtless liable to an error of several degrees. When the curve is drawn by the aid of a fairly long piece of steel held at the ends so as to avoid too sudden changes of curvature, it cuts the zero abscissa at a point corresponding with a temperature of  $-34^{\circ}$ , and this number has been adopted for the purposes of the following argument. In a similar way, the curve for *n*-propyl tartrate may be produced, and is found to cut the zero axis at  $-60^{\circ}$ , the probable error in this case being still greater than for ethyl tartrate. All three curves have also been extrapolated in the opposite direction up to  $120^{\circ}$ , which can be done with greater certainty.

\* Within one degree

We are not far wrong then in assuming that methyl tartrate becomes inactive at  $0^\circ$ , ethyl tartrate at  $-34^\circ$ , and *n*-propyl tartrate at  $-60^\circ$ ; these molecules, at the temperatures named, lose their asymmetry so far as it is revealed by its effect on polarised light,\* and in this we seem to find the required criterion. It appears rational and legitimate to assume that the molecules of the different substances at those temperatures at which their rotations vanish are in corresponding optical states, although this may not be the same thing as correspondence in the sense of van der Waals' equation, and this appears to be the solitary point which the subject presents for attack. Setting out then from the assumption that since methyl, ethyl, and *n*-propyl tartrates are inactive, and therefore in corresponding optical states, at  $0^\circ$ ,  $-34^\circ$ , and  $-60^\circ$  respectively, it may be assumed, as a first approximation, that the rotations of methyl tartrate at  $T^\circ$ , ethyl tartrate at  $(T-34^\circ)$ , and *n*-propyl tartrate at  $(T-60^\circ)$  are directly comparable.

The following tables, each of which is analogous to one of those previously referred to, give the results of comparisons based on this idea, but with a very slight modification.

The data in Table VI have been obtained by selecting points on the methyl tartrate curve  $10^\circ$  apart, from which lines have been drawn to intersect the *n*-propyl tartrate curve at temperatures  $60^\circ$  lower. These lines cut the ethyl tartrate curve, and the three points of intersection are assumed to correspond as regards temperature and rotation.

To follow the guiding idea completely, it would be necessary to select points on the ethyl tartrate curve exactly  $34^\circ$  below those taken on the methyl tartrate curve, but the above construction almost realises this; it gives, indeed, slightly better results, and is in the meantime quite as good a basis of calculation, inasmuch as the two fundamental temperatures for the ethyl and *n*-propyl esters are not accurately known.

TABLE VI.

	1.			2.		
	$t^\circ$ .	$\Delta_{t^\circ}$ .	$[M]_D^\circ$ .	$t^\circ$ .	$\Delta_{t^\circ}$ .	$[M]_D^\circ$ .

Methyl „ .....	+110		11.35	+120		11.65	

In the above table, each group of figures is denoted by a numeral, and when any compound is cited as belonging to one of these groups the temperature stated must be understood. With regard to these data, attention may, in the first place, be directed to the temperature differences. The temperature difference for *n*-propyl and methyl tartrates is of course always 60°, whilst those between *n*-propyl and ethyl tartrates and between ethyl and methyl tartrates vary a little and are given in the  $\Delta t$  column. It must be noted that the numbers given in groups 1, 2, 3, and even in 4, since they are taken from the extrapolated parts of the *n*-propyl and ethyl tartrate curves, cannot claim the same accuracy as those in the later groups. Nevertheless,  $\Delta t$  varies only 2° in the groups 4 to 12, the mean values being 26° between the *n*-propyl and ethyl, and 34° between the ethyl and methyl compounds, so that the variation is only 1° on either side of the mean, which has thus the value we assumed as a starting point.

The increase of rotation which these three esters undergo between two given temperatures, namely, 0° and 100°, was shown on p. 769 to be irregular. Taking another similar example, we find that between 60° and 120° the rotation of methyl tartrate increases by 3.2°, whilst between the same temperatures the increase for ethyl tartrate is 6° and for *n*-propyl tartrate 4.8°. From what has been said above, however, it is probable that the change in rotation of methyl tartrate between 60° and 120° should be compared with the change in ethyl tartrate between 26.7° and 85° and with that in *n*-propyl tartrate between 0° and 60°, and the three increments between these corresponding temperatures, namely, 3.2°, 8.85°, and 12.15°, stand at least in the order which might *a priori* be expected.

Taking now the rotation ratios in order to compare them with those in Table II, we obtain :

TABLE VII.

*Ratios of Rotations of n-Propyl and Methyl Tartrates at Corresponding Temperatures.*

Group :	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.
Ratio :	2.79	2.74	2.79	2.84	2.87	2.93	2.97	3.01	3.05	3.07	3.11	3.16

It is obvious at once that this is a great improvement on Table II, in which the ratios varied from  $\infty$  to 3.58, and it would appear that when propyl and methyl tartrates are in corresponding optical conditions the rotation of the former is approximately 2.95 times that of the latter.

Comparing in the same manner the rotations of ethyl and methyl tartrates we obtain :

TABLE VIII.

*Ratios of Rotations of Ethyl and Methyl Tartrates at Corresponding Temperatures.*

Group :	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.
Ratio :	2.05	1.96	1.98	1.99	2.03	2.08	2.10	2.14	2.17	2.18	2.20	2.26

Here again there is only a slight alteration in the value of the ratio, and we may say that the rotation of ethyl tartrate is rather more than twice as great as that of methyl tartrate when the constants are taken at corresponding temperatures.

Again, comparing the rotation values of *n*-propyl and ethyl tartrates, we obtain :

TABLE IX.

*Ratios of Rotation of n-Propyl and Ethyl Tartrates at Corresponding Temperatures.*

Group :	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.
Ratio :	1.36	1.40	1.41	1.42	1.41	1.41	1.41	1.41	1.41	1.41	1.40	1.40

In this case, the agreement is still better, and at corresponding temperatures the rotation of *n*-propyl tartrate is 1.41 times that of ethyl tartrate.

Finally, we may examine the ratios of the differences of the rotations at corresponding temperatures for comparison with Table V. We obtain then,  $\Delta_1$  being the difference between the rotations of *n*-propyl and ethyl tartrates and  $\Delta_2$  that between the rotations of ethyl and methyl tartrates, and R being the ratio of  $\Delta_1$  to  $\Delta_2$ , the following :

TABLE X.

Group:	3.	R.	5.	R.	7.	R.	9.	R.	11.	R.
$\Delta_1$ .....	4.2	0.833	6.27	0.811	7.98	0.786	9.18	0.753	10.15	0.733
$\Delta_2$ .....	5.04		7.73		10.15		12.20		13.85	

In this case, the ratio does not remain quite constant, but the variation is much less than that shown in Table V, where the alteration was from 1.282 to 0.709 within the same range of temperature. The foregoing variation is also linear, and therefore might easily be allowed for if necessary.

It will doubtless be admitted from what has been said that the method of comparison suggested presents considerable advantages, and it is only necessary to draw attention to one other point in its favour. It has already been shown that when comparisons are made at identical temperatures the ratios of the rotations can have very various values, so that at  $0^\circ$  the ratios of the rotations of both *n*-propyl and ethyl tartrates to that of methyl tartrate will be positive and infinite, becoming negative at a slightly lower temperature; at  $-34^\circ$ , when the rotation of ethyl tartrate vanishes, the rotation of *n*-propyl tartrate is positive and infinitely great compared with that of the ethyl ester, whilst the rotation of methyl tartrate is negative and infinitely great compared with the same standard; at  $-60^\circ$ , the rotations of both methyl and ethyl tartrates are negative and infinitely great compared with that of *n*-propyl tartrate.

The method of comparison suggested above eliminates difficulties of this kind. The ratios which have been shown to exist at higher temperatures persist not only down to the point where all the rotations simultaneously become zero, but, since by taking corresponding temperatures all the rotations become negative at the same time and not one after another, they would presumably hold even for still lower temperatures.

It will also be noticed, if the figures in Tables II and VII, III and VIII, IV and IX are compared, that the ratios of each pair tend at higher temperatures towards the same limiting value. This is, of course, owing to the fact that at higher temperatures the curvature in each case diminishes, and if these curves become, above  $120^\circ$ , practically horizontal straight lines, the ratios obtained at identical temperatures would become the same as those obtained at corresponding temperatures. This would seem to show that for analogous substances at least a true estimate of the effect of chemical constitution on rotation may be derived by direct comparison of rotations at one temperature provided that the curves in the neighbourhood of that temperature are almost horizontal.

It remains to be seen whether this idea is capable of extension. It will be applied in some other simple cases, and for that purpose data are at present being collected.

#### SUMMARY.

1. It is shown that methyl tartrate is capable of existence in a solid form melting at  $61.5^{\circ}$ .

2. Data for the variation of rotation with change of temperature of methyl, ethyl, and *n*-propyl tartrates are given.

3. It is shown that comparisons of these data at identical temperatures are of little value, especially at low temperatures.

4. Since the rotations of methyl, ethyl, and *n*-propyl tartrates vanish at  $0^{\circ}$ ,  $-34^{\circ}$ , and  $-60^{\circ}$  respectively, it may be assumed that these substances are in corresponding optical conditions at these temperatures, and in general that at  $T^{\circ}$ ,  $(T-34^{\circ})$ , and  $(T-60^{\circ})$  the methyl, ethyl, and *n*-propyl esters will also be in corresponding conditions as regards rotation.

5. It is shown that comparisons effected at corresponding temperatures are much more satisfactory than those obtained at identical temperatures.

6. If the rotations are taken at corresponding temperatures, the increment of  $2\text{CH}_2$  in passing from methyl to ethyl tartrate rather more than doubles the rotation, whilst the next increment of  $2\text{CH}_2$  in passing to *n*-propyl tartrate increases the rotation 1.41 times. The rotation of *n*-propyl tartrate is therefore almost three times that of methyl tartrate.

7. These regularities persist within wide limits of temperature.

## LXXVIII.—*A Revision of the Atomic Weight of Rubidium.*

By EBENEZER HENRY ARCHIBALD.

THE results obtained from the investigation of the atomic weight of caesium (Richards and Archibald, *Proc. Amer. Acad. Arts and Sciences*, 1903, 38, 443) seemed to show that the analysis of the chloride, bromide and nitrate of this element could be carried out with considerable accuracy. It was thought that the methods elaborated for the analysis of the caesium salts could be applied

with almost equal advantage to the case of the salts of rubidium. If then pure rubidium compounds could be prepared, it would be desirable to subject the atomic weight of this element to the same rigorous test which had been applied in the case of caesium.

*Review of Earlier Investigations.*

Bunsen, who first determined the atomic weight of rubidium (*Poggendorff's Ann.*, 1861, 113, 339), estimated the amount of silver chloride precipitated by a weighed amount of rubidium chloride, and his weighings, when corrected for air displacement, gave the following values for the atomic weight of rubidium: 85·36, 85·36, 85·59, 85·28, giving a mean value of 85·40, these being calculated on the basis of  $O = 16$ , with  $Cl = 35·455$  and  $Ag = 107·93$ .

To remove traces of potassium, Bunsen precipitated his rubidium several times as the platinichloride. Whilst this treatment would eventually remove the potassium, it would nevertheless require a very large number of precipitations.

The next observer to study the atomic weight of rubidium was Piccard (*J. pr. Chem.*, 1862, 86, 454; *Zeit. anal. Chem.*, 1862, 1, 519), who used the same methods of purification and analysis as those employed by Bunsen, but appears to have subjected his rubidium carbonate to many more fractionations with alcohol in order to get rid of any trace of caesium; this treatment would tend to raise the percentage of potassium present, whereas, as already indicated, the previous precipitations as the platinichloride would hardly be sufficient to remove the last traces of this metal.

Moreover, in correcting the observed weights of silver chloride, this experimenter assumed that the portion of the precipitate finally adhering to the filter was entirely reduced to silver during ignition, and as total reduction is highly improbable this assumption may have vitiated the results to an appreciable extent. The results of Piccard's four determinations gave a mean value of 85·44 ( $O = 16·0$ , &c.).

In 1876, Godeffroy (*Ann. Chim. Pharm.*, 1876, 181, 185) published the results of four determinations of the chlorine in rubidium chloride, the method of analysis being practically the same as that used by the earlier investigators. His method of purifying the rubidium material was based on the work of Redenbacher (*Sitzungsber. Wiener Acad.*, 1865, 51, 247), who pointed out the difference in solubility of the alums of rubidium and caesium, and showed how this fact might be made use of in separating these elements. As the caesium alum is the less soluble, the impossibility of getting rid of the last trace of caesium from a sample of rubidium alum by recrystallisation is apparent; and this might account for the higher values obtained

by this observer. His analysis gave the mean value of 85.50 ( $O = 16.0$ ). The results of a number of analyses of rubidium chloride and bromide were published by Heycock (*British Association Report*, 1882, 499), but as the details regarding his experiments were not given, one cannot form an opinion as to their accuracy. He found the ratio of silver to rubidium chloride and of silver to rubidium bromide. The mean of seven analyses of the chloride gave the ratio  $Ag : RbCl :: 107.93 : 120.801$ , indicating an atomic weight for rubidium of 85.344. From the analysis of the bromide, the ratio found was  $Ag : RbBr :: 107.93 : 165.390$ , or an atomic weight of 85.389.

If an average is taken of the mean results calculated from the data given by the earlier investigators, the value 85.42 is obtained.

### *The Analysis of Rubidium Chloride.*

In preparing a pure salt of rubidium from material which contains traces of both potassium and caesium, one must keep in view the relation of rubidium to these two elements. As regards the properties of its compounds, it stands midway between potassium and caesium, and any treatment which will lower the proportion of one in the material may tend to increase the percentage of the other. For example, when the last traces of potassium have been removed from a rubidium compound by recrystallisation, the rubidium compound being more insoluble than the corresponding compound of potassium, then if any caesium was originally present, the final portion of rubidium salt will contain a much higher percentage of this impurity. It is also evident that a rubidium compound free from caesium cannot be prepared by taking a middle portion from which several fractions of crystals have been deposited, as the mother liquor from these crystals will always contain a quantity of caesium, depending on the solubility of the caesium salt in this medium. It will therefore be necessary to convert this salt into that of another acid, the rubidium salt of which is less soluble than the caesium; recrystallisation of this compound will then give a rubidium compound practically free from caesium.

This principle was kept in view in the preparation of the pure rubidium salts. The material used was rubidium iodide obtained from two sources, one specimen coming from Haen, of List, Germany, the other from Eimer and Amend, of New York. Whatever be their origin, these samples differed to a considerable extent as regards purity; the former containing a large percentage of potassium and traces of caesium, whilst the latter was spectroscopically free from both these metals.

It was thought that the best method of removing the potassium from the rubidium material would be by recrystallising one of the trihalide salts. This method has been suggested and used by Wells

(*Amer. J. Sci.*, 1901, [iii], 43, 17; *Chem. News*, 1901, 84, 2184), and was found to give very pure material in the case of caesium. As the rubidium dichloriodide is nearly ten times less soluble than the corresponding potassium compound, and crystallises quite readily on cooling a saturated solution, this salt was first tried. About 150 grams of the German sample of rubidium iodide was converted into the dichloriodide and subjected to many fractional crystallisations. An approximately equal amount of the New York sample, which showed in the spectroscope no indication of the presence of potassium or caesium, was also converted into this salt, and likewise recrystallised. After each crop of crystals had been separated from their mother liquor, they were carefully drained and washed with a little aqua regia. The iodine, a little of which had to be added during these fractionations, had been carefully resublimed.

When ten crystallisations had been made of the first portion of salt, 35 grams were set aside for treatment which would remove the caesium present. It was noted that after five crystallisations the potassium line could not be found in the spectrum of the salt when a good single prism spectroscope was employed, and hence the five subsequent fractionations should give a salt practically free from this impurity; nevertheless, after the 35 grams had been removed, the remainder was thrice recrystallised, and the product converted into another salt in order to remove the caesium.

As another test for the presence of potassium, the mother liquors from the last four fractionations of the dichloriodide were combined, the trihalide salt converted into the normal chloride, and fractionated by precipitating with hydrochloric acid, but no potassium could be detected in the final precipitate.

The second 150 grams of rubidium iodide were treated like the first sample, except that, as the salt was purer at the beginning, only eight crystallisations were made before a portion was set aside, and the remainder received three additional crystallisations. The portion which had been fractionated eleven times gave a very faint caesium line when tested in the spectroscope, whereas the caesium lines could not be found in the original salt or even in the sample which had been fractionated eight times.

It will be seen that four different samples of rubidium dichloriodide have thus been obtained. If the potassium has not been entirely removed from the portion which has received the least number of recrystallisations, it will be present in different proportions in all four samples, and therefore, if all are treated in the same manner when removing the caesium, four different values for the atomic weight of rubidium should be obtained on analysis, the first portion giving the lowest value and the last the highest.

The removal of the caesium was the next point to be considered. Whereas the methods used by Bunsen and Godeffroy for separating rubidium and caesium can be employed with advantage in preparing pure caesium material, they are not suitable for removing the last traces of caesium from a rubidium salt; Johnson and Allen (*Amer. J. Sci. and Arts*, 1863, [ii], 35, 94), however, have shown that rubidium hydrogen tartrate is about eight times less soluble than the caesium salt, and fractional recrystallisation of this salt should therefore remove all traces of caesium.

It was also thought advisable to see whether the caesium could not be removed by precipitating the chlorides with hydrochloric acid. As the rubidium chloride is much less soluble in hydrochloric acid than the caesium chloride, this might prove a simple and convenient method of removing this impurity. For this purpose, the two portions of dichloriodide first prepared, which had been recrystallised eleven and eight times respectively, were converted into the normal chloride by heating in a porcelain basin in an electric drying oven at a temperature of  $75^{\circ}$  until all the iodine and excess of chlorine had been expelled. These preparations were then dissolved separately in platinum basins in the least amount of hot water, and precipitated with hydrogen chloride, generated by boiling a moderately concentrated hydrochloric acid solution. The salt which separated was washed on a platinum Gooch crucible with a little hydrochloric acid, redissolved in water, and again precipitated. This process of precipitation was repeated ten and fifteen times respectively for the above samples of salt; the portion which, as the dichloriodide, had been recrystallised eight times was now reprecipitated fifteen times, whilst the portion which had received eleven recrystallisations as the trihalide salt was reprecipitated ten times with hydrogen chloride. These two fractions of rubidium chloride will be referred to as samples I and II. It is evident that from the treatment sample I has received, both as the trihalide salt and also when precipitated as the chloride, it should contain the higher percentage of potassium; whilst according to the same reasoning a greater percentage of caesium should be found in sample II.

The tendency for the formation of the platinichloride when the chloride is in contact with platinum in the presence of an excess of hydrochloric acid is not so marked here as in the case of caesium; nevertheless, the temperature was not allowed to rise above  $60^{\circ}$  or  $70^{\circ}$  when precipitating with hydrogen chloride.

The two other portions of rubidium dichloriodide referred to above were treated differently for the removal of the caesium present. After converting them into the normal chloride in the same manner as before, each portion was dissolved in water and evaporated with pure redistilled sulphuric acid. Barium hydroxide, which had been repeatedly crystal-

lised, was then added to the solution of rubidium sulphate, until only a trace of sulphuric acid remained. After the barium sulphate, tartaric acid was added in double the quantity necessary to neutralise the rubidium hydroxide, when crystals of the hydrogen tartrate at once separated. The tartaric acid employed, which had been crystallised several times, was perfectly free from ammonia, and left no residue on ignition.

The portion of the hydrogen tartrate which had separated was now fractionally crystallised five times, then converted into the chloride, precipitated twice with hydrogen chloride, and set aside for analysis. This fraction will be referred to as sample III. The second portion of the hydrogen tartrate, which received eight fractional crystallisations, was then converted into the chloride and precipitated with hydrogen chloride. This treatment furnished sample IV.

While these fractionations for the removal of the caesium were being carried out, portions were tested from time to time by means of the spectroscope to ascertain whether the treatment was having the desired effect. In the case of samples I and II it was found that after four precipitations as the chloride the caesium lines had entirely disappeared from the spectrum, although they were quite distinct when the original sample of chloride was tested. After two crystallisations as the hydrogen tartrate, the caesium lines were no longer present in the spectrum of portions of sample IV, but in this case the percentage of caesium present in the original salt was much smaller.

The last three mother liquors from each of all these samples were evaporated to dryness, the residues converted into the dichloriodide, and repeatedly fractionated by recrystallising, until a very small quantity remained. Portions from each of these four end-products, when examined in the spectroscope, did not exhibit any caesium.

It would seem that a few more fractionations—perhaps in the ratio of three to two—are required when the caesium is being removed from the rubidium compound by precipitating the chloride with hydrogen chloride, than when the separation is effected by recrystallising the hydrogen tartrate, but the ease with which the former process can be carried out will often render it preferable, whilst there is much less likelihood of introducing impurity.

Shortly, we have now four samples of rubidium chloride to be analysed. The first two, prepared from the German salt, have been crystallised ten and fifteen times as the dichloriodide, and fifteen and ten times respectively as the chloride. The last two preparations, from the salt obtained in New York, have been crystallised eight and eleven times as the dichloriodide, and eight and five times respectively as the hydrogen tartrate.

The method of preparing the silver was practically the same as that

pursued by Richards and Parker (*Proc. Amer. Acad.*, 1896, 32, 55) in their investigation on the atomic weight of magnesium. After precipitating the silver as chloride, the precipitate was thoroughly washed with several litres of distilled water, treated for several days with aqua regia, and then reduced with a solution of invert sugar and sodium hydroxide. After thorough washing, the reduced silver was redissolved in nitric acid, reprecipitated, and washed as before, and then, having been reduced from the chloride and again washed, fused on sugar charcoal before the blow-pipe. A portion of this fused silver was now dissolved in nitric acid, the excess of acid removed, the silver nitrate dissolved in water, and the solution diluted until it contained about twenty per cent. of silver. The greater part of the silver was deposited electrolytically from this solution, using a very weak current, when silver crystals of considerable size were obtained. The anode was wrapped in filter paper to prevent the anode dust from contaminating the rest of the solution.

The silver crystals were now removed from the solution, thoroughly washed, and fused in a boat made by igniting a mixture of pure lime and anhydrous calcium nitrate. The fused silver was cut into pieces of the proper weight with a clean steel chisel, and these, after successive treatment with hydrochloric acid, ammonium hydroxide, and nitric acid, were kept under distilled water.

The acids used were carefully redistilled, rejecting the first and last portions of the distillate; the nitric acid was always tested in the nephelometer for the presence of chlorine ions (Richards, *Proc. Amer. Acad.*, 1894, 30, 385).

The water used in this research, which had been redistilled and condensed in block tin vessels, had a very low electrical conductivity, and showed no evidence of the presence of ammonium compounds or chlorides.

#### *Method of Analysis.*

It has been shown by Richards (*Proc. Amer. Phil. Soc.*, 1903, 42, 28, 42, 172) that the fusion of such a salt as rubidium chloride is necessary before one can be certain that the last traces of moisture have been expelled. It has also been shown by Johnson and Allen (*loc. cit.*) that fusion of caesium or rubidium chloride in a moist atmosphere was likely to cause decomposition; as in their analysis of caesium chloride, where the fusion took place in the air of the laboratory, a solution of the fused salt was always found to be slightly alkaline. In the present instance, the fusion of the substance was effected in an atmosphere of pure dry nitrogen, the product being subsequently bottled in an atmosphere of dry air. To secure the first conditions, air was forced through a strong solution of ammonia, then over heated copper, and the

resulting nitrogen passed successively through dilute sulphuric acid, two wash-bottles containing strong sulphuric acid, an eprouvette containing caustic potash, a tube packed with freshly sublimed phosphoric oxide, and a combustion tube where the fusion and subsequent bottling took place. A detailed account of this bottling apparatus will be found in Richards and Parker's paper already cited, and the following figure will give an idea of its construction.

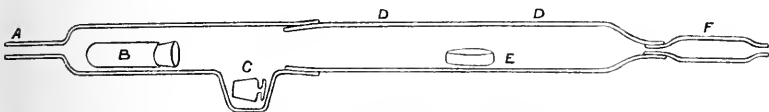

FIG. 1.—*Bottling Apparatus, Horizontal Section.*

*A* = tube leading from phosphoric pentoxide; *B* = weighing bottle; *DD* = hard glass tube; *E* = platinum boat containing fused rubidium chloride; *F* = tube containing phosphoric oxide to prevent any moist air from diffusing inward.

By means of a Y-tube, a stream of dry air can, at any time, be substituted for the nitrogen. A platinum boat of known weight was placed in a weighing bottle provided with a tightly-fitting glass stopper. Another weighing bottle was prepared having the same weight as the first and containing a quantity of platinum equal in weight to the platinum boat. After prolonged desiccation, the platinum boat and its bottle were carefully weighed, using the other bottle and its platinum as a counterpoise. A few grams of the rubidium chloride were weighed into the platinum boat, the boat then placed in the combustion tube, the weighing bottle pushed into position, and the tubes connected.

A current of dry nitrogen was now passed through the apparatus for about half an hour in order to sweep out any moist air, and while this stream of gas was still passing, the salt was gradually heated until it melted. After it had been fused for a few minutes, it was allowed to cool slowly, and the apparatus then swept out with a stream of dry air. When the air had completely displaced the nitrogen, the boat was pushed into its bottle, the stopper pushed home, and the bottle and contents transferred to the desiccator.

The bottles were left in the desiccator for perhaps two hours; a careful weighing was then made before the salt was dissolved in about two-thirds of a litre of water contained in an Erlenmeyer flask, fitted with a ground glass stopper. These solutions were always found to be neutral and quite free from any insoluble residue. The platinum boat lost only 0.3 milligram after about twenty determinations, and never showed any sign of having been acted on by the fused salt.

A quantity of silver, slightly in excess of the amount necessary to precipitate the chlorine in the rubidium chloride taken, was now weighed out and dissolved in nitric acid. Every precaution was taken, while the metal was dissolving, to prevent any of the silver being carried away with the escaping vapours. After the metal had dissolved, the solution was diluted to about 500 c.c. The silver nitrate was slowly added to the solution of rubidium chloride in a dark room. The contents of the flask were now vigorously shaken for half an hour, in order to coagulate the precipitate and shake out any occluded silver nitrate, the mixture being then left in the dark for several hours.

A Gooch crucible fitted with a mat of carefully selected asbestos, which had been thoroughly purified by treatment with acids, was dried in an electric oven for an hour at  $125^{\circ}$  and then tared against another platinum crucible having approximately the same weight.

The mother liquor from the precipitated silver chloride was filtered through the crucible and the precipitate washed twice by shaking it vigorously each time with about 150 c.c. of water, these washings being then added to the main filtrate. An additional 300 c.c. of water were shaken up with the precipitate, and after several hours poured through the filter, this filtrate being kept separate. This treatment was repeated with about the same amount of water, and the silver chloride then washed on to the filter, dried for several hours at  $125^{\circ}$ , desiccated for two or three hours, and then weighed.

The foregoing operations were carried out in either a very subdued or a ruby-red light; the precipitate was also protected from the light while drying and was never exposed to strongly actinic rays.

The amount of silver chloride which had been dissolved by the 600 c.c. of washing water was estimated by the method worked out by Richards (*loc. cit.*). By means of a nephelometer, a solution containing a known amount of silver was compared with the unknown solution, hydrochloric acid being added to the former and silver nitrate to the latter. The amount of silver chloride found in the washing water was of course added to the observed weight of the precipitate.

The asbestos carried away in the filtrate was estimated when necessary by filtering the solution through an ashless filter and weighing the residue after ignition; it never amounted to more than 0.25 milligram.

The amount of moisture still remaining in the dried pellet of silver chloride was estimated by Stas's method, namely, by heating the precipitate just to fusion in a tared porcelain crucible, the loss being then subtracted from the observed weight of silver chloride.

Before the ratio of silver to rubidium chloride could be determined, it was necessary to know the excess of silver in the filtrate from the

silver chloride precipitate. This was estimated by adding hydrochloric acid in slight excess to the filtrate, washing and weighing the precipitated silver chloride in the manner previously indicated. In this case, a little hydrochloric acid in the washing water prevented any appreciable amount of the silver chloride from dissolving.

In order to correct the observed weights of rubidium chloride for the buoyancy of the atmosphere, it was necessary to know the specific gravity of this salt. For this purpose, pure dry redistilled toluene was employed (b. p.  $110^{\circ}$ ), since rubidium chloride was found to be quite insoluble in this liquid. The specific gravity of the toluene at  $20^{\circ}$  referred to water at  $4^{\circ}$  was found to be 0.8650, whilst Richards found the value 0.8646 (*Proc. Amer. Acad.*, 1895, 31, 158).

1.1170	fused RbCl displaced	0.3511	toluene at $20^{\circ}$ .	Sp. gr. = 2.752.
1.8080	"	"	0.5678	" 20°. Sp. gr. = 2.755.

The mean specific gravity of the rubidium chloride is therefore 2.753, this being a little lower than the value 2.807 given by Setterberg (*Oefvers. Stockh. Acad. Forh.*, 1882, 39, 23).

The specific gravity of silver chloride has been carefully determined by several observers; for the purpose of this research it was taken to be 5.55.

The long-armed Troemner balance, which was employed in this work, was sensitive to 0.02 milligram with a load of forty grams, and had an aluminium beam, the rest of the metal being gold-plated. The weights were carefully compared among themselves, according to the method suggested by Richards (*J. Amer. Chem. Soc.*, 1900, 22, 144).

During the course of the investigation on the atomic weight of caesium (*loc. cit.*), several analyses were made of a sample of very pure potassium chloride in order to test the method and also the purity of the silver used. This precaution was taken in the present case with equally satisfactory results. The value found for the atomic weight of potassium agreed closely with the number given in the former paper, which in turn was in accord with the value found by Stas. The results do not appear here, as the observations are being extended, and will form the subject of a future communication.

### *Results of the Analysis of Rubidium Chloride.*

The ratios of silver chloride to rubidium chloride obtained from the analysis of the four samples of material are shown in Table I. In computing these values, and any others given below, the atomic weights of silver, chlorine, and bromine were taken to be 107.93, 35.455, and 79.955 respectively; oxygen being 16.000.

				Average (f)...	85·490
21	III	2·19692	1·96076	112·044	85·475
22	III	2·14543	1·91462	112·055	85·486
23	III	2·12164	1·89346	112·052	85·483
24	III	2·25777	2·01515	112·040	85·471
				Average (g)...	85·479
25	IV	2·18057	1·94594	112·057	85·489
26	IV	2·32699	2·07668	112·053	85·484
27	IV	4·00035	3·56998	112·055	85·486
28	IV	2·43440	2·17233	112·064	85·496
				Average (h)...	85·488

In the foregoing experiments, 28·69865 grams of silver yielded 38·12529 grams of silver chloride, giving the ratio

$$\text{AgCl} : \text{Ag} = 100\cdot000 : 75\cdot274.$$

The ratio found by Stas was 75·276. This agreement serves to show the purity of the silver used, and also indicates that the amount of occlusion of alkali chloride or silver nitrate by the precipitated silver chloride must have been inappreciable.

From the above average values it will be seen that the different samples of salt have given the following results :

Sample I	mean of (a) and (e)	85·487
Sample II	„ „ (b) „ (f)	85·494
Sample III	„ „ (c) „ (g)	85·480
Sample IV	„ „ (d) „ (h)	85·488

The varied treatment to which the different samples have been subjected does not seem to have altered them as regards their purity, and one is therefore justified in assuming that the potassium or caesium has been practically all removed, even from that sample which received the least number of crystallisations. Further treatment of the chloride or additional analysis of this salt would seem at present to be of little use.

#### *The Analysis of Rubidium Bromide.*

It now appeared desirable to obtain another ratio from which to calculate the atomic weight of rubidium, as this would necessitate a certain amount of variation in the experimental conditions of the analysis, and thereby render it possible to eliminate any constant error which might be present in the analysis of the chloride.

A number of analyses of rubidium bromide were accordingly carried out by precipitating the bromine as silver bromide and estimating the amount of silver necessary for complete precipitation, as well as the amount of silver bromide produced. The bromine used in preparing the rubidium bromide and hydrobromic acid was purified by dissolving in calcium bromide and reprecipitating by adding a large volume of water. The bromine was then redistilled six times, the first and last portions of the distillate being rejected in each operation. The hydrobromic acid was prepared from the rectified bromine and thoroughly washed red phosphorus. It was washed, collected, and redistilled five times, the first and last portions of the distillate being discarded in each case.

The rubidium material for the bromide determinations, which consisted of the residues from the previous analyses together with a

portion of sample IV, was converted into the hydrogen tartrate, and after three crystallisations had been made of this salt, one portion was analysed, whilst the remainder received two more fractionations. These two portions were converted successively into the bromide and tribromide, and the latter thrice crystallised in order to remove any sodium or potassium which might have found its way into the material during these operations; as in the case of the chloride, the final mother liquors, both from the hydrogen tartrate and tribromide fractionations, were examined in the spectroscope for the presence of caesium or potassium, but there was no indication of the presence of either of these metals. The normal bromide was now prepared from the trihalide salts by gently heating in an electric oven, dissolved in a little hot water, twice precipitated with hydrobromic acid, and dried. The two samples will be referred to as I and II. The method of analysis was essentially the same as in the case of the chloride, with this exception, that dry hydrogen bromide was mixed with the nitrogen which passed through the apparatus while the bromide was being fused. The solutions of the fused salt were always found to be neutral and the platinum boat was not attacked.

In each case, the amount of silver necessary to precipitate the bromine from the portion of salt taken was estimated by precipitating the excess with hydrobromic acid, filtering, and weighing in the manner already described in the case of the chloride. The correction for the solubility of the silver bromide in water was of course much smaller than that for the chloride.

In order to reduce the weighings of rubidium bromide to the vacuum standard, the following specific gravity determinations were made. The bromide was found to be insoluble in pure toluene, which, as before, had a sp. gr. 0.865 at 20°.

1.2401 fused RbBr displaced	0.3271 toluene at 20°.	Sp. gr. = 3.279
0.9795    "       "       "	0.2580       "       "   20°.	Sp. gr. = 3.284

---

Mean..... 3.282

This mean result is appreciably smaller than the value 3.358 found by Setterberg (*loc. cit.*).

The results of the analysis of the two samples of rubidium bromide given on p. 789 are expressed in the units already employed in the case of the chloride.

From these results, we see that 13.97953 grams of silver produced 24.33539 grams of silver bromide; therefore the bromide must have contained 57.445 per cent. of silver. This is identical with the

The final mean value = 85·48 gram being gram), it was

It seems most unlikely that, after such varied treatment, an appreciable quantity of potassium or caesium can be present in all these samples in the same proportion, or in such proportion as to give identically equivalent weights for the rubidium. If an appreciable amount of caesium still remains in this material, there is not much hope of its being removed by any known method of separation.

The lower value obtained by former investigators must have been due chiefly to the presence of potassium in their material. This metal is almost as difficult to remove as the caesium, whilst its detection by means of the spectroscope gives a great deal more trouble. In fact, the amount of either caesium or potassium which may be present in the rubidium material before its presence can be detected by a good prism spectroscope is much larger than is generally supposed, so effectually are the lines masked by the bright rubidium spectrum.

The foregoing results seem to show that the atomic weight of rubidium cannot be far from 85.48. It is hoped that a study of the decomposition of rubidium nitrate in the presence of silica will be taken up before long and made the subject of a future communication.

In conclusion, I wish to thank Dr. B. J. Harrington, director of the chemistry building, for his kindness in placing valuable apparatus and material at my disposal.

## LXXIX.—*The Action of Sodium Methoxide and its Homologues on Benzophenone Chloride and Benzylidene Chloride. Part II.*

By JOHN EDWIN MACKENZIE and ALFRED FRANCIS JOSEPH.

In a previous paper on this subject, one of us described the preparation of dipropoxy- and diisobutyloxy-diphenylmethanes and dihydroxy-tetraphenylmethane as well as the products obtained by the action of certain sodium alkyl oxides on benzylidene chloride. The research has been extended to the naphthols, and some experiments with aliphatic alcohols have been repeated.

By the action of sodium *iso*amyloxyde on benzophenone chloride, a minute quantity of crystals melting at 66—67° had been obtained, the constitution of which could not then be explained, but on repeating the experiment larger amounts have been separated, and the crystals have been proved to be benzhydrol. The formation of benzhydrol may be explained by supposing that di*iso*amyloxydiphenylmethane is first decomposed into benzophenone and *iso*amyl ether, the former being then reduced by the *iso*amyl alcohol present :

This substance is also formed in the preparation of di*isobutyloxy*- and di*isopropyloxy*-diphenylmethanes. It is curious that this reaction should take place only in the case of secondary alcohols.

Satisfactory products have not yet been obtained as a result of the action of  $\alpha$ -naphthol on benzylidene chloride, but from  $\beta$ -naphthol a substance has been isolated which is identical with that produced by Claisen (*Annalen*, 1887, 237, 261) on condensing  $\beta$ -naphthol with benzaldehyde in the presence of hydrochloric acid under increased pressure, or of acetic and sulphuric acids under the atmospheric pressure. The reaction may be supposed to take place according to the equation :

A study of the interactions of the naphthols and benzophenone chloride is being carried on by Mr. Albert Shrimpton.

## EXPERIMENTAL.

### *Benzhydrol.*

In attempting to prepare di*iso*amyloxydiphenylmethane, 4·6 grams of sodium dissolved in 80·5 grams of amyl alcohol (b. p. 131—131·5°) were heated at 150° for 14 hours with 23·7 grams of benzophenone chloride, and as the product was still alkaline, 2·3 grams of benzophenone chloride were then added and the heating continued for another 10 hours. Ether was added to the cold product in order to precipitate the sodium chloride, and, after evaporating the ether, the excess of amyl alcohol was distilled off under reduced pressure. The residue, when placed in a mixture of ice and salt, became semi-solid and remained so at the ordinary temperature, but melted at a slightly higher temperature. An analysis of this product indicated that it is a mixture of amyl alcohol with di*iso*amyloxydiphenylmethane.

As the product still contained sodium chloride (0·0153 gram being found in the platinum boat after the combustion of 0·71 gram), it was

extracted with dry ether, the solution filtered and evaporated, and the residue cooled in a freezing mixture. In this way, crystals were separated which melted at 65—66°, the melting point not altering when the substance was mixed with benzhydrol prepared by other methods. On combustion, the following figures were obtained :

0.3376 gave 1.0473 CO<sub>2</sub> and 0.2082 H<sub>2</sub>O. C = 84.60 ; H = 6.85.

C<sub>13</sub>H<sub>12</sub>O requires C = 84.78 ; H = 6.52 per cent.

The following cryoscopic determinations were made by Mr. G. W. Clough :

0.0402 in 16.448 benzene gave  $\Delta t = 0.079^\circ$ . M. W. = 154.7.

0.0968 „ 16.448 „ „  $\Delta t = 0.185^\circ$ . M. W. = 159.0.

C<sub>13</sub>H<sub>12</sub>O requires M. W. = 184.0.

To prove the absence of optical activity, polarimetric readings were taken of a 5 per cent. solution in benzene, but no rotation was observed in a polarimeter reading to 0.01°.

As a further proof that the substance was benzhydrol, some crystals were kept over sulphuric acid in a vacuum desiccator for twelve days, at the end of which time the loss in weight only amounted to 1 per cent. Had the substance been the diisoamyl compound, it should have become decomposed into benzophenone and diisoamyl ether,

in accordance with the behaviour of its homologues.

In the former description of the preparation of diisobutyloxydiphenylmethane (Trans., 1901, 79, 1207), it will be noticed that a very small amount of crystalline substance melting at 62—64° and generally agreeing in properties with benzhydrol was obtained. The analytical numbers (C = 84.53 ; H = 6.86 per cent.) showed it to have a composition agreeing closely with that of benzhydrol.

### *Dibenzoyldiphenylmethane.*

To the description of this substance formerly given (Trans., 1896, 69, 992) may be added the fact that, like its homologues, it may be decomposed into benzophenone and dibenzyl ether. On heating in a dry test-tube at 220° for half an hour, a colourless liquid condensed on the upper part of the tube, and the residual oil solidified on cooling. The solid distilled between 250° and 300° under atmospheric pressure, and the colourless crystals which separated in the distillate, after drying on a porous plate, melted at 48—49° and showed the characteristic properties of benzophenone.

*The Anhydride of Phenyl-di- $\beta$ -hydroxynaphthylmethane.*

Benzylidene chloride (14.7 grams) was mixed with a large excess of  $\beta$ -naphthol (52 grams) in a round-bottomed flask and heated at  $100^{\circ}$ , at which temperature a copious evolution of hydrogen chloride took place. As the reaction subsided, the temperature was raised to  $120^{\circ}$  and kept there for eight hours, at the end of which time no further evolution of gas took place. The loss in weight amounted to 7.3 grams, the theoretical loss calculated for  $2\text{HCl}$  being 6.6 and that for  $2\text{HCl} + \text{H}_2\text{O}$  being 8.3. In another experiment, the actual loss was 8.3 grams, the calculated numbers being 7.3 and 9 respectively. The violet residue was powdered and extracted with carbon disulphide, in which it readily dissolved. From the solution, a colourless, crystalline powder was precipitated by the addition of a large volume of alcohol, the yield amounting to 73 per cent. of the calculated amount. This powder was found to be sparingly soluble in cold alcohol, ether, or acetic acid, easily so in chloroform or carbon disulphide, and moderately so in hot acetic acid. By recrystallisation from the last-named solvent, colourless, glistening leaflets were obtained, melting at  $190\text{--}191^{\circ}$  (Claisen gives  $189\text{--}190^{\circ}$ ). A specimen which had been kept in a vacuum desiccator over soda-lime was employed in the following analysis:

0.1632 gave 0.5397  $\text{CO}_2$  and 0.07887  $\text{H}_2\text{O}$ .  $\text{C} = 90.19$ ;  $\text{H} = 5.37$ .

$\text{C}_{27}\text{H}_{18}\text{O}$  requires  $\text{C} = 90.50$ ;  $\text{H} = 5.03$  per cent.

Attempts to determine the molecular weight by the cryoscopic method were unsuccessful owing to the slight solubility of the substance. The following results were obtained by the ebullioscopic method, using chloroform as solvent:

0.2034 in 21.24 chloroform gave  $\Delta t\ 0.108^{\circ}$ .  $\text{M. W.} = 325$ .

$\text{C}_{27}\text{H}_{18}\text{O}$  requires  $\text{M. W.} = 358$ .

This substance does not yield  $\beta$ -naphthol on fusion with caustic potash.

Other modifications of the method of preparation have been tried, but with less favourable results. On gradually adding a xylene solution of benzylidene chloride to a boiling solution of  $\beta$ -naphthol in the same solvent, a steady evolution of hydrogen chloride takes place, but the product is decolorised with great difficulty.

In the hope of obtaining phenyl-di- $\beta$ -hydroxynaphthylmethane,  $\text{C}_{27}\text{H}_{20}\text{O}_2$ , itself, experiments were made with sodium naphthoxide and benzylidene chloride, but only the anhydride,  $\text{C}_{27}\text{H}_{18}\text{O}$ , could be isolated. An alcoholic solution of 15.7 grams of  $\beta$ -naphthol was added to

a solution of 2.5 grams of sodium in the same solvent, and the alcohol removed by heating first in a water-bath and then in an air-bath, a current of dry air being passed over the residue, which was then mixed with 8.7 grams of benzylidene chloride and the mixture heated at 130° for 15 hours. No hydrogen chloride was evolved, and the solid mixture was extracted with carbon disulphide, leaving a residue of sodium chloride which weighed 6.5 grams, the calculated amount being 6.3 grams. The solution, when concentrated and treated with alcohol, gave a sandy, crystalline precipitate. When crystallised from glacial acetic acid, the crystals melted at 191° and agreed in all their properties with the foregoing anhydride.

Qualitative experiments with acetylated naphthols and benzylidene chloride yielded negative results.

#### *Nitration of the Anhydride.*

Although the experimental conditions were varied, pure compounds could not be isolated, the analytical numbers indicating that di-, tri-, penta-, and hexa-nitro-compounds had been formed.

A mixture of 20 grams of fuming nitric acid (sp. gr. 1.5) and 100 grams of glacial acetic acid was added to 5 grams of the anhydride suspended in 50 grams of glacial acetic acid, the whole being well cooled. A yellow powder and a deep orange solution resulted, the former being collected, then washed with boiling glacial acetic acid and dried in a vacuum desiccator over solid caustic soda. This substance melted with decomposition at 252—253° and was analysed with the following result, which indicated a dinitro-derivative :

0.4074 gave 23.3 c.c. moist nitrogen at 20° and 766 mm.  $N = 6.59$ .

$C_{27}H_{16}O(NO_2)_2$  requires  $N = 6.25$  per cent.

In another experiment, 1.8 grams of the anhydride mixed with 20 c.c. of nitric acid (sp. gr. 1.4) were heated in a water-bath for 3 hours, a red solution being produced, from which a yellow powder separated on cooling. The filtrate from this powder was poured into a large volume of water, and the yellow precipitate thus obtained was heated with glacial acetic acid, in which it only partially dissolved. The portion insoluble in acetic acid charred at about 250° and gave the numbers recorded in analysis I.

The solution in acetic acid on dilution with water yielded a precipitate, the analysis (II) of which showed it to consist mainly of the trinitro-compound.

I. 0.16069 gave 9.6 c.c. moist nitrogen at 16.2° and 762 mm.

$N = 7.0$ .

II. 0.13122 gave 10.3 c.c. moist nitrogen at 13° and 744 mm.  
N = 9.03.

$C_{27}H_{16}O(NO_2)_2$  requires N = 6.25 per cent.

$C_{27}H_{15}O(NO_2)_3$  „ N = 8.52 „

In a third experiment, the anhydride (3.5 grams) was added to 40 c.c. of nitric acid (sp. gr. 1.5) cooled in ice; it dissolved with effervescence, and after half an hour the mixture was poured on to crushed ice. The yellow precipitate (I) thus obtained was dissolved in glacial acetic acid, and on cooling a yellowish-red powder separated which charred at about 200°. Fractional precipitation of the acetic acid solution by the addition of water gave several precipitates, the last of which was analysed (II).

I. 0.1118 gave 11.7 c.c. moist nitrogen at 14.2° and 752 mm.  
N = 12.17.

II. 0.1633 gave 18.75 c.c. moist nitrogen at 15.5° and 760 mm.  
N = 13.5.

$C_{27}H_{13}O(NO_2)_5$  requires N = 12.0 per cent.

$C_{27}H_{12}O(NO_2)_6$  „ N = 13.38 „

#### *Action of Sulphuric Acid on the Anhydride.*

According to Trzcinski (*Ber.*, 1883, 16, 2839, and 1884, 17, 500), an acid, which he calls “melinoin-trisulphonic acid,” is obtained by the action of concentrated sulphuric acid on benzaldehyde and  $\beta$ -naphthol. In our experiments, the only product obtained was a  $\beta$ -naphthol-disulphonic acid, which was isolated in the form of its barium salt.

Five grams of the powdered anhydride were mixed with 20 c.c. of fuming sulphuric acid and left for a week, after which the mixture was poured on to ice; the product, which dissolved completely, was neutralised with barium carbonate, and on concentrating the clear solution, crystals were obtained, which, when recrystallised from hot water, yielded colourless needles (1.8 grams). Analysis of these crystals (I) showed them to be a barium  $\beta$ -naphtholdisulphonate containing six molecules of water of crystallisation. By evaporating the mother liquors, 3.6 grams of a red, glassy substance (II) were obtained having approximately the same composition:

I. 0.6408 at 105° lost 0.1216.  $H_2O = 18.98$ .

II. 0.7526 „ 105° „ 0.1404.  $H_2O = 18.68$ .

I. 0.4225 salt dried at 105° gave 0.212  $BaSO_4$ . Ba = 29.27.

II. 0.5347 salt not dried at 105° gave 0.235  $BaSO_4$ . Ba = 25.86.

I. 0.452 salt dried at 105° gave 0.4532  $CO_2$  and 0.0902  $H_2O$ .

C = 27.34; H = 2.2.

$C_{10}H_6O_7S_2Ba \cdot 6H_2O$  requires  $H_2O = 19.72$ ; Ba = 25.05 per cent.

$C_{10}H_6O_7S_2Ba$  requires C = 27.4. H = 1.38; Ba = 31.26 „

These results show that the anhydride has undergone decomposition.

When warmed in the water-bath for some hours with concentrated sulphuric acid (sp. gr. 1.84), the anhydride gives a red solution, which, when poured on to ice, slowly deposits an orange-red powder, leaving a bright red liquid. The colour is removed from both powder and liquid by the addition of caustic alkalis, and is restored by acids.

BIRKBECK COLLEGE,

### LXXX.—*The Formation of Periodides in Nitrobenzene Solution. Part II. Periodides of the Alkali and Alkaline Earth Metals.*

By HARRY MEDFORTH DAWSON and ETHEL ELIZABETH GOODSON, B.Sc.

PREVIOUS experiments on the nature of nitrobenzene solutions containing iodine and potassium iodide (Dawson and Gawler, Trans., 1902, 81, 524) have now been extended to iodides of the other alkali metals, to ammonium and substituted ammonium iodides, including phenyl-, phenyldimethyl-, and tetramethyl-ammonium iodides, and to the iodides of the alkaline earth metals. These experiments consist in measuring both the solubility of the various iodides in nitrobenzene containing dissolved iodine and also the solubility of iodine in nitrobenzene containing one or other of the foregoing iodides. The iodides, with the exception of lithium iodide, are not appreciably soluble in nitrobenzene, but dissolve readily in the presence of iodine; similarly, iodine only dissolves to the extent of 0.2 gram-molecule per litre in pure nitrobenzene, whereas its solubility is much greater in presence of the iodides. These facts are of essential importance in drawing conclusions from the experimental data.

The object of the present investigation being to ascertain and compare the general behaviour of the various iodides towards iodine rather than to determine with the greatest possible accuracy the quantitative relationships in any particular case, it was considered sufficient, as the result of some preliminary experiments, to carry out the solubility measurements at the ordinary temperature. In a few cases, *o*-nitrotoluene was used as solvent instead of nitrobenzene, previous experiments (Dawson, Trans., 1904, 85, 467) having shown that in the case of potassium iodide these behave very similarly in regard to the formation of periodides.

In the analysis of the solutions, the iodine was determined by titration with sodium thiosulphate, and, in order to obtain the concentration

of the iodide, a measured volume of the solution was in most cases subjected to distillation in steam, the last traces of the solvent being removed by extraction with carbon disulphide and subsequent repeated evaporation to dryness on the water-bath. The residue was then heated for some time at  $130^{\circ}$ , and finally over the free flame. In some cases, this mode of procedure could not be adopted, but reference will be subsequently made to special methods.

*Solutions Saturated with Iodide.*

The following table contains the experimental data for solutions containing iodine and saturated with regard to the iodide indicated. The iodine and iodide concentrations are given in grams and gram-molecules per litre, and in the last column the ratio of iodine to iodide molecules is represented.

TABLE I.  
Sodium iodide.

## Barium iodide.

66.0	0.260	35.1	0.90	2.9
186	0.735	89.9	0.23	3.2

In the case of the lithium solutions, the concentration of the iodide was determined by distilling in steam, and, after removing the nitrobenzene by extraction with carbon disulphide and subsequent evaporation, by precipitating the aqueous solution with silver. The strontium and barium solutions were treated in a similar manner and the metals precipitated as sulphates. In the case of ammonium iodide, the measured volume of solution was first shaken up with sufficient sodium thiosulphate solution to react with all the periodide iodine; the mixture was then made alkaline, and the ammonia estimated by distillation in steam and absorption in standard acid.

An inspection of the experimental data recorded in the previous table shows that the behaviour of the various iodides subjected to investigation is in general very similar to that previously observed in the case of potassium iodide. For small iodine concentrations (0.2 gram-molecules per litre), the molecular ratio of dissolved iodine to iodide is approximately equal to unity, the inference being that triiodides of the type  $MI_3$  are, under these conditions, the essential components of the solutions. This holds, at any rate, for the more completely investigated potassium, sodium, rubidium, caesium, and tetramethylammonium iodide solutions. As the iodine concentration increases, the molecular ratio  $I_2/\text{iodide}$  also increases, and this in all

probability corresponds with the formation in solution of periodides of gradually increasing complexity. In the case of sodium iodide, where the range of concentration investigated is greatest, the molecular ratio  $I_2/NaI$  increases from unity at the smallest concentrations to 2.6 at a concentration of 960 grams of iodine per litre.

All the iodides investigated, with the exception of lithium iodide, exhibit similar relationships, but considerable differences are evident when a quantitative comparison is made. If the iodine concentrations are plotted as abscissæ and the values of the molecular ratio  $I_2/\text{iodide}$  as ordinates, the curves obtained for the different iodides are by no means coincident. The curve for sodium iodide lies above that for the potassium salt and this lies above the rubidium iodide curve. At a concentration of 2 gram-molecules of iodine per litre, the values of the molecular ratio are respectively 1.90, 1.75, and 1.60. The different values thus obtained for the molecular ratio are probably caused by differences in stability of the corresponding periodides of the various metals. Whether the curves become coincident at low concentrations and run approximately parallel to the abscissa corresponding with  $I_2/\text{iodide} = 1$ , or whether, as seems more likely, the corresponding tri-iodides undergo considerable dissociation with increasing dilution, cannot be decided on the basis of the present experiments. To establish this point it would be necessary to carry out further experiments at small concentrations using larger volumes of solvent. The values of the molecular ratio for strontium and barium iodides are, roughly, twice as large as those obtained for the iodides of the univalent radicles at corresponding concentrations; this difference evidently corresponds with the presence of two iodine atoms in the molecule of the alkaline earth iodides.

Some other points in connection with this series of experiments also require notice. In the investigation of caesium iodide, using *o*-nitrotoluene as solvent, it was found impossible to prepare solutions saturated with caesium iodide containing more than about 0.5 gram-molecule of iodide per litre (Expts. 3 and 4). The addition of iodine in quantities corresponding with much larger concentrations always leads to a solution, the composition of which is represented by the numbers of Expts. 3 and 4. The iodine is evidently used up in the formation of caesium tri-iodide, which is present as a solid phase, the solution of maximum concentration being thus in equilibrium with caesium tri-iodide and caesium iodide. In accord with this view, it was found that on decanting off the solution obtained by agitating for several hours 10 c.c. of *o*-nitrotoluene with 4 grams of iodine and 6 grams of caesium iodide, and on shaking the residue with a further 10 c.c. of the solvent until equilibrium had been attained, the second solution had the same composition as the original one. The molecular

concentration of iodine in this limiting solution is greater than that of caesium iodide; it seems probable, therefore, that the periodide is partially decomposed in contact with the solvent, caesium iodide separating, and excess of iodine passing into solution. With nitrobenzene as solvent, more concentrated caesium iodide solutions can be obtained than with *o*-nitrotoluene.

The abnormal behaviour of lithium iodide, which is clearly shown in the small value of the molecular ratio  $I_2/LiI$ , is due to the fact that the iodide itself dissolves to a considerable extent both in nitrobenzene and in *o*-nitrotoluene. On shaking lithium iodide with either of these solvents, it is rapidly changed and light yellow, crystalline plates are formed of considerably smaller specific gravity than the original iodide, which subside very slowly. Analysis of the solutions obtained by agitating the iodide with nitrobenzene and *o*-nitrotoluene for about 12 hours gave respectively 51 and 30 grams of lithium iodide per litre. These numbers are only to be regarded as approximate, for the solutions were yellow in colour and contained small quantities of free iodine. The observations are, however, quite sufficient to account for the abnormal behaviour of lithium iodide as compared with that of the other iodides examined.

To prepare the yellow, crystalline compound, lithium iodide carefully dehydrated by heating in a current of hydrogen was agitated with nitrobenzene in a closed vessel at about  $60^\circ$ , the solution being then filtered and allowed to remain in the cold. The crystals, which were freed as far as possible from mother liquor by filtering and pressing on porous plate, are very hygroscopic, and in contact with water immediately decompose into lithium iodide and nitrobenzene. According to the analysis of the crude material thus obtained, the substance has the formula  $LiI, C_6H_5 \cdot NO_2$ , and the compound of the iodide with *o*-nitrotoluene has a similar composition.

#### *Solutions Saturated with Iodine.*

In the second series of experiments, the composition of solutions saturated with iodine and containing one or other of the iodides in the following table was investigated. The arrangement of the experimental data is exactly the same as in the previous table.

TABLE II.

809	3.19	158.5	0.405	7.9

The analysis of the various solutions was carried out by the methods already described, except in the case of aniline and dimethylaniline hydriodides. For the purpose of the present investigation, it was considered sufficient to estimate the iodide concentration in these two cases by comparison with corresponding solutions of the other iodides. The increase in volume of the solvent in the formation of solutions of aniline and dimethylaniline hydriodides containing quantities of iodine represented by the experimental data in the above table has been assumed to be the same as in the formation of solutions containing the same quantity of iodine and one of the easily estimated metallic iodides. By carrying out the solubility experiments with a weighed quantity of each of the two iodides and a measured volume of the solvent, the concentration of the substituted ammonium iodides in the resulting solution could be thus determined comparatively with sufficient accuracy.

According to the data in the table, the solubility of iodine in nitrobenzene is very largely increased by the presence of iodides of the alkali and alkaline earth metals and of ammonium and substituted ammonium iodides, and this increased solubility is most simply explained by the assumption of the formation of complex periodides in

the solution. In general, four molecules of iodine pass into solution for each molecule of dissolved alkali, ammonium, or substituted ammonium iodide, whilst eight molecules dissolve for each molecule of the dissolved iodide of an alkaline earth metal.

A few points regarding the individual iodides may be mentioned before considering further the general nature of these experimental results. As in the first series, the solubility measurements have been made over a considerably greater range of concentrations in the case of sodium iodide than in that of the other iodides. As previously observed for potassium iodide solutions (*loc. cit.*), the molecular ratio  $I_2/NaI$  is considerably greater than 4 when the amount of dissolved iodide is small, but this is undoubtedly due to the simple solubility of iodine in the solvent independently of the formation of soluble periodides. According to Expts. 8 and 9, the molecular ratio, after remaining constant over a considerable range of concentration, diminishes at very large concentrations, and although the cause of this has not been determined with certainty, yet there is some evidence to show that under these conditions the solution is approximating to a condition of saturation with regard to two components.

In the case of tetramethylammonium iodide, the quantities of iodine and iodide employed in each of the two experiments were both in excess of the amounts found in the resulting solutions. The two solutions are practically identical, and the observations indicate that a solution of this composition is in equilibrium with two solid phases, one of which is iodine and the other a tetramethylammonium periodide. By reference to Table I, it will be seen that, with excess of iodide, solutions containing much larger quantities of tetramethylammonium iodide than the solution in Table II can be obtained. The solution being thus in equilibrium with two solid phases, the molecular ratio  $I_2/\text{iodide}$  has not the same significance as in the case of the other iodides, although its value does not differ much from the value obtained from the remaining iodides at a corresponding concentration.

In general, the relationships evidenced by the solubility data in Table II are in accord with the conclusion that complex periodides of the type  $M'I_9$  are the essential components of the solutions saturated with iodine. These enneaiodides are formed not only by the alkali metals, but also by the ammonium and substituted ammonium radicles. In a similar manner, it may be inferred that, in the case of the alkaline earth metals, strontium and barium periodides of the type  $M''I_8$  are formed, and these may also be referred to as enneaiodides. In both series, each iodine atom in the simple iodide combines with eight other atoms of iodine, and the formation of these enneaiodides appears to be essentially independent of the positive radicle. The fact that the solutions of these periodides are good conductors of

electricity is evidence of their electrolytic dissociation, and it is probable that complex iodine anions represented by  $\overline{I_9}$  are present in the various solutions. It is proposed to examine the electrochemical properties of these solutions more closely.

The conclusion that enneaiodides of the alkali and alkaline earth metals exist in solution receives perhaps some support from the fact that such enneaiodides of substituted ammonium and diammonium radicles have been obtained as solid, crystalline substances. Tetramethyl- and trimethylethyl-ammonium enneaiodides were obtained by Geuther (*Annalen*, 1887, 240, 66) by dissolving the calculated quantities of the simple iodide and iodine in warm alcohol previously saturated with iodine in the cold and allowing to cool. In a paper published since the completion of our experiments, Strömholm (*J. pr. Chem.*, 1903, 67, 345) describes crystalline enneaiodides derived from phenyltrimethyl-, phenyldimethylethyl-, and possibly triethylmethyl-ammonium iodides. The method used by this investigator consists in shaking the simple iodide (or the corresponding tri- or penta-iodide) with a saturated ethereal solution of iodine, repeating the operation with fresh quantities of solution so long as iodine is taken up by the solid substance. Several of the less complex (tri- and penta-) periodides used in these experiments have been previously described by Weltzien (*Annalen*, 1854, 91, 33; 1856, 99, 1) and by Müller (*Annalen*, 1858, 108, 1), and several hepta-iodides were obtained by Geuther (*loc. cit.*). By the same method, Strömholm prepared the enneaiodide of the bivalent radicle trimethylenehexamethyldiammonium, corresponding with the formula  $CH_2(CH_2 \cdot NMe_3 I_9)_2$ . Of eight such tetra-substituted ammonium iodides, five, or possibly six, were found to yield enneaiodides by treatment according to the foregoing method. In no case were periodides higher than the enneaiodide obtained, and, as Strömholm points out, it seems probable that the enneaiodide represents the highest limiting type of periodide.

This view is in agreement with the results of our experiments on the composition of solutions containing iodides of the alkali and alkaline earth metals when saturated with iodine. In these experiments, with the conditions favourable to the formation of the highest type of periodide, the data obtained indicate the formation of soluble enneaiodides. In respect of their capacity to yield periodides, the alkali and alkaline earth metals are therefore to be placed in the same class as the substituted ammonium derivatives, for some of which the limiting enneaiodides have been isolated.

It is perhaps not unnecessary to point out that the experiments in this paper have reference solely to the nature of the periodides in solution, and are not concerned with their possible existence in the

free state. The substances separating from solution are by no means necessarily identical with the chief components of the solution, and it is therefore noteworthy that the investigation of the products of crystallisation and of the soluble components both lead to the result that the highest periodides of the substituted ammonium radicles are the enneaiodides. In regard to the question of the dependence of the affinity of the iodide for the periodide iodine on the nature of the positive radicle, our experiments give no information.

No special attempts have been made during the course of the investigation to isolate the periodides present in the various solutions. In some few cases the more concentrated solutions were cooled to  $-20^{\circ}$ , with the object of promoting crystallisation, but without success. The two most concentrated solutions obtained in the experiments on the solubility of sodium iodide (Table I, Expts. 7 and 8), however, slowly deposited crystals, which were separated and pressed on porous plate. The crystals from the two solutions gave almost identical results on analysis, the mean percentages being  $I = 53.9$ ,  $NaI = 16.9$ , and  $C_6H_5 \cdot NO_2$  (by difference)  $= 29.2$ . The mother liquors, on the other hand, differed considerably in composition, the values of the molecular ratio,  $I_2/NaI$ , being respectively 2.2 and 2.6. The substance thus obtained is probably a compound of sodium penta iodide and nitrobenzene, represented by the formula  $NaI_5 \cdot 2C_6H_5 \cdot NO_2$ , which requires  $I = 56.0$ ,  $NaI = 16.6$ , and  $C_6H_5 \cdot NO_2 = 27.4$  per cent. For a crude product thus obtained, the agreement between the numbers is sufficiently good. The crystals have a green metallic appearance and deliquesce in the air; benzene, carbon disulphide, or carbon tetrachloride extracts iodine and nitrobenzene, leaving sodium iodide.

To ascertain whether the iodides of the other metals of the first and second groups of the periodic table, namely, copper, silver, and gold, or zinc, cadmium, and mercury, are capable of forming soluble periodides under the same conditions, similar experiments were made with the iodides of silver and cadmium. These were shaken with a nitrobenzene solution of iodine, but the resulting liquids were quite free from iodide, indicating that periodides are not formed in these cases. An attempt to examine the behaviour of hydrogen iodide was foiled by the reducing action of this substance on the solvent leading successively to the production of aniline and aniline hydriodide.

Solutions containing periodides are also obtained when iodine and the bromides of the alkali metals are brought together in the presence of nitrobenzene. Although the nature of these solutions has not been investigated in detail, yet it may be of some interest to record the data obtained in experiments with potassium bromide. The numbers in the following table express the composition of solutions containing

potassium bromide and iodine when saturated with respect to one or other of these substances.

Solutions saturated with potassium bromide.

Iodine concentration, gram-mols.					
per litre .....	0.375	0.758	1.40	2.01	(2.52)
KBr concentration, gram-mols. per					
litre .....	0.157	0.270	0.45	0.61	(0.71)
Mol. ratio $I_2/KBr$ .....	2.4	2.8	3.1	3.3	(3.55)

Solutions saturated with iodine.

Iodine concentration, gram-mols. per					
litre .....	0.765	1.187	1.58		(2.52)
KBr concentration, gram-mols. per litre.	0.169	0.304	0.415		(0.71)
Mol. ratio $I_2/KBr$ .....	4.5	3.9	3.8		(3.55)

To determine the concentration of bromide in the solution, a measured volume was distilled in steam, extracted with carbon disulphide, evaporated to dryness, and the residue weighed, this being afterwards precipitated with silver solution and reweighed as silver salt.

The two series of solutions approximate in composition as the concentration increases, and the identity of the two final solutions indicates that saturation with regard to both components has now been reached. The composition of the solutions saturated with iodine makes it appear probable that the complex perhalogen compounds present in solution are of the same type as those in solutions of the alkali iodides, although the evidence in support of this view is not nearly so decisive.

The chlorides of the alkali metals also form periodides in nitrobenzene solution, although only to a comparatively small extent, for, whereas the chlorides are practically insoluble in pure nitrobenzene, they dissolve to some extent in the presence of iodine. Experiments were made with the chlorides of potassium, rubidium, and caesium, and the solubility of these in nitrobenzene containing 0.2 gram-molecule of iodine per litre was found to be respectively 0.030, 0.044, and 0.080 gram-molecule per litre. These data scarcely admit of comparison with those obtained in the case of the iodides, being of quite a different order of magnitude. The increase in the molecular proportion of dissolved chloride from potassium to caesium is probably to be taken as an indication of the increasing stability in solution of their corresponding perhalogen derivatives. The influence of the

metal as thus indicated agrees with that observed in experiments made with the view of preparing perhalogen derivatives of the alkali metals in the free state.

This work has been carried out with the aid of a grant from the Government Grants Committee of the Royal Society, for which the authors desire to express their thanks.

### LXXXI.—*Caproylthiocarbimide*.

By AUGUSTUS E. DIXON, M.D.

IN previous papers, the author has described the formation of various aliphatic acidic "thiocarbimides" and their combinations with bases, alcohols, &c.; the compounds of this class hitherto obtained include, amongst the purely aliphatic derivatives, propionylthiocarbimide (Trans., 1896, 69, 855), isobutyrylthiocarbimide (*ibid.*), valerylthiocarbimide (*ibid.*, 1895, 67, 1040), and the thiocarbimides of palmitic and stearic acids (*ibid.*, 1896, 69, 1593); to this series, caproylthiocarbimide may now be added.
